1. **Introduction**

1.1 Lowland grassland features qualify a large number of SSSIs and SACs in England, Scotland and Wales, and also ASSIs and SACs in Northern Ireland. The features include a wide range of semi-natural plant communities on acid, neutral and calcareous soils, together with a variety of rare and scarce individual plant and animal taxa. Both dry and damp pastures and hay meadows are included. These guidelines concentrate on monitoring procedures for plant community features.

1.2 For several years prior to the present attempt to develop SSSI condition assessment procedures, considerable attention has been given to grassland monitoring by the country agencies, led in particular by English Nature. Over a three-year period from 1997, EN grassland specialists have undertaken extensive field trials, in conjunction with local staff and representatives from other parts of the UK, to develop a practical approach to grassland condition appraisal. The resulting methodological framework has been published (Robertson & Jefferson, 2000), together with a comparative test of the methods against a more rigorous data gathering exercise at a group of neutral hay-meadows and calcareous grasslands in England (Robertson, Bingham & Slater, 2000).

1.3 The guidelines outlined here are developed from the EN method, with guidance included for incorporating local characteristics of designated site grassland features. Primary attributes, which are the main determinants of condition assessment, are distinguished from secondary attributes. The former largely concern the composition of the grassland sward, while the latter are principally concerned with sward structure.

1.4 Some of the attribute thresholds specified in Robertson & Jefferson (2000), and in particular sward composition, more or less equate to the minimum standards for SSSI selection (NCC, 1989); that is, they attempt to define the state of grassland features below which a grassland stand is no longer in acceptable condition. We have attempted here to introduce and infuse characters of local stands within the target-setting procedures, for a very similar set of grassland attributes.

1.5 The guidelines developed here do not include generic condition features specifically for invertebrates or other animal groups. Guidance on grassland structure beneficial for invertebrates needs to be formulated for the full range of lowland grassland types. In some cases, a mixed structure or mosaic of tussocky and short patches may be optimal. However, grassland invertebrate conservation needs to take a wider range of local site attributes into account, including associated habitat types, as well as the cutting or grazing regime.

2. **Definition of features**

2.1 For the purposes of this guidance, ‘lowland’ grasslands (including upland hay meadows) are essentially those which lie below the limit of agricultural enclosure. Grasslands in unenclosed, upland landscapes are covered by the Upland habitat guidance section (see Table 1). For grasslands in coastal habitats the relevant coastal section should also be consulted. For fen meadows and related grasslands on lowland peatlands the Lowland wetland guidance should be consulted.
2.2 For lowland grassland features, the focus of attention is on plant communities (and sub-communities) defined by the National Vegetation Classification (Rodwell, 1992). The NVC syntaxa are now widely used in operational work on designated sites throughout Britain. They provide a workable framework into which special lowland grasslands can be subdivided. There is no implication that the NVC dataset represents a blueprint for SSSI grassland composition; it simply provides a convenient classification. For applying condition assessment protocols, the communities are aggregated into broader categories covering calcareous, neutral, acid and marshy grasslands (i.e. priority habitats for which Biodiversity Habitat Action Plans are in place). The plant communities covered include the full range for which designated sites are selected, also lowland forms of metallophyte or calaminarian grassland (Table 1). Further details of relevant NVC, Phase 1 and Habitats Directive Annex I types are given in Tables 2-6.

3. Attributes and targets

3.1 Selection of attributes

3.1.1 Attributes have been selected to provide information about changes in condition brought about by nutrient treatment, grazing and cutting management, and hydrological changes, as well as more obvious damaging impacts, such as ploughing and reseeding. Other influences, such as impacts of disease organisms and subtle shifts in climate, may interact with management effects. Grasslands have a relatively simple structure compared to many other habitats, with one principal layer of vegetation, usually ranging in height from about 2-100 cm. There may be patches of bare ground and scrub, but for the most part habitat condition is determined primarily by the species composition of the herbaceous sward.

3.1.2 For all lowland grasslands, habitat extent and specified features of the sward composition (according to grassland type) should be treated as primary attributes. These are the habitat characteristics that are recommended for determination of community condition. If a sward falls below the quality threshold or target for one or more of these, then the feature is deemed to be in unfavourable condition.

