## CONTENTS

### Part 1. Introduction

Address by the Patrons of 'Waterbirds around the world' .....	2
Acknowledgements .....	3
The Edinburgh Declaration .....	7
Déclaration d'Edimbourg .....	10
Declaración de Edimburgo .....	13
Address by His Royal Highness The Prince of Wales .....	16
Address by Elliot Morley MP, UK Minister for Environment and Agri-Environment .....	19
Address by Cees Veerman, The Netherlands' Minister for Agriculture, Nature and Food Quality .....	21
Address by Max Finlayson, President, Wetlands International .....	23
Address by John Markland, Chairman of Scottish Natural Heritage .....	27
Address by Allan Wilson MSP, Deputy Minister for Environment and Rural Development, Scotland .....	28
Waterbird conservation in a new millennium — where from and where to?	
David A. Stroud, Gerard C. Boere, Colin A. Galbraith & Des Thompson .....	29
The flyway concept; what it is and what it isn't	
Gerard C. Boere & David A. Stroud .....	40

### Part 2. Plenary papers

2.1 A short history of waterbird conservation	
Eckhart Kuijken .....	52
2.2 North American flyway management: a century of experience in the United States	
Paul R. Schmidt .....	60
2.3 African-Western Eurasian Flyways: current knowledge, population status and future challenges	
Nicholas C. Davidson & David A. Stroud .....	63

2.4	Migration in the balance: tight ecological margins and the changing fortunes of shorebird populations Theunis Piersma .....	74
2.5	Successes and challenges of promoting conservation of migratory waterbirds and wetlands in the Asia-Pacific region: nine years of a regional strategy Taej Mundkur .....	81
2.6	Climate variability and change and other pressures on wetlands and waterbirds: impacts and adaptation C. Max Finlayson, Habiba Gitay, Maria Bellio, Rick van Dam & Iain Taylor .....	88
2.7	Sustainable harvest of waterbirds: a global review Niels Kanstrup .....	98
2.8	Cross-cutting research on a flyway scale - beyond monitoring David B. Lank & Silke Nebel .....	107
2.9	Conservation of albatrosses and petrels of the Southern Ocean John Cooper .....	113
2.10	The Arctic – origin of flyways Kenton D. Wohl .....	120

## Part 3. Geographic regions

<b>3.1</b>	<b>The Arctic: source of flyways .....</b>	<b>126</b>
3.1.1	Monitoring Arctic-nesting shorebirds: an international vision for the future Richard B. Lanctot (on behalf of the Committee for Holarctic Shorebird Monitoring) .....	127
3.1.2	Breeding performance of tundra waders in response to rodent abundance and weather from Taimyr to Chukotka, Siberia Mikhail Y. Soloviev, Clive D.T. Minton & Pavel S. Tomkovich .....	131
3.1.3	The Arctic connection: monitoring coastal waders in South Africa - a case study Doug M. Harebottle & Les G. Underhill .....	138
3.1.4	Thirty years of Arctic wader monitoring in the Dutch part of the Wadden Sea Meinte Engelmoer, Gerard C. Boere & Ebel Nieboer .....	140
3.1.5	Stable isotope analysis and threats in the wintering areas of the declining Spoon-billed Sandpiper <i>Eurynorhynchus pygmeus</i> in the East Asia-Pacific Flyway Christoph Zöckler, Evgeny E. Syroechkovskiy, Jr., Elena G. Lappo & Gillian Bunting .....	147
3.1.6	Declines in breeding waterbirds following a redistribution of Arctic Terns <i>Sterna paradisaea</i> in West Greenland Carsten Egevang, Kaj Kampp & David Boertmann .....	154
3.1.7	Long-term study of Bewick's Swans <i>Cygnus columbianus bewickii</i> nesting in the Nenetskiy State Nature Reserve, Russia: preliminary results and perspectives Eileen C. Rees & Anna V. Belousova .....	155

<b>3.2</b>	<b>Waterbirds in the Neotropics</b>	157
3.2.1	Potential new Ramsar sites in northwest Mexico: strategic importance for migratory waterbirds and threats to conservation X. Vega, M.A. González & A. Muñoz del Vieja	158
3.2.2	The importance of Costa Rica for resident and migratory waterbirds Ghisselle M. Alvarado Quesada	161
3.2.3	Shorebird monitoring in the Upper Bay of Panama Loyda E. Sánchez, Deborah M. Buehler & Alberto I. Castillo	166
3.2.4	Rice culture in Cuba as an important wintering site for migrant waterbirds from North America Lourdes Mugica, Martín Acosta, Dennis Denis, Ariam Jiménez, Antonio Rodríguez & Xavier Ruiz	172
3.2.5	Waterbird monitoring and conservation in protected areas of the Colombian Pacific Luis Germán Naranjo, Luis Fernando Castillo, Richard Johnston-González, Carlos Hernández, Carlos Ruiz & Felipe Estela	177
3.2.6	Important areas for waterbirds on the Pacific coast of Colombia Luis Germán Naranjo, Alexandra Aparicio & Patricia Falk	181
3.2.7	Status of the Black-necked Swan <i>Cygnus melancorypha</i> and Coscoroba Swan <i>Coscoroba coscoroba</i> in the south of Brazil Joao Oldair Menegheti & Joao Carlos Dotto	183
3.2.8	Opportunism required - migratory shorebirds at variable tidal flats in the northeast of Brazil Kerstin Kober	185
3.2.9	Biodiversity and conservation in the Bañados del Este, southeastern Uruguay Adrian B. Azpiroz & Francisco Rilla	186
3.2.10	Abundance, distribution and migration chronology of shorebirds on exposed sandy beaches of south central Chile Alexandra Aparicio	188
3.2.11	The conservation status of migratory waterbirds in Argentina: towards a national strategy Sergio D. Goldfeder & Daniel E. Blanco	189
3.2.12	The Ruddy-headed Goose <i>Chloephaga rubidiceps</i> mainland population: a flyway perspective Daniel E. Blanco, Ricardo Matus, Olivia Blank, Victoria M. de la Balze & Sergio M. Zalba	195
<b>3.3</b>	<b>Flyway conservation in North America</b>	197
3.3.1	Integrated waterfowl management in North America Robert J. Blohm, David E. Sharp, Paul I. Padding, Ronald W. Kokel & Kenneth D. Richkus	199
3.3.2	Summary of the Workplans for 2005 of the Waterbird Conservation Council's committees Jennifer Wheeler	204
3.3.3	Canada's Waterbird Conservation Plan - building on 30 years experience on the North American Great Lakes Donna L. Stewart, D.V. Chip Weseloh, Brigitte Collins, Steve Timmermans & Jon McCracken	206
3.3.4	Population declines in North American shorebirds: ecology, life-history and sexual selection Gavin M. Thomas, Richard B. Lanctot & Tamás Székely	207
3.3.5	Coordinated waterbird monitoring in the Pacific flyway of the western U.S.: the Idaho Bird Inventory and Survey (IBIS) Rex Sallabanks & Colleen E. Moulton	209