3.1.3 Structural aspects of semi-natural grasslands, such as sward height, litter accumulation and bare ground, are valid and informative monitoring attributes, although it is recommended that in most cases they are treated as secondary or supporting attributes, rather than primary determinants of grassland condition. This is because they may change rapidly and usually reversibly in response to changes in the local grazing and/or cutting regime. Nevertheless, they are important characteristics of grassland habitats, and may provide early indication of impending decline in compositional attributes. It should often be possible to ameliorate structural deterioration before unfavourable condition is reached. For example, a neutral grassland site that is currently favourable for both positive and negative indicator species and yet exceeds the upper limits for sward height and litter accumulation may be subject to under-grazing which, unless rectified, would probably affect the species composition in the near future. Thus the structural secondary attributes should be used to prompt a management response where necessary, but should not be used for formal condition appraisal.

3.1.4 There are two grassland attributes that are not taken directly into account, because of resource constraints. These are species diversity and productivity. Many conservationists may be concerned at the absence of species richness as a primary attribute of grassland condition, but to obtain good diversity data would be prohibitively time-consuming. A reduction in species diversity could theoretically occur while a sward is scored as being in favourable condition, but the expectation is that other surrogate attributes will indicate such changes. Likewise, measures of sward productivity may give the best indication of undesirable changes in nutrient loading, but again would be too costly to obtain. It is also worth noting that soil attributes are not considered, for similar reasons.
3.1.5 In the sub-sections below, attributes and target setting are considered in outline, and further detail for particular grassland habitats and communities is summarised in Tables 2-6. For structural attributes, limits are mostly set fairly broadly to accommodate site-to-site and seasonal variation. If local targets need to be set to maintain particular structural conditions, they should normally fall within the generic ranges given in the tables.

3.2 **Primary attribute: extent**

3.2.1 In general, it is recommended that there should be no loss in extent of stands of qualifying lowland grassland vegetation. Trivial reductions due to slightly increased poaching in the vicinity of gateways or other localised disturbance that frequently occur on lowland farms are not considered as serious losses. Similarly, it may be appropriate to consent minor loss to ensure continuation of suitable site management, e.g. the installation of a water source for livestock. But in many other cases, such as the construction of a new farm track through a special lowland grassland, the loss is likely to be significant.

3.2.2 There may occasionally be a target to exceed the current stand extent (e.g. when invasive scrub or bracken is earmarked for clearance to promote the grassland interest). Conversely, at some sites (usually of large extent) there may be an aim to increase the cover of scrub somewhat, especially when this is required for qualifying invertebrates or other associated features. In addition, there may be some acceptable flux in the extent of different grassland conservation communities in the same recording unit, and this should be taken into account when interpreting changes in stand area.

3.3 **Primary attribute: sward composition - grass:herb ratio**

3.3.1 The relative cover of grasses and forbs provides a coarse indication of conservation status. In general, semi-natural swards in good condition have a much higher broad-leaved herb component compared to agricultural grasslands.

3.3.2 Robertson & Jefferson (2000) suggest that for neutral and calcareous grasslands, the broadleaved herb component should lie within a specified range, often 40-90%. Local thresholds could be set within these limits. It should be noted that some broad-leaved herbaceous species (e.g. *Trifolium repens* and *Cirsium arvense*) might respond to fertiliser treatment so that a high forb cover is not necessarily desirable. Also, weather patterns can influence the relative cover of grasses and other grassland constituents. So this attribute has to be treated judiciously, and the target ratio of non-graminaceous taxa should not be unrealistically high.

3.3.3 Since the grass: herb ratio may often be estimated by eye at points across a stand, observer effects need to be taken into account. It is suggested that local targets should be set to register a decrease in herb cover by 20% or more as unfavourable.

3.3.4 Both wet pastures and dry acid grassland often have high grass cover when in good condition. Forb cover may also be difficult to estimate even when such grasslands are in favourable condition, so this attribute is not recommended for these types of conservation grassland.

3.4 **Primary attribute: sward composition - positive indicator species**

3.4.1 In recognition of the impracticality of monitoring species diversity in full, the frequency of a sub-set of component taxa can be used to gauge condition. It is intended
that such species will indicate whether the ecological conditions are suitable for the maintenance of the local form of grassland. For the most part, it is predicted that their frequency (and/or cover) will decline in the face of unfavourable developments, notably eutrophication impacts. Alterations in nutrient status may take place as a result of fertiliser treatment, contamination of groundwater and surface run-off inputs, as well as atmospheric sources. Changes in indicator species frequency may also come about through excessive grazing and other disturbances, as well as successional development following management neglect.

3.4.2 Several factors make condition indicators suitable. The taxa should be characteristic of unimproved and usually low nutrient-status lowland grassland habitats (i.e. they will often be ‘stress-tolerators’, *sensu* Grime, Hodgson & Hunt, 1988). They should exhibit high fidelity to designated site features as opposed to derivative communities. The species should also be relatively straightforward to identify and be evident in the sward for much of the growing season.

3.4.3 Two differing but compatible approaches are available for assessing positive indicator status in a lowland grassland stand in a designated site. In the scheme of Robertson & Jefferson (2000), sets of indicator taxa are pre-selected for individual grassland communities (and some sub-communities) that qualify SSSIs. Threshold requirements are identified for each community across its geographical range, so that at least $x$ indicator taxa should be frequent and $y$ occasional for any example in favourable condition. The lists of community indicators are quite long, and it is anticipated that they should accommodate the range of floristic variation expressed locally in special conservation sites across Britain.

3.4.4 Alternatively or additionally, indicator species can be chosen separately for each stand, and it is recommended that usually two to six locally frequent indicators be selected for a particular community feature. In many cases, locally selected indicators are likely to include (but do not necessarily include) constant or preferential taxa recognised in the NVC. Thus for neutral *Cynosurus cristatus-Centaurea nigra* grassland (MG5), indicator species may often include *Centaurea nigra* and *Lotus corniculatus*, while for calcareous *Festuca ovina-Avenula pratensis* grassland (CG2), equivalent indicators may be *Leontodon hispidus*, *Sanguisorba minor* and *Thymus* spp. But choice of indicators should reflect local frequencies, and there is no intention that the NVC data set provides a standard to which stands in designated sites should aspire. In some instances, there may be certain management-dependent taxa that could serve as appropriate indicators (e.g. *Sanguisorba officinalis*, which can be frequent in hay-meadows but is not associated with pasture systems). Further examples are listed in Tables 2-6.

3.4.5 Threshold values can be set as the starting point frequencies of the local taxa. Despite best efforts to choose species with stable characteristics, populations will still vary to some extent in the absence of damaging perturbation (e.g. as a result of seasonal effects or changes in associated invertebrate or fungal populations). Normally, decline in frequency class of key indicators, associated with declining quality, will be accompanied by changes in other primary or secondary attributes. In such cases, a decline in frequency of one key indicator species would normally be sufficient to register the stand as unfavourable. In order to take account of possible natural fluctuations, if key indicator species have declined without associated changes in other attributes, it is recommended that two or more species should have declined in frequency class before the stand is scored as unfavourable.
3.4.6 It should be emphasised that future refinement in the guidelines concerning use of indicator species for lowland grassland condition assessment is likely to come about once practice in different parts of the UK is assessed. It must also be acknowledged that we know little detail of how species frequency alters with minor change in agricultural treatment.

3.4.7 The frequency classes should be interpreted as follows: 1-20% rare, 21-40% occasional, 41-60% frequent, >60% constant. Frequency is defined as the chance of finding a species at a point positioned at random in a stand.

3.5 **Primary attributes: sward composition - negative indicator species**

3.5.1 There are four ecological groups of species which can indicate that undesirable developments are taking place when they increase in frequency or cover within a special semi-natural grassland community.

- Agricultural weeds, such as *Cirsium arvense* and *Rumex obtusifolius*, may indicate an increase in soil nutrient levels when they become prominent in previously low-nutrient status swards. Other forms of disturbance may also result in an increase in weed species; a well-known example is *Senecio jacobaea* which responds to poaching, associated with high grazing levels.

- Other negative trends, especially again indicating eutrophication, are due to increases in agriculturally favoured species, notably *Lolium perenne* and *Trifolium repens*. Such taxa may be present at low cover in semi-natural mesotrophic swards. Since a number of the species can be difficult to identify and assess in the field, this group of negative indicators is included as an optional primary attribute. These species should be recorded if apparent, but not if cover estimation is problematic due, for example, to heavy grazing.

- Another group of negative indicators comprises bulky grasses, rushes and sedges. These are characteristic at moderate to quite high cover in a range of good quality semi-natural lowland grasslands, but when unchecked by grazing, cutting or waterlogging they may become overwhelmingly abundant, suppressing a number of less competitive associated taxa.