3.3.6	Individual behaviour, population genetics and phylogeography of North American mergansers John M. Pearce .....	211
3.3.7	Using national plans in North America to conserve shorebirds at an international scale Garry Donaldson, Brad Andres, Aurea Estrada & Stephen Brown .....	213
3.3.8	Issues and challenges facing migratory bird conservation programs in North America Steve Wendt, Paul Schmidt & Garry Donaldson .....	214
<b>3.4</b>	<b>Intra-African migration .....</b>	<b>217</b>
3.4.1	Conservation dilemmas for intra-African migratory waterbirds Tim Dodman & Cheikh Hamallah Diagana .....	218
3.4.2	An investigation into inter-colony movements of African Penguins <i>Spheniscus demersus</i> Philip A. Whittington, J. Griffin, P. Bartlett, R.J.M. Crawford, N.T.W. Klages, R.M. Randall & A.C. Wolfaardt .....	224
3.4.3	Anatidae numbers and distribution in West Africa in winter Bernard Trollet & Olivier Girard .....	226
3.4.4	Anatidae wintering in the Inner Niger Delta, Mali Olivier Girard .....	228
3.4.5	Lesser Flamingo <i>Phoenicopterus minor</i> counts in Tanzanian soda lakes: implications for conservation Charles Mlingwa & Neil Baker .....	230
3.4.6	Satellite tracking documents the East African flyway and key site network of the Lesser Flamingo <i>Phoenicopterus minor</i> Brooks Childress, Baz Hughes, David Harper, Wim Van den Bossche, Peter Berthold & Ulrich Querner .....	234
3.4.7	Movements of three Greater Flamingos <i>Phoenicopterus ruber roseus</i> fitted with satellite transmitters in Tanzania N. E. Baker, E.M. Baker, W. Van den Bossche & H. Biebach .....	239
3.4.8	Waterbirds in Tanzania: what we know and what we do not; where are the knowledge gaps? N. E. Baker & E.M. Baker .....	245
3.4.9	Conservation biology of an endemic waterbird of Madagascar, the Madagascar Plover <i>Charadrius</i> <i>thoracicus</i> : distribution, surveys and photographs Sama Zefania & Tamás Székely .....	250
3.4.10	Madagascar Teal <i>Anas bernieri</i> : the ecology and conservation of a short distance migrant Hywel Glyn Young .....	252
3.4.11	Subsistence use of waterbirds at Lake Chilwa, Malawi Roy Bhima .....	255
3.4.12	Waterbird ringing in Africa H. Dieter Oschadleus .....	257
<b>3.5</b>	<b>Flyway conservation in the Central Asian Flyway .....</b>	<b>263</b>
3.5.1	Waterbirds in the valleys of the Ob river tributaries (Western Siberia) and their conservation Tatiana K. Blinova, I.V. Gromyshev & M.M. Samsonova (Mukhacheva) .....	264
3.5.2	Study and conservation of the Lesser White-fronted Goose <i>Anser erythropus</i> on the Putorana Plateau, southern Taimyr: results and perspectives Alexey A. Romanov .....	265

3.5.3	Waterbird surveys in the Tobolo-Irtyshskaja forest-steppe and steppe of Western Siberia Sergei A. Soloviev .....	266
3.5.4	Waterbird populations in the Barabinsk Lowland, Russia, 1976-2003 Alexander P. Yanovsky .....	267
3.5.5	Past and current status of Anatidae populations in Kazakhstan Sergey N. Yerokhov .....	269
3.5.6	Creating protected areas on Lake Balkhash and Ile River Delta in the Kazakhstan Republic Altay Zhumakan-Uly Zhatkanbayev .....	275
3.5.7	The effect of habitat change on the distribution of waterbirds in Uzbekistan and the possible implications of climate change Elena A. Kreuzberg-Mukhina .....	277
3.5.8	The Aral Sea basin: changes in migratory and breeding waterbird populations due to major human-induced changes to the region's hydrology Elena A. Kreuzberg-Mukhina .....	283
3.5.9	The importance of Uzbekistan's wetlands for supporting wintering waterfowl of the Central Asian Flyway Yevgeniya Lanovenko .....	285
3.5.10	A review of the wetlands of Afghanistan Ahmad Khan .....	287
3.5.11	Strategic role of Pakistan wetland resources: prospects for an effective migratory waterbird conservation network Kashif M. Sheikh & Naseem Kashif .....	292
3.5.12	Decreases in size of lakes and numbers of birds in selected wetlands in Pakistan Zulfiqar Ali & Muhammad Akhtar .....	294
3.5.13	The decline in wader populations along the east coast of India with special reference to Point Calimere, south-east India S. Balachandran .....	296
3.5.14	Important Bird Areas in western India Aeshita Mukherjee & Burkhard Wilske .....	302
3.5.15	Importance of wetlands for conservation of bird life in the dry lands of western India Aeshita Mukherjee & Burkhard Wilske .....	303
3.5.16	Status of migratory shorebirds at Bhitarkanika and Chilika wetlands on the east coast of India Anup Kumar Nayak .....	305
3.5.17	Residential, population and conservation status of Indian wetland birds Arun Kumar, P.C. Tak & J.P. Sati .....	308
3.5.18	Protection of habitat of Sarus Crane <i>Grus antigone</i> in Bhoj wetland, India Pradip Kumar Nandi .....	309
3.5.19	Nesting sites and breeding success of Black-necked Cranes <i>Grus nigricollis</i> in Ladakh, India Pankaj Chandan, Parikshit Gautam & Archana Chatterjee .....	311
<b>3.6</b>	<b>East Asia-Pacific Flyway .....</b>	<b>315</b>
3.6.1	Shorebird migration studies in Kamchatka Yuri N. Gerasimov .....	316

3.6.2	Conserving migrating shorebirds in the Yellow Sea region C. Kelin & X. Qiang	319
3.6.3	The North East Asian Crane Site Network Simba Chan	320
3.6.4	The role of Asian wetland centres in the conservation of wetlands and migratory waterbirds Lew Young	324
3.6.5	Shorebird research in the East Asian-Australasian Flyway: looking to the future Phil J. Straw, Ken B. Gosbell & Clive D.T. Minton	328
3.6.6	Threatened waterbird species in eastern and southern Asia and actions needed for their conservation Michael J. Crosby & Simba Chan	332
3.6.7	Monitoring waterbirds in the Asia-Pacific region David Li Zuo Wei & Taej Mundkur	339
3.6.8	Shorebird abundance and diversity in Sungei Buloh Wetland Reserve, Singapore James T.W.M. Gan & R.K. Ramakrishnan	343
3.6.9	Using predictive modelling to investigate large-scale shorebird migration in the Russian Far East for Great Knot <i>Calidris tenuirostris</i> , Red Knot <i>Calidris canutus</i> and Bar-tailed Godwit <i>Limosa lapponica</i> Kyle Kusch & Falk Huettmann	345
3.6.10	Status and conservation of the Little Curlew <i>Numenius minutus</i> on its over-wintering grounds in Australia Maria G. Bellio, P. Bayliss, S. Morton & R. Chatto	346
<b>3.7</b>	<b>Sustainable use of natural resources in the African-Eurasian Flyway</b>	<b>349</b>
3.7.1	The Agreement on the Conservation of African-Eurasian Migratory Waterbirds Bert Lenten	350
3.7.2	Conservation problems of migratory waterfowl and shorebirds and their habitats in the Kaliningrad region of Russia Dimitri Grishanov	354
3.7.3	The state and conservation problems of key stop-over sites of migratory Common Snipe <i>Gallinago gallinago</i> in the Kaliningrad region of Russia Julia Yarovikova	355
3.7.4	The Neman River Delta: a potential Ramsar site in Kaliningrad, Russia Gennady Grishanov & Dimitri Grishanov	356
3.7.5	The migration routes of waterfowl and their protection in Baikal Siberia Yuri I. Mel'nikov	357
3.7.6	Enigmas about Whimbrel <i>Numenius phaeopus</i> in the East Atlantic Flyway Bertrand Trollet	363
3.7.7	The European Non-Estuarine Coastal Waterbird Survey Steve J. Holloway, Niall H.K. Burton & Mark M. Rehfisch	364
3.7.8	The evaluation of some key wetlands for waterfowl in Central Anatolia, Turkey Utku Perktas, Atıl Barış Albayrak & Zafer Ayaş	366
3.7.9	Changes in abundance and diversity of waders and wintering waterfowl on the southern coast of the Caspian Sea Ahmad Barati & Olia Gholi Khalilipoor	368