- More adverse and obvious successional changes following management neglect in grasslands are demonstrated by incursion and spread of bracken, scrub and other woody species. The presence of scrub and bracken often provides structural and ecological diversity to grassland features, and long-established stands that help significantly to support a site’s biodiversity value should often be retained. However, scrub and bracken can rapidly invade grassland features if left unchecked by sufficient grazing or management. Introduced scrub (and forb) species in calcareous swards are considered to be particularly detrimental.

3.5.2 Target levels for the cover of these grassland constituents are considered for a range of communities in Tables 2-6. Generic minimum targets are set, to register grasslands with an unacceptable frequency or cover of one or more of these species groups as unfavourable. For grassland features in significantly better condition at baseline
recording, targets could be set on a site-by-site basis to register an increase in any one species group as (locally) unfavourable.

3.6 **Primary attribute - indicators of local distinctiveness**
This attribute is intended to cover any site-specific aspects of this habitat feature (forming part of the reason for notification) which are not covered adequately by the previous attributes, or by separate guidance (e.g. notified species features).

3.6.1 **Rare and scarce species**
Rare grassland plant species that are selection features in designated sites have independent monitoring protocols (see Plants guidance section). Many grasslands also have less rare yet often declining species. Examples might include *Colchicum autumnale*, *Genista tinctoria*, *Platanthera chlorantha*, *Trollius europaeus* or *Vicia orobus*. There are many other such taxa that impart an important local conservation dimension to the site, and may have influenced selection of grassland site features. Where they are particularly significant as part of the grassland interest, targets should be set locally for such taxa that will at least maintain the existing population size class and will often retain local distribution characteristics.

3.6.2 **Transitional zonation**
Transition zones between different habitats and communities may be a special feature of some grasslands, for instance in a site with intergrading stands of dry and wet grassland, or grassland and heath or flush. Targets may be put forward to ensure the conservation of such features. In most cases, confirmation that these transitions remain intact where originally mapped will be all that is required. Such zonation is only important at certain sites and is thus treated as a discretionary attribute, but where it is applicable it should be treated as mandatory.

3.6.3 **Other factors**
Any further local attributes should be approved by specialist staff within each agency. Examples may include habitat requirements for invertebrate or bird features.

3.7 **Secondary attribute: sward structure - height**
Ranges for sward height are suggested for lowland grassland habitats in Tables 2-6. An attempt is made to define a generic target for the height of grassland vegetation that is not considered to be either over- or under-grazed, both of which may lead to a decline in species diversity. If local targets are appropriate, these should normally be set within the specified range, taking into account the particular site conditions and especially the requirements of noteworthy associated taxa.

3.8 **Secondary attribute: sward structure - litter**
Litter accumulation is often a sign that a grassland is being under-managed, with an excess of plant material not being removed by grazing or hay-making. Litter build-up and extent are difficult to estimate and in most cases an upper level of cover (25%) is used to trigger a conservation response. The presence of some litter is acceptable on many grassland sites, although local targets below 25% cover may be required in some circumstances.
3.9 Secondary attribute: sward structure - bare ground

3.9.1 There is a widely held view that some bare ground is required in many forms of semi-natural lowland grassland to promote regeneration from seed. Evidence from in-depth studies is generally lacking, and since it is also very difficult to estimate the extent of small amounts of bare ground, lower limits are omitted at this stage. Until the relationship between disturbance and propagule regeneration in the long-term maintenance of British lowland meadows and pastures is better understood, it seems more appropriate to concentrate on higher undesirable levels of bare ground brought about by poaching and other disturbance, which may favour ingress of undesirable and often competitive species, such as *Cirsium arvense*, *Senecio jacobaea* and *Juncus effusus*.

3.9.2 It is usually recommended that only quite low cover of bare ground (often <5%) is acceptable. Exceptions include calaminarian (OV37) grassland and some forms of acid (U1) and calcareous (CG1, CG7) grasslands, where relatively high cover of bare ground is perfectly acceptable. For some acid and calcareous grassland the extent of bare ground associated with rabbit burrows is taken into account. At some sites, higher cover of bare ground may be required, at least locally, to provide suitable micro-habitat for various insect taxa and other invertebrates.

3.10 Mixtures and mosaics

3.10.1 In many lowland grassland designated sites, special grassland communities (and sub-communities) exist in intimate mosaics or fine-scale zonation, and such patterning needs to be taken into account in monitoring conservation attributes. Both within-habitat (e.g. mixtures of different forms of wet grassland) and between-habitat (e.g. mixtures of acid and neutral grassland or heath) combinations occur frequently in lowland designated sites. In such circumstances, there should be a target for the relative amounts of each vegetation type, and the cover of each component can probably be estimated to the nearest 10%. Supplementary recording, for instance use of fixed-point photography or GPS, may be helpful.

3.10.2 Difficulties can arise over the selection of positive indicators, but it is recommended that representative taxa of the target communities be examined separately in each component. For negative indicators, there may be common targets for some species across the mixed stands, but for others (e.g. the cover of bulky grasses in mixtures of dry and wet swards) community-specific targets may be required.

3.11 Future considerations

3.11.1 At this early stage in the development of monitoring protocols, it is essential that flexibility and adaptation in methodological approaches be accepted. There is still much to learn about the most efficient and effective procedures for assessing monitoring attributes and also about how to set targets in a judicious and ecologically appropriate manner. Considerable future refinement is likely to be required as field experience with the monitoring procedures is gained.

3.11.2 Spatial and temporal floristic variation in composition may be normal features of many semi-natural grasslands, so restrictive target setting may lead to inappropriate negative evaluation of grassland condition. Conversely, targets that are too lax may result in carefree acceptance of condition when negative trends are taking place. For some attributes, it may be appropriate to assess time-series floristic changes in grassland composition under stable management conditions to assess the magnitude of flux in attribute values under acceptable conditions. Finally, it is worth noting that many of the
grassland attributes considered here are unlikely to vary independently in response to perturbation. It may thus be possible to reduce the number of attributes for measurement of lowland grassland condition in due course.

4 Field procedures

4.1 General approach and timing

4.1.1 Grassland designated sites vary in size from small uniform stands of one plant community occupying a single field, to much more extensive sites covering several or many enclosures with a number of different plant communities. In the latter case, feature condition may be highly variable and such sites may need to be subdivided into floristically homogeneous stands. Difficulties can arise when the condition of a particular community is variable within compartments, and special consideration is required for fine-scale mosaics and community mixtures (see 3.10).

4.1.2 In view of the likely resource constraints, a practical approach for most lowland grassland designated sites may be to make observations in a structured and consistent fashion during a fairly brief field inspection. This should only be undertaken by experienced staff, familiar with lowland grassland vegetation and the floristic cues and signals necessary for the accurate scoring of attribute features. If these skills are not available, particularly for features in borderline condition, systematic recording at 20 or more sample points is strongly advised. These approaches to routine designated site feature monitoring could be supplemented by rigorous recording at a set of reference sites covering the range of UK designated site habitat features. Fuller discussion of field methods is given in Robertson & Jefferson (2000).

4.1.3 Timing of monitoring needs to be planned in advance. In most cases, pasture sites can be assessed over much of the spring-summer growing season when the indicator species are evident. Hay-meadow stands should be visited before cutting wherever practical.

4.2 Requirements for monitoring

A guiding principle has been to keep field procedures for attribute assessment straightforward and practical, with the aim of acquiring maximum amount of useful information with the minimum amount of field recording effort. Nevertheless, certain basic information and observer skills are required, and these are outlined below.

- Monitors are required to be able to recognise NVC units in the field, for assessing community extent and other attributes.

- For the most part, it is recommended that there should be no significant reduction in the extent of special grassland at a particular site. A good quality vegetation map is thus a prerequisite for this aspect of condition assessment. It may be necessary to undertake careful field survey to establish a base-line vegetation map during the initial phase of monitoring. In some cases where scrub or bracken expansion is an issue, aerial or fixed-point photographs may also be valuable.

- Sward composition plays a key role in determining condition. Observers thus need to be able reliably to identify a range of British grassland vascular plant species. It is suggested that critical and difficult taxa should be avoided in target formulation; even so, field
identification can be troublesome especially in heavily grazed pastures when determination has to rely on vegetative characters.