3.7.10	Results of eight years of monitoring wintering and nesting waterbirds in Azerbaijan Elchin Sultanov .....	370
3.7.11	Evolution of freshwater lagoons in Daghestan and their importance for waterbirds on the west Caspian coast E. V. Vilkov .....	372
3.7.12	An overview of the Office National de la Chasse et de la Faune Sauvage (ONCFS) research programmes on Anatidae Vincent Schricke .....	373
3.7.13	Waterbirds of Baie de Baly, Madagascar Rivo Rabarisoa, Odon Rakotonomenjanahary & Julien Ramanampamonjy .....	374
3.7.14	Trends in numbers of migrant waders (Charadrii) at Langebaan Lagoon, South Africa, 1975-2003 Doug M. Harebottle, Rene A. Navarro, Les G. Underhill & Manfred Waltner .....	376
3.7.15	The breeding sites and distribution of Red-crested Pochard <i>Netta rufina</i> in Hungary Attila Bankovics .....	379
3.7.16	The Lesser White-fronted Goose <i>Anser erythropus</i> at the verge of the millennium Vladimir V. Morozov .....	380

## Part 4. Cross-cutting issues

4.1	<b>The implications of climate change for waterbirds</b> .....	384
4.1.1	Developing an integrated approach to understanding the effects of climate change and other environmental alterations at a flyway level Mark J. O'Connell, A.H.L. Huiskes, M.L. Loonen, J. Madsen, M. Klaassen & M. Rounsevell .....	385
4.1.2	Climate change and coastal waterbirds: the United Kingdom experience reviewed M. J. Rehfish & Graham E. Austin .....	398
4.1.3	Effects of the North Atlantic Oscillation and El Niño-Southern Oscillation on return rates, body mass and timing of migration of Common Terns <i>Sterna hirundo</i> breeding in Germany Marco Favero & Peter H. Becker .....	405
4.2	<b>Disease emergence and impacts in migratory waterbirds</b> .....	410
4.2.1	Evolving changes in diseases of waterbirds Milton Friend .....	412
4.2.2	Emerging viral diseases in waterbirds Thijs Kuiken, Ron A.M. Fouchier, Guus F. Rimmelzwaan & Albert D.M.E. Osterhaus .....	418
4.2.3	The global importance of avian botulism Tonie E. Rocke .....	422
4.2.4	Domestic poultry and migratory birds in the interspecies transmission of avian influenza viruses: a view from Hong Kong Kennedy F. Shortridge & David S. Melville .....	427

4.2.5	Migratory waterbirds and avian influenza in the East Asian-Australasian Flyway with particular reference to the 2003-2004 H5N1 outbreak David S. Melville & Kennedy F. Shortridge	432
4.2.6	Recurring waterbird mortalities of unusual etiologies Rebecca A. Cole & J. Christian Franson	439
4.2.7	Consequences of an unforeseen event: effects of foot-and-mouth disease on the Barnacle Goose <i>Branta leucopsis</i> population wintering on the Solway Firth Larry Griffin, Mark O' Brien & Eileen C. Rees	441
4.2.8	Snow Goose <i>Chen caerulescens caerulescens</i> overabundance increases avian cholera mortality in other species Michael D. Samuel	443
4.2.9	Ukraine as an ecological corridor for transcontinental migration of birds in the Afro-Eurasian region and questions of epidemiological safety Ivan Rusev & A. Korzuykov	446
<b>4.3</b>	<b>Flyway monitoring – rising to the challenge</b>	447
4.3.1	Monitoring North America's waterfowl resource Robert J. Blohm, David E. Sharp, Paul I. Padding & Kenneth D. Richkus	448
4.3.2	The African Waterbird Census (1991-2004): fourteen years of waterbird surveys in Africa Cheikh Hamallah Diagana, Tim Dodman & Seydina Issa Sylla	453
4.3.3	Ten years of continuous waterbird monitoring at Lutembe Bay, Lake Victoria, Uganda Achilles Byahuranga & Dianah Nalwanga	457
4.3.4	Priority needs for co-ordinated research at flyway level in order to improve monitoring and management of waterbird populations as identified by the French National Observatory of Wildlife Michel Vallance & Yves Ferrand	459
4.3.5	Long-term waterbird monitoring in The Netherlands: a tool for policy and management Marc van Roomen, Kees Koffijberg, Ruurd Noordhuis & Leo Soldaat	463
4.3.6	Monitoring geese in the Vinogradovo floodplain – the core stop-over site in Moscow region Alexander L. Mischenko, Olga V. Sukhanova & Sergei P. Kharitonov	471
4.3.7	Estuarine waterbirds at low tide: the WeBS low tide counts 1992-1993 to 1998-1999 Andy Musgrove	473
4.3.8	Waterfowl marking in Portugal: main results and future perspectives David Rodrigues, M. Ester Figueiredo, António Fabião & Paulo Tenreiro	474
4.3.9	Britain's first Winter River Bird Survey: a new approach to surveying waterbirds on linear waterways James A. Robinson, Melanie Kershaw, Jenny Worden & Peter Cranswick	476
4.3.10	Fluctuations and trends in Swedish waterfowl populations during the last four decades Leif Nilsson	478
4.3.11	Conflicting trends in Ruddy Shelduck <i>Tadorna ferruginea</i> populations: a myth or reality? Anastasia B. Popovkina	480
4.3.12	The Swan Goose <i>Anser cygnoides</i> research and conservation programme in Russia Nikolay D. Poyarkov	482
4.3.13	Current status of the International Waterfowl Census in the Czech Republic Zuzana Musilová & Petr Musil	484