<td><strong>Sward composition:</strong></td>
<td>Target should be set to register a low or decreasing herb cover as</td>
<td>Structured observation.</td>
<td>The grass:herb ratio is often regarded as a useful indicator of soil nutrient status, where competitive grasses generally increase at the expense of other taxa under high nutrient conditions. Care must be taken with this attribute, as some herbs (e.g. <em>Trifolium repens</em> and several agricultural weeds) also respond to nutrient enrichment. The grass:herb ratio can also fluctuate due to weather effects; for example, a wet spring may favour grasses over herbs. Therefore the target should give scope for natural variation. Occasionally, examples may be considered favourable at a lower ratio, for example some floristically rich Welsh MG4 stands have only 30% herb cover.</td>

<td>conditions, and those that are visible in the sward for much of the growing season. Normally, a decline in the frequency of key indicators will suggest declining quality, where accompanied by changes in other primary or secondary attributes. If this were the case, a decline in frequency of one key indicator species would normally be sufficient to register the stand as unfavourable. If key indicator species have declined without associated changes in other attributes, in order to allow for possible natural population fluctuations, it is recommended that 2 or more species should have declined in frequency class before the stand is judged unfavourable.</td>
</tr>
<tr>
<td>Sward composition: frequency of negative indicators - agricultural weeds</td>
<td>Target should be set to register high or increasing frequency/cover as unfavourable. As a generic standard, no species should be more than occasional throughout the sward or together more than 5% cover. Occasionally, local targets for S. jacobaea and A. sylvestris may be set to accept swards with either species frequent as favourable. More stringent local frequency targets can be set, if appropriate, to register increase in frequency of 10% or more as unfavourable.</td>
<td>Examples of negative indicators (agricultural weeds): Anthriscus sylvestris, Cirsium arvense, Cirsium vulgare, Galium aparine, Plantago major, Rumex crispus, Rumex obtusifolius, Senecio jacobaea, Urtica dioica, Equisetum arvense Bracken is considered with scrub. The majority of the listed agricultural weeds respond to some form of nutrient enrichment. Therefore high or increasing frequency/cover will generally indicate unfavourable condition. However, S. jacobaea often reflects grazing management rather than soil nutrient status, and some horse-grazed pastures with frequent S. jacobaea can be potentially favourable, where other agricultural weeds are absent or at very low levels. Likewise, potentially favourable MG3 stands can support frequent A. sylvestris, in the absence of high levels of other agricultural weeds. At some sites, with very low levels of agriculturally favoured species, it</td>

| **Sward structure: litter** | Target should be set to register high or increasing cover as unfavourable.  
As a generic standard, total extent should be no more than 25% cover of the sward.  
More stringent local targets can be set, if appropriate, to register increase in litter cover of 10% or more as unfavourable. It is probably unlikely that the threshold would need to be raised. | Structured observation. | The percentage litter cover can be difficult to estimate, so it is recommended that only a continuous, readily observable layer is included in the cover estimate. Beyond 25% cover, this would generally indicate insufficient removal of biomass by grazing or cutting. Some stands have negligible litter cover, and it may be appropriate in these cases to reduce the threshold. |
| **Sward structure: extent of bare ground (not rock)** | Target should be set to register high or increasing cover as unfavourable.  
As a generic standard, total extent should be no more than 5% of the sward.  
Locally it may be appropriate to increase the threshold if there are specific conservation objectives requiring bare ground. Targets of less than 5% are not recommended and would be hard to assess. | Structured observation. | The percentage bare ground can also be difficult to estimate, so it is recommended that only the bare ground visible without disturbing the vegetation be included in the cover estimate. Occasionally a higher cover of bare ground may be acceptable in May – early June, particularly for MG8. Rabbit warren activity is unlikely to be welcome, as in general neutral grasslands are not tolerant of heavy grazing. In some stands, higher amounts of bare ground may be required for specialist taxa. |

<td>Structured observation or sampling.</td>
<td>informative and readily identifiable taxa. Care should be taken to choose species that show high fidelity to lowland calcareous grassland, that have reasonably stable populations given suitable ecological conditions, and those that are visible in the sward for much of the growing season. Normally, a decline in the frequency of key indicators will suggest declining quality, where accompanied by changes in other primary or secondary attributes. If this were the case, a decline in frequency of one key indicator species would normally be sufficient to register the stand as unfavourable. If key indicator species have declined without associated changes in other attributes, in order to allow for possible natural population fluctuations, it is recommended that 2 or more species should have declined in frequency class before the stand is judged unfavourable.</td>
</tr>
<tr>
<td>Sward composition: frequency of negative indicators - agricultural weeds</td>
<td>Target should be set to register high or increasing frequency/cover as unfavourable. As a generic standard, no species should be more than occasional throughout the sward or together at more than 5% cover. More stringent local frequency targets can be set, if appropriate, to register an increase in frequency of 10% or more as unfavourable.</td>
<td></td>
<td>Examples include negative indicators (agricultural weeds): <em>Anthriscus sylvestris</em>, <em>Bellis perennis</em>, <em>Cirsium arvense</em>, <em>Cirsium vulgare</em>, <em>Carduus spp.</em>, <em>Chamerion angustifolium</em>, <em>Galium aparine</em>, <em>Plantago major</em>, <em>Rumex crispus</em>, <em>Rumex obtusifolius</em>, <em>Senecio jacobaea</em>, <em>Sonchus spp.</em>, <em>Urtica dioica</em> Bracken is considered with scrub. The majority of the listed agricultural weeds respond to some form of nutrient enrichment. Therefore high or increasing frequency/cover will generally indicate unfavourable condition. For MG2, <em>Anthriscus sylvestris</em> and <em>Urtica dioica</em> may be present at up to combined cover of 25% before the stand would be considered unfavourable. At some sites, with very low levels of agriculturally favoured species, it may be appropriate to set more stringent targets, for example no more than rare (20% frequency).</td>

<tr>
<td>concern.</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

As a generic standard, total extent should be no more than 10% of the sward.

Locally it may be appropriate, particularly for CG1 and CG7, to increase the threshold and to include a minimum extent of 5% bare ground. For other communities, occasionally an upper threshold of 5% may be appropriate, particularly for CG2 and CG6. Targets of less than 5% are not recommended and would be hard to assess.

For some communities a higher cover of bare ground may be acceptable, particularly CG1 (up to 25%) and CG7 (up to 15% or 50% for CG7c). For these communities, cover of bare ground at less than 5% (or 10% for CG7c) would normally indicate unfavourable conditions.

Care should be taken here, particularly in relation to rabbit warrens. Rabbit grazing is important in maintaining some grasslands, but large population size can lead to undue disturbance associated with warren activity. The area of warrens that can be tolerated is at least partially dependent upon site size. As a general guide, localised bare ground around rabbit warrens should be no more than 0.05 ha (20 x 20 m) for large sites (>50 ha) or 0.1% of the stand (up to 0.25 ha / 0.5% for CG7).

In some stands, areas of bare ground may also be required for specialist invertebrate taxa.

Table 5. UK GUIDANCE ON CONSERVATION OBJECTIVES FOR MONITORING DESIGNATED SITES: LOWLAND PURPLE MOOR GRASS AND RUSH PASTURES

Interest feature: Lowland purple moor grass and rush pastures

Includes the following NVC types: M22-26

Equivalent Phase 1 categories: B5 Marsh/marshy grassland

Includes the following Annex I types: 6410 Molinia meadows on calcareous, peaty or clayey-silt-laden soils (Molinion caeruleae)

Reporting category: Fen, marsh and swamp

NB All primary attributes (listed in bold) are mandatory. Secondary or supporting attributes (marked *) often provide valuable substantiating evidence but should not generally be used as primary indicators of condition. Hashed attributes (#) are to be used when conditions allow (see text) and/or when appropriate.

Frequency classes for positive indicator species should be as follows: 1-20% rare, 21-40% occasional, 41-60% frequent, >60% constant. Frequency is defined as the chance of finding a species at a point positioned at random in a stand.

<tr>
<td><strong>Sward composition: frequency and cover of <em>Molinia caerulea</em> and bulky <em>Juncus spp</em></strong></td>
<td>Target should be set to register both high and low cover as unfavourable. As a generic standard, the cover of all species combined should be within the range 25-80%. For M24-26, <em>Molinia</em> should be at least frequent throughout the sward. Within this range, it may occasionally be appropriate to set local targets to register an increase in cover by 20% or more as unfavourable. Smaller increases or decreases within the generic range may not necessarily be unfavourable.</td>
<td>Structured observation or sampling.</td>
<td>Both taxa may expand to become over-dominant in neglected stands when they may shade out smaller growing species and become highly impoverished. Conversely, the cover of <em>Molinia</em> and <em>Juncus</em> spp. may decline in response to unfavourable treatments including over-grazing and drainage. Although <em>Juncus effusus</em> may be dominant in some good quality stands of M23, in general an increase in cover of 20% or more of <em>J. effusus</em> (and to a lesser extent, <em>J. conglomeratus</em> and <em>J. inflexus</em>) is undesirable and should be considered when setting local limits.</td>
</tr>
<tr>
<td><strong>Sward composition: frequency of negative indicators - agricultural weeds</strong></td>
<td>Target should be set to register high or increasing frequency/cover as unfavourable. As a generic standard, no species should be more than occasional throughout the sward or together more than 5% cover. More stringent local frequency targets can be set, if appropriate, to register an increase in frequency of 10% or more as unfavourable.</td>
<td>Structured observation or sampling.</td>
<td>Examples of negative indicators (agricultural weeds): <em>Anthriscus sylvestris, Cirsium arvense, Cirsium vulgare, Rumex crispus, Rumex obtusifolius, Urtica dioica</em> Bracken is considered with scrub. The majority of the listed agricultural weeds respond to some form of nutrient enrichment. Therefore high or increasing frequency/cover will generally indicate unfavourable condition. At some sites, with very low levels of agriculturally favoured species, it may be appropriate to set more stringent targets, for instance no more than rare (20% frequency). Cover targets of less than 5% are not generally recommended.</td>