4.3.14	Waterbird censuses in Slovakia Jozef Ridzoň	487
4.3.15	Measuring wader recruitment Jacquie A. Clark, Robert A. Robinson, Nigel A. Clark & Philip W. Atkinson	488
4.3.16	Dynamics of breeding duck populations over the last two decades in key wetlands of the Moscow region Olga V. Sukhanova & Alexander L. Mischenko	490
4.3.17	Spotted Crakes <i>Porzana porzana</i> in the UK – a history and evaluation of current status Ian Francis & David A. Stroud	491
4.3.18	The sixth International White Stork Census: 2004-2005 Kai-Michael Thomsen & Hermann Hötker	493
4.3.19	Monitoring of waterbirds at Bourgas wetlands, Bulgaria Lyubomir Profirov, Milko Dimitrov, Tanyo Michev & Konstantin Nyagolov	496
4.3.20	Monitoring overlapping populations: the Greylag Goose <i>Anser anser</i> in the Iceland-Britain flyway Richard Hearn & Morten Frederiksen	498
4.3.21	Monitoring and mapping of waders breeding in northernmost Sweden Åke Lindström	500
4.3.22	The development of a database for the Spoon-billed Sandpiper <i>Eurynorhynchus pygmeus</i> Gillian Bunting & Christoph Zöckler	501
4.3.23	Population size and trend of the Red-crested Pochard <i>Netta rufina</i> in southwest/central Europe: an update Verena Keller	503
<b>4.4</b>	<b>Migration ecology</b>	505
4.4.1	Elucidating the movements of migratory birds through the combined use of stable isotope ‘signatures’ and DNA markers Lisette Coiffait, Richard Bevan, Chris Redfern, Jason Newton & Kirsten Wolff	506
4.4.2	Long-term trends in numbers and distribution of wintering geese in the Oostkustpolders, Flanders (Belgium) Eckhart Kuijken, Christine Verschure, Wouter Courtens & Patrick Meire	508
4.4.3	East-Atlantic flyway populations of seaducks in the Barents Sea region Yuri Krasnov, Maria Gavrilov, Natalie Nikolaeva, Yuri Goryaev & Hallvard Strøm	512
4.4.4	Changes in migration patterns and wintering areas of south Swedish Greylag Geese <i>Anser anser</i> Leif Nilsson	514
4.4.5	Identifying and characterising the feeding areas of Dark-bellied Brent Geese <i>Branta bernicla bernicla</i> in and around Special Protection Areas in the UK Helen E. Rowell & James A. Robinson	517
4.4.6	Flyways of the East Canadian High Arctic Light-bellied Brent Goose <i>Branta bernicla hrota</i> : results of a satellite telemetry study James A. Robinson, G.A. Gudmundsson & P. Clausen	519
4.4.7	A review of the effects of intensive fish production on waterbird breeding populations Petr Musil	520
4.4.8	Identification of Common Snipe <i>Gallinago gallinago</i> flyways in the Western Palearctic by means of analysis of ringing recoveries and genetic studies Saulius Svazas & Algimantas Paulauskas	522

4.4.9	Crossing the ultimate ecological barrier: evidence for an 11 000 km long non-stop flight from Alaska to New Zealand and eastern Australia by Bar-tailed Godwits <i>Limosa lapponica</i> Robert E. Gill, Jr., Theunis Piersma, Gary Hufford, Rene Servranckx & Adrian Riegen	524
4.4.10	Using stable isotope ratios to unravel shorebird migration and population mixing: a case study with Red Knot <i>Calidris canutus</i> Philip W. Atkinson, Allan J. Baker, Karen A. Bennett, Nigel A. Clark, Jacquie A. Clark, Kimberly B. Cole, Amanda Dey, Andre G. Duiven, Simon Gillings, Patricia M. González, Brian A. Harrington, Kevin Kalasz, Clive D.T. Minton, Jason Newton, Lawrence J. Niles, Robert A. Robinson, Ines de Lima Serrano & Humphrey P. Sitters	535
4.4.11	Geographical segregation in wintering Dunlin <i>Calidris alpina</i> populations along the East Atlantic Flyway: evidence from mitochondrial DNA analysis Ricardo J. Lopes & Liv Wennerberg	541
4.4.12	Spring migration patterns in Western Sandpipers <i>Calidris mauri</i> Mary Anne Bishop, Nils Warnock & John Y. Takekawa	545
4.4.13	Indicators of body condition, energy demand and breeding success in the Ruddy Turnstone <i>Arenaria interpres</i> , a species of concern Deborah E. Perkins & Rebecca L. Holberton	551
4.4.14	Migration of Pontic Gulls <i>Larus cachinnans</i> form 'ponticus' ringed in the south of Ukraine: a review of recoveries from 1929 to 2003 Antonina G. Rudenko	553
4.4.15	Modelling survival and movement probability of Little Tern <i>Sterna albifrons</i> at a post-breeding moulting site: the effect of the colony of origin Giacomo Tavecchia, Nicola Baccetti & Lorenzo Serra	560
4.4.16	Greater Flamingo <i>Phoenicopterus ruber</i> ringing at Lake Uromiyeh, I.R. Iran Sadegh Sadaghi Zadegan	562
4.4.17	The Sivash Bay as a migratory stopover site for Curlew Sandpiper <i>Calidris ferruginea</i> Sergei V. Khomenko	564
<b>4.5</b>	<b>Migration and flyway atlases</b>	568
4.5.1	EURING: its role in migration and flyway atlases Fernando Spina & Jacquie Clark	569
4.5.2	Wetlands International's Flyway Atlas series: establishing the geographical limits of waterbird populations Simon N. Delany & Derek A. Scott	574
4.5.3	The Russian waterbird migration atlas: temporal variation in migration routes Inna N. Dobrynina & Sergei P. Kharitonov	582
4.5.4	Logistics of a migration atlas project for a small ringing scheme: the waterbird migration atlas of southern Africa H. Dieter Oschadleus	590
4.5.5	Progress on 'The Atlas of breeding waders of the Russian Arctic' Elena G. Lappo, P.S. Tomkovich & E.E. Syroechkovski Jr.	595

## Part 5. Integrated approaches to waterbird conservation

<b>5.1</b>	<b>Flyway management for species of conservation concern</b>	600
5.1.1	Saving Europe's most endangered birds: lessons to be learnt from implementing European Species Action Plans Szabolcs Nagy & Ian Burfield	602
5.1.2	Conservation action plans for the Black Crowned Crane <i>Balearica pavonina</i> and Black Stork <i>Ciconia nigra</i> in Africa Cheikh Hamallah Diagana, Tim Dodman & Seydina Issa Sylla	608
5.1.3	Approaches to freshwater bird species conservation: Wattled Cranes <i>Bugeranus carunculatus</i> and Shoebill Storks <i>Balaeniceps rex</i> in Zambia Hewitt Chizyuka	613
5.1.4	Co-ordinating conservation action across the Atlantic: development of a Flyway Management Plan for the East Canadian High Arctic Light-bellied Brent Goose <i>Branta bernicla hrota</i> James A. Robinson	614
5.1.5	The Red-breasted Goose <i>Branta ruficollis</i> in the new millennium: a thriving species or a species on the brink of extinction? Sergey G. Dereliev	619
5.1.6	Conservation of the White-headed Duck <i>Oxyura leucocephala</i> in Central and South Asia David Li Zuo Wei, Taej Mundkur, Elena A. Kreuzberg-Mukhina, Sergey Yerokhov, Alexander Solokha, Zulfiqar Ali & Abdul Aleem Chaudhry	624
5.1.7	The Lesser White-fronted Goose <i>Anser erythropus</i> in the south-east Caspian region of Turkmenistan Vladislav V. Vasiliev, Mirra E. Gauzer, Eldar A. Rustamov & Anna V. Belousova	629
5.1.8	Reintroduction of the Lesser White-fronted Goose <i>Anser erythropus</i> in Fennoscandia with the help of microlight aircraft Johan Mooij, Axel Paulsch & Wolfgang Scholze	633