<td></td>
<td></td>
<td>Normally, decline in frequency of metallophyte species associated with declining quality, will be accompanied by changes in other primary or secondary attributes. If this were the case, a decline in frequency of one metallophyte species would normally be sufficient to register the stand as unfavourable. If metallophyte species have declined without associated changes in other attributes, in order to allow for possible natural population fluctuations it is recommended that 2 or more species should have declined in frequency before the stand is judged unfavourable.</td>

</table>
| frequency of negative indicators – undesirable taxa | unfavourable. | sampling. | Examples of undesirable taxa: *Anthriscus sylvestris, Cirsium arvense, Cirsium vulgare, Heracleum sphondylium, Urtica dioica, coarse grasses (e.g. Arrhenatherum elatius, Holcus lanatus)*  
At some sites, with very low levels of agriculturally favoured species, it may be appropriate to set more stringent targets, for instance no more than rare (20% frequency). Cover targets of less than 5% are not generally recommended. |
| **Sward composition:** cover of negative indicators – scrub and tree species and bracken | Targets should be set to register high or increasing cover as unfavourable. | Structured observation or sampling. | These targets to be used with caution. Scrub and tree cover can form a useful transition habitat across part of a site, but if more than occasional throughout a sward, even at less than 5% cover, scrub and bracken can soon become a problem if grazing levels are not sufficient or if scrub control is not being carried out.  
High scrub cover may be required at sites with specialist invertebrate interest. |
| #Indicators of local distinctiveness | Targets should be set to register low or declining population size/extent (species) or loss of cover (transitions) as unfavourable. Additional targets may be set for other attributes as appropriate. | Structured observation or sampling. | This attribute is intended to cover any site-specific aspects of this habitat feature (forming part of the reason for notification) which are not covered adequately by the previous attributes, or by separate guidance (e.g. notified species features)  
It is recommended that the appropriate size class and extent of scarce taxa be recorded. For plants, recommended size classes are as follows for number of shoots (or ramets): very small 1-10; small 11-100; |

<tr>
<td>attribute.</td>
<td>Local targets should be set to ensure: - existing populations of rare/scarce species are maintained at least at current levels and often local distribution characteristics - community and habitat transitions are maintained at current levels and in current locations - other locally distinctive attributes are maintained.</td>
<td>medium 101-1000, large 1001-10000; very large &gt;10000.</td>
<td>In principle, equivalent approximate population measures could be developed for invertebrates and other taxa. Check that significant transitions have not been adversely modified.</td>
</tr>
<tr>
<td>*Sward structure: average height</td>
<td>Targets should be set to register under-grazed conditions as unfavourable. As a generic standard: upper limit of 5 cm.</td>
<td>Direct measurement at points across stand.</td>
<td>Locally, sward height may vary, and in some cases may be in patchily unfavourable condition. Bear in mind that some invertebrates require a range of sward heights.</td>
</tr>
<tr>
<td>*Sward structure: extent of bare ground (not rock)</td>
<td>Target should be set to register high or increasing cover as unfavourable. As a generic standard, total extent between 10 and 90% of the sward. In some cases it may be appropriate to set a local target of decrease in cover by 20% or more as unfavourable.</td>
<td>Structured observation.</td>
<td>The percentage bare ground can at times be difficult to estimate, so it is recommended that only the bare ground visible without disturbing the vegetation be included in the cover estimate.</td>