## Part 6. Waterbirds and people

<b>6.1 Conflict resolution</b>	782
6.1.1 Reducing waterbird mortality in severe cold weather: 25 years of statutory shooting suspensions in Britain	
David A. Stroud, John Harradine, Colin Shedden, Julian Hughes, Gwyn Williams, Jacquie A. Clark & Nigel A. Clark	784
6.1.2 From conflict to coexistence: a case study of geese and agriculture in Scotland	
David R. Cope, Juliet A. Vickery & J. Marcus Rowcliffe	791
6.1.3 Case study of conflict resolution in the management of overabundant light geese in North America	
Bruce D.J. Batt, Paul R. Schmidt & Steve Wendt	795
6.1.4 Assessing the degree of habitat loss to marine birds from the development of offshore wind farms	
A.D. Fox & Ib Krag Petersen	801
6.1.5 The impact of the Cardiff Bay barrage on wintering waterbirds	
Niall H.K. Burton	805
6.1.6 The conflict between shellfisheries and migratory waterbirds in the Dutch Wadden Sea	
Bruno J. Ens	806
6.1.7 Managing shorebird flyways: shrimp aquaculture, shorebird populations and flyway integrity	
Yara Schaeffer-Novelli, Gilberto Cintrón-Molero & Clemente Coelho, Jr.	812
6.1.8 Waterbirds and aviation: how to mediate between conservation and flight safety?	
Luit Buurma	817
6.1.9 Recent measures to control Ruddy Ducks <i>Oxyura jamaicensis</i> in the United Kingdom	
Iain S. Henderson	822
6.1.10 Resolving Double-crested Cormorant <i>Phalacrocorax auritus</i> conflicts in the United States: past, present, and future	
Shauna L. Hanisch & Paul R. Schmidt	826
6.1.11 Variation in the behavioural responses of Whooper Swans <i>Cygnus cygnus</i> to different types of human activity	
Eileen C. Rees, Jennifer H. Bruce & George T. White	829
<b>6.2 Let the waterbirds do the talking</b>	831
6.2.1 Shorebird Sister Schools Program – shorebird education in North America and beyond	
Hilary Chapman, Brad A. Andres & Suzanne Fellows	832

6.2.2	Ten years of International Migratory Bird Day Jennifer Wheeler & Susan Bonfield	833
6.2.3	Wetlands International's Communication, Education and Public Awareness Programme on wetlands for west Africa Mame Dagou Diop & Charles Beye	836
6.2.4	Wetland Link International (WLI): a global network for wetland centres Malcolm Whitehead	838
6.2.5	Birding in the United States: a demographic and economic analysis Genevieve Pullis La Rouché	841
6.2.6	Wetlands as part of the natural heritage: the educational response Yu. L. Mazurov & T.Yu. Zengina	847
<b>6.3</b>	<b>Sustainable waterbird harvest</b>	<b>848</b>
6.3.1	Estimating waterfowl harvest in North America Paul I. Padding, Jean-François Gobeil & Cynthia Wentworth	849
6.3.2	Migratory bird harvest surveys in Canada Jean-François Gobeil	853
6.3.3	Sustainable hunting of migratory waterbirds: the Danish approach Thomas Bregnballe, Henning Noer, Thomas Kjær Christensen, Preben Clausen, Tommy Asferg, A. D. Fox & Simon Delany	854
6.3.4	Non-toxic shot – Danish experiences Niels Kanstrup	861
6.3.5	The monitoring of hunting bags and hunting effort in the Camargue, France Jean-Yves Mondain-Monval, Pierre Defos du Rau, Nathalie Mathon, Anthony Olivier & Laurent Desnouhes	862
6.3.6	Duck harvest in the Po delta, Italy Michele Sorrenti, Lorenzo Carnacina, Davide Radice & Alessandro Costato	864
6.3.7	Considerations on the use of leadshot over wetlands Guy-Noël Olivier	866
6.3.8	Harvesting status of migratory waterbirds in northern Iran: a case study from Gilan Province Behnam Balmaki & Ahmad Barati	868
6.3.9	Harvest of migratory geese <i>Chloephaga</i> spp. in Argentina: an overview of the present situation Daniel E. Blanco & Victoria M. de la Balze	870
6.3.10	The Wetlands International Waterbird Harvest Specialist Group: challenges and objectives Gilles Deplanque & Tunde Ojei	874
<b>6.4</b>	<b>Financing global flyway conservation: innovation, linkages, options</b>	<b>876</b>
6.4.1	Conservation finance for waterbird flyways: key issues and emerging opportunities Gonzalo Castro	878
6.4.2	Partnering to finance and deliver local flyway conservation in Nova Scotia, Canada G. Randy Milton, Glen J. Parsons & Reginald Melanson	881

<b>6.5</b>	<b>Building and sustaining capacity for waterbird conservation and research</b>	883
6.5.1	Building capacity in Africa through a regional training programme Abdoulaye Ndiaye, Tim Dodman & Cheikh H. Diagana	884
6.5.2	Building capacity in Central Asia and the Caucasus to promote waterbird research and conservation Alexander Solokha, Ward Hagemeyer & Taej Mundkur	885
6.5.3	Building capacity in waterbird and wetland monitoring in eastern Africa Oliver Nasirwa, Mark O'Connell, Seb Buckton & Tim Dodman	889
6.5.4	The role and potential of the Central-Asian Scientific Information Centre of the Interstate Sustainable Development Commission (SIC ISDC) for studying wetlands and waterbirds Bahar Tashlieva	892
	<b>Species Index</b>	894
	<b>Geographical Index</b>	924

	<b>Author Index</b>	937

## Foreword

They are one of the world's most attractive group of birds — and the most threatened: albatrosses, flamingos, swans, geese, ducks, cranes, waders, gulls, terns and auks and all the rest of the world's waterbirds. They share a dependency on the world's wetlands - seas, coasts, estuaries, lagoons, lochs, rivers, marshlands, swamps, tundra and other peatlands, and they have come to symbolize the changing, fragile nature of planet Earth. With the publication of *Waterbirds around the world*, five years of planning, meetings, fundraising and writing come to fruition. And with the publication of this book, we close one chapter and begin another — to improve research and conservation efforts to secure a healthier environment for waterbirds, building on the body of knowledge gathered together in this volume.

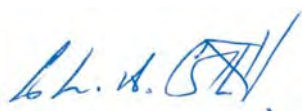

It is an honour for us to have been involved in the production of this book. It is the outcome of a major international conference on waterbirds held in Edinburgh in April 2004, and attended by 456 people from 90 countries. In October 2005 we published an overview of the results of the conference. This included the text of *The Edinburgh Declaration*, which calls for urgent action to halt and reverse wetland loss and degradation, and to extend and strengthen networks of key sites for waterbirds along all flyways. Subsequently, at various inter-governmental meetings there have been discussions to assist waterbird flyway conservation, and formal resolutions calling on countries to implement *The Edinburgh Declaration*.

We hope that readers of this book will enjoy the wealth of material drawn together here from across the globe. We are especially pleased to include the presentations by His Royal Highness The Prince of Wales, Government Ministers and leading authorities on waterbird conservation and global flyways. The publication of this book has been a major undertaking, with the core editorial team working together closely since May 2004. All papers presented as part of the conference symposia have been

peer-reviewed by a total of almost 70 experts, to whom we are very grateful. The short notes, based on more than a hundred poster presentations, were refereed by the editorial team. It is a pleasure for us to extend our thanks to the team and, of course, to the authors for their unstinting labours, not least in trying to keep the length of submissions short — something which may not be apparent at first sight given the size of this book!

In looking to the future we sincerely hope, and indeed believe, that this volume of work will improve our collective understanding of the needs of waterbirds, and in so doing will stimulate further international cooperation. We live in a world where the spoken or written word can reach anywhere in seconds. Some waterbirds make global journeys which take considerably longer and where they encounter all manner of perils. When you next make a long distance telephone call, or send an email to a friend in some distant country, or enjoy a comfortable airline meal at 9 000 m, spare a thought for waterbirds in flight facing a multitude of hazards over land and sea, very often across scores of national boundaries: travelling between countries the hard way. Unless we act together, uniting our efforts in research, conservation, management and awareness-raising, we shall fail these birds and the human populations enriched by their presence.

What a challenge lies ahead, not least in the face of global concerns about avian flu, climate change and wholesale losses of natural habitats! Quite simply, we now have no alternative but to deploy our shared knowledge and understanding of waterbirds to provide for a better world. People around the world have a right to marvel at the sight and sound of waterbirds as part of a wider, sustainable ecosystem. The conference has shown us how much we can achieve when we work together to help ensure that the planet becomes healthier for wildlife and for humanity.

## Address by the Patrons of 'Waterbirds around the world'

We were pleased to be part of nearly 500 waterbird conservationists from all parts of the world, and honoured to act as patrons of the conference. It was good to see three Ministers presenting their views on the importance of migratory water bird conservation and to hear His Royal Highness The Prince of Wales draw attention to the current major threats to albatrosses, those 'perpetual oceanic migrants'.

Boyd, H., Kuijken, E., Hoffman, L., Matthews, G. & Nelson, H. 2006. Address by the Patrons of 'Waterbirds around the world'. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 2.

Since we began to be involved in waterbird research, management and conservation in the late 1940s and 1950s, much has changed. (From 6 x 30 binoculars to magnificent telescopes and digiscoping photography, from simple handwritten notebooks to laptops). Research techniques have developed enormously, with the arrival of video-recording, radio-marking and satellite tracking, geographical data-loggers and automatic electronic data collection in the field. There have been corresponding improvements in the presentation and availability of data, illustrations and text. Coloured illustrations are now no longer prohibitively expensive and 'Power Point presentations' full of sound, light and action are now commonplace. Detailed remote sensing images can now be downloaded for every site, even the most isolated or secret place on Earth. For our own field explorations in so many wetlands reliable maps were hardly available!

Yet perhaps the most important change has been in the numbers of players on the conservation scene. Both professionals and volunteers, especially bird people have founded the base of conservation world wide. Where there were hardly any reserve wardens or researchers there are now hundreds. Professional administrators of conservation programmes have inserted themselves too, as they have in so many areas of government.

Participants enjoy a conference talk in Edinburgh. Photo: Dougie Barnett.

During the second half of the 20th century, international policy instruments proliferated. Unfortunately, if unsurprisingly, they have not been accompanied by sufficient funding to enable them to be fully effective. In particular, enforcement of laws and regulations has often been feeble and far too little effort has been devoted to following up the effectiveness of the reserve networks that have been created. Communication with the public at large in order to raise awareness still is an essential priority in conservation.

Patrons of *Waterbirds around the world*: from left to right: Harvey Nelson (USA), Hugh Boyd (Canada), Geoffrey Matthews (UK) and Eckhart Kuijken (Belgium); Luc Hoffmann could not be present at the conference. Photo: Dougie Barnett.

Waterbird conferences since the 1950s organised by IWRB (now Wetlands International) succeeded to attract specialists from over the world and have convinced participants about their growing power to encourage ecologically sound conservation. In this regard the Ramsar Convention is a real masterpiece that sets the scene for further multilateral treaties, and (in a European context) Directives related to biodiversity to follow in later decades.

The Edinburgh conference heard many accounts of progress in research and the development of management tools. Much remains to be done, especially in broadening out from 'saving threatened species' to bringing about major changes in land use beyond the boundaries of reserves, for the benefit of entire ecosystems, including the people who depend on them.

We saw and listened to many outstanding performers. By definition, they will always be scarce. One of the continuing requirements of wetland and waterbird conservation world-wide is to encourage and enable these talented people to flourish, in a far more complicated world than confronted us at the start of our careers. One major feature of the conservation world is its massive dependence on volunteers and their 'citizen science'. This must surely be healthy and help to ensure that ever-broadening circles of people around the world come to understand the importance of keeping it fit for many forms of life to flourish.

We are very grateful for the opportunity we were given to be symbolically involved in the *Waterbirds around the world* conference on such undemanding terms, just presenting a glimpse of historical facts in the growing movement of conservation that we are happy to be part of as pioneers of the mid 20th century. We especially hope that we were able to encourage those now active in the field to continue to work as hard as they can to create and maintain a better world, where biodiversity conservation is an integrated part of sustainable development.

## Acknowledgements

*Waterbirds around the world* could not have happened without the inputs and support of many people. The conference organisers are grateful to all who have given their support over the last six years.

We are especially grateful to: His Royal Highness The Prince of Wales; Minister Elliot Morley, MP; Minister Cees Veerman; Max Finlayson; John Markland; and Deputy Minister Allan Wilson, MSP.

**Board of Patrons:** Hugh Boyd, Luc Hoffmann, Eckhart Kuijken, Geoffrey Matthews and Harvey Nelson.

**The Conference Team:** Gerard Boere, Colin Galbraith, David Stroud, Les Underhill, George Anderson, Ian Enlander, Jenny Griffin, Saskia Henderikse, Adam Kidson, René Looyen, Jane Madgwick, Angela McTeir, Ash Murray, Simon Nash, Daniëlle Nieuwenhuijse, Colin Robertson, Susan Ross, Evert Rougoor, Paul Schmidt, Jan Willem Snee, Doug Taylor, Des Thompson, Robert Vagg, Inge Veenstra, Marion Whitelaw and Andy Williams.

**The UK Organising Committee** comprised: Colin Galbraith (Chairman), David Stroud (Secretary), Susan Ross, Robert Vagg, Andy Williams, Angela McTeir, Deborah Gooch, Colin Sheddson, John Doherty, Jo Wilson, Duncan Orr-Ewing, Ian Francis, Bill Gardner and Ashley Murray, with additional inputs from Mark Rehfish, Catherine Gray and Ian Enlander.

**JNCC and SNH:** Deryck Steer, Ian Jardine, Ian McLean, Helen Baker, Janet Sprent, Heather Pegg, Jean Lambert, Saville Gunn, Kerry Jepson, Zena Bailey, Carl Cilenti, Sandra Groome, Sue Wenlock, Alison Lee, Geoff Beall and Kenny MacLean.

The Conference dinner was held in the main hall of the Royal Museum, part of the National Museum of Scotland, following a reception during which delegates explored the museum's extensive collections. Photo: Taej Mundkur.

The Conference Team is most grateful to Janet Hunter, David Ness, Orela Deane and all the staff of the James Watt Conference Centre at Heriot-Watt University, Edinburgh for their professional support throughout the planning and execution of the conference.

**Many volunteers** freely gave their time and expertise to help during the conference and to lead excursions. We are grateful to them all: Zul Bhatia, Liz Campbell, Zoe Clelland, Hugh Conner, Neil Cowie, John Doherty and staff of WWT's Caerlaverock Wetlands Centre, Richard Evans, Ian Francis, Adam Kidson, Alan Leitch, Andy McFarlane, Duncan Orr-Ewing, Jack Fleming and staff of RSPB's Mersehead Reserve, Catherine Quigley, Jeremy Roberts, Colin Sheddson, Chris Spelding, Ian Thomson, Winnie Thomson, Lornie Wilkie, Andy Williams, Mike Thornton, Susan Haysom, Ellen Wilson and Simon Zisman.

Many people volunteered to help with the conference excursion programme, including to the Bass Rock – which holds an internationally important colony of Northern Gannets *Morus bassana* breeding on the rock, after which the species is named. Photo: Colin Galbraith.

We are grateful to the following organisations for their in-kind support of the excursions: British Association for Shooting and Conservation; the Wildfowl and Wetlands Trust; the Royal Society for the Protection of Birds; and the Scottish Ornithologists' Club.

The Royal Dutch Natural History Society (KNNV), with Paul Kemmeren, facilitated the free distribution of the recently published book *Shorebirds: an illustrated behavioural ecology* to all the conference delegates.

The European Commission (DG Environment) supported the conference through holding a meeting of the Scientific Working Group of the Birds Directive's Ornith Committee within the framework of the conference. This allowed the support of additional delegates from the EU.

The conference programme was developed by the **Conference Scientific Committee**, comprising: Les Underhill (Chairman), Gerard Boere (Secretary), Marco Barbieri, Peter Bayliss, Leon Bennum, Bart Ebbinge, Gudmundur Gudmundsson, Noritaka Ichida, Jim Kushlan, Randy Milton, Charles Mlingwa, Mark O'Connell, Theunis Piersma, Robert Schlatter, Paul Schmidt, David Stroud and Pavel Tomkovich.

**The production of these proceedings** would not have happened without the efforts of: Derek Scott, Linda Bridge, Iain Colquhoun, Des Thompson, Les Underhill, Nick Davidson, Ron Wilson, Karen Pope, Jane McNair, Denise Dalrymple, Chris Dalrymple and Jon Dalrymple.

The Conference Team, in October 2003, wrestling with the complexities of the conference programme! Photo: David Stroud.

We thank all **peer-reviewers** who freely gave their time and expertise to review and improve submitted papers: Åke Andersson, Brad Andres, Anny Anselin, Bruce Batt, Albert Beintema, Bob Blohm, Gerard Boere, Stephen Browne, Kees Camphuys, Nick Davidson, Kees van Dijk, Gary Donaldson, Mennobart van Eerden, Morten Ekker, Meinte Engelman, Michael Exo, Yves Ferrand, Bob Gill, Lyle Glowka, Adam Gretton, Antti Haapanen, Barry Hartup, Tom van der Have, Hermann Hötker, Marshall Howe, Verena Keller, Roger Jaensch, Alan Johnson, Torsten Larsson, Konstantin Litvin, Frank Majoor, Randy Milton, Clive Minton, Claire Mirande, Johan Mooij, Mike Moser, Wim van Muiswinkel, Harvey Nelson, Leif Nilsson, Guy-Noel Olivier, Tunde Oje, Sander van Opstal, Dieter Oschladeus, John O'Sullivan, Mike Pienkowski, Eileen Rees, Mark Rehfish, Klaus Riede, David Rodrigues, Hans-Ulrich Rosner, Clayton Rubec, Frank Saris, Yara Schaeffer-Novelli, Roberto Schlatter, Humphrey Sitters, Ken Smith, Arie Spaans, Melanie Steinkamp, David Stroud, Kees Swennen, John Swift, Zhenya Syroechkovski, Des Thompson, Christophe Tourenq, Jan Veen, Joost van der Ven and Rinse Wassenaar.

We are indebted to **the many photographers** who have allowed us to enliven the pages of these proceedings with their pictures of waterbirds and their habitats worldwide, as well as all those who helped source these photos and/or provided images that unfortunately were not possible to use: Else Ammentorp, Adrian Azpiroz, Mark Barter, Helen Baker, Dougie Barnett, Daniel Bergmann, Gerard Boere, Adrian Boyle, Andy Brown, Ian Carter, Albert Chipps, Nigel Clark, John Cooper, Peter Cranswick, Ruth Cromie, Alistair Crowle, Danmarks Jægerforbund/Danish Hunters Association, Nick Davidson, Hans Dekkers, Sergey Dereliev, C. Donald, Tim Dodman, Andy Douse, Allan Drewitt, Sergey Eliseev, Meinte Engelman, Ian Francis, Milton Friend, Colin Galbraith, Niels Gilissen (MIRATIO), Ward Hagemeijer, Doug Harebottle, Gareth Hartford, David Hatton, Richard Hearn, Jemi & John Holmes, Menno Hormman, Dave Humburg, J. Jave, Niels Kanstrup, Florian Keil, Verena Keller, Gary Kramer, John Marchant, Ian Mackenzie, Paul Marshall, Brian McKean, David Melville, Randy Milton, Ian Mitchell, Jean-Yves Mondain Monval, Johan Mooij, Steve Moore, Anders Mosbech, Christian Moullec, Taej Mundkur, Petr Musil, Zuzana Musilová, P.K. Nandi, Steve Newton, Ingar Jostein Oien, Dieter Oschladeus, Matt Parsons, Dwight Peck, Ib Krag Petersen, Margaret Petersen, Nikolai Petkov, Anastasia Popovkina, Crawford Prentice, Press Association, Eileen Rees, Rob Robinson, Paul Schmidt, Michael Samuel, Scottish Natural Heritage, David Sowter, Simon Stirrup, David Stroud, Tom Stroud, Katerina Svadova, Niels Søndergaard, Stan Tekiela, Kai-Michael Thomsen, Les Underhill, US Fish & Wildlife Service, US Geological Survey, Jaap de Vlas, Peter Wakerly, Alyn Walsh, Keith Wearne, Richard Webster, Jennifer Wheeler, the Wildfowl & Wetlands Trust, Chris Wilson, Rebecca Woodward, Niklaus Zbinden, Sama Zefania and Christoph Zöckler. Special thanks, in particular, are due to Paul Marshall for the cover photo and his many other beautiful images of the world's waterbirds.

## The Edinburgh Declaration

*An international conference on waterbirds, their conservation and sustainable use was held in Edinburgh, Scotland, from 3-8 April 2004, attended by 456 participants from 90 countries.*

**Conscious that** waterbird flyways are biological systems of migration paths that directly link sites and ecosystems in different countries and continents;

**Recalling that** the conservation and wise-use of waterbirds is a shared responsibility of nations and peoples and a common concern of human-kind;

**Recalling also** the long history of international co-operation for waterbird conservation developed over a hundred years with treaties such as that concerned with migratory birds in 1916 between USA and UK (on behalf of Canada), and that over 40 years ago, the first European Meeting on Wildfowl Conservation held in St. Andrews, Scotland in 1963, started a process leading to the establishment of the Convention on wetlands especially as waterfowl habitat in Ramsar, Iran, in 1971;

**Noting that** major international conferences in Noordwijk aan Zee, The Netherlands (1966), Leningrad, USSR (1968), Ramsar, Iran (1971), Astrakhan, USSR (1989), St. Petersburg Beach, Florida, USA (1992), Kushiro, Japan and Strasbourg, France (1994), have further developed international technical exchanges on waterbird conservation;

**Aware of** the development of further inter-governmental co-operation through the establishment and implementation of further treaties, agreements, strategies and programmes; and of the development of considerable non-governmental national and international co-operation in waterbird conservation and monitoring;

**Conscious that** at the World Summit on Sustainable Development, Johannesburg, South Africa, in 2002, world leaders expressed their desire to achieve “a significant reduction in the current rate of loss of biological diversity” by 2010, and that in February 2004 this target was further developed by the Seventh Conference of the Parties to the Biodiversity Convention, and **aware that** achieving this target will require significant investments and highly focused and co-ordinated conservation activity on all continents, and **recognising that** communication, education and public awareness and capacity building will play a key role in achieving this target;

**Further conscious** of the urgent need to strengthen international co-operation and partnerships between governments, inter-governmental and non-government organisations, local communities and the private sector;

**Alarmed at** the perilous state of many populations of waterbirds, in both terrestrial and marine ecosystems, and at the continued decline in quality and extent of the world’s wetlands;

**Noting** the conclusions and priorities for further action identified by the many technical workshops and presentations made at this conference, and recorded subsequently in this Declaration.

**Welcoming** the joint initiative of Wetlands International, and government authorities in the United Kingdom and The Netherlands, with the support also of Australia, Denmark, USA, Japan, Germany, Sweden, Ireland, Belgium, Switzerland, UNEP/CMS, UNEP/AEWA, FACE, and CIC and with the input of many other organisations and individuals, in convening the conference *Waterbirds Around the World* in Edinburgh so as to review the current status of the world’s waterbirds;

*The Conference Participants, assembled together in Edinburgh –*

**Consider that** although significant progress has been made to conserve waterbirds and their wetland habitats leading to some major successes, overall there remain important challenges, which, together with uncertainties about implications of future changes, requires further efforts and focused actions;

**Reaffirm that**, in the words of the Ramsar Convention, “waterbirds, in their seasonal migrations may transcend frontiers and so should be regarded as an international resource” and “that the conservation of wetlands and their flora and fauna can be ensured by combining far-sighted national policies with co-ordinated international action” and accordingly **urge that** efforts between countries to conserve waterbird populations and their wetland habitats are extended, not only for the values that waterbirds have in sustaining human populations, but also for their own sakes;

**Consider that** flyway conservation should combine species- and ecosystem-based approaches, internationally co-ordinated throughout migratory ranges;

**Acknowledge that** the conservation and sustainable use of waterbirds and wetland resources require co-ordinated action by public and private sectors, dependent local communities and other stakeholders;

**Call in particular** for urgent action to:

- Halt and reverse wetland loss and degradation;
- Complete national and international wetland inventories, and promote the conservation of wetlands of importance to waterbirds in the context of surrounding areas, especially through the participation of local communities;
- Extend and strengthen international networks of key sites for waterbirds along all flyways;
- Establish and extend formal agreements and other co-operation arrangements between countries to conserve species, where possible within the frameworks provided by the Conventions on Migratory Species, Biological Diversity and Wetlands;
- Fund and implement recovery plans for all globally threatened waterbird species;
- Halt and reverse recently revealed declines of long-distance migrant shorebirds through sustainable management by governments and others of human activities at sites of unique importance to them;
- Restore albatross and petrel populations to favourable conservation status through urgent and internationally co-ordinated conservation actions, especially through the framework provided by the Agreement on the Conservation of Albatrosses and Petrels;
- Substantially reduce pollution in the marine environment and establish sustainable harvesting of marine resources;
- Underpin future conservation decisions with high-quality scientific advice drawn from co-ordinated, and adequately funded, research and monitoring programmes notably the International Waterbird Census, and to this end, urge governments and other partners to work together collaboratively and supportively;
- Develop policy-relevant indicators of the status of the world's wetlands, especially in the context of the 2010 target, using waterbird and other data generated from robust and sustainable monitoring schemes;
- Invest in communication, education and public awareness activities as a key element of waterbird and wetlands conservation;
- Assess disease risk, and establish monitoring programmes in relation to migratory waterbird movements, the trade of wild birds, and implications for human health.

**Urge that** particular priority be given to capacity building for flyway conservation in countries and territories with limited institutions and resources, given that the wise-use of waterbirds and wetlands is important for sustainable development and poverty alleviation;

**Strongly encourage** countries to ratify and implement relevant conventions, agreements and treaties so as to encourage further international co-operation, and to make use of available resources including the Global Environment Facility in order to finance action required under this Declaration;

**Consider that**, with the long history of co-operative international assessments, waterbirds provide excellent indicators by which to evaluate progress towards achievement of the 2010 target established by world leaders in 2002, and to this end **Call**

**on** the Conventions on Migratory Species, Biological Diversity and Wetlands, and other international agreements to work together and with other partners on such assessments, and in particular with Wetlands International to further develop the analytical content, of the triennial publication *Waterbird Population Estimates* and its use;

**Stress** the need for wide international dissemination of this Declaration and the technical outcomes of this Conference; and

**Agree** to meet again as a conference in ten years time to review progress.

Edinburgh  
7 April 2004

**In support of the recommendations above, the Conference concluded the following:**

- For the Flyways of the Americas, collaboration between North, Central and South America and Caribbean nations is developing, based on conclusions of the conference of nations to consider the status of migratory birds held during the VIII<sup>th</sup> Neotropical Congress in Chile, and in the recent completion of a Waterbird Conservation Plan for the Americas. Despite more than a century of conservation efforts in North America and emergence of a shared vision for biologically-based, landscape orientated partnerships, it is clear that international co-operation amongst Pan-American countries sharing migratory birds should increase.
- In African-Eurasian Flyways, the generally good knowledge of waterbirds is not being effectively transferred into necessary national and local actions. Nor have conservation efforts led to maintaining or restoring the health of many waterbird populations, including globally threatened species. There are urgent needs to integrate waterbird conservation as part of sustainable development, to the greater benefit of local communities and other stakeholders dependent on wetlands as well as benefiting biodiversity. The African-Eurasian Waterbird Agreement (UNEP/AEWA) provides a good basis to achieve this.
- Intra-African Flyways are extremely poorly known and would benefit from greater attention.
- Many of the waterbirds of the Central Asian Flyway appear to be declining, although information on status and trends is generally poor. In most countries there has been little previous investment in conservation and low involvement of local stakeholders in the sustainable management of wetlands. An international framework for the development of conservation initiatives for migratory waterbirds in Central Asia is urgently required to promote co-operative action. Better information is needed to identify priority conservation issues and responses.
- The waterbirds of Asian-Australasian Flyways are the most poorly known, and the greatest number of globally threatened waterbirds occur here. This flyway extends across the most densely populated part of the world, where there are extreme pressures not only on unprotected wetlands but also

on protected sites. Effective protection of wetlands of major importance is a critical need, as in other regions of the world. There are huge, and crucial, challenges in ensuring effective wise-use of key sites, as well as ensuring that consumptive uses of waterbirds are sustainable.

Black-browed Albatross *Diomedea melanophrys*. Photo: Chris Wilson.

- Science has identified the critical importance of a small number of key sites to long-distance migrant shorebirds and that human activities at some of these are responsible for recent dramatic declines in certain shorebird populations.
  - Recent research has highlighted the genetic and demographic risks incurred by species that have small populations. These have implications for the design of species recovery programmes.
  - The frequency and magnitude of disease losses among waterbirds (from emerging or re-emerging disease agents) have increased to the extent that they demand attention. These diseases not only affect waterbirds but have impacts on humans. Solutions require a multi-disciplinary approach.
  - An integrated approach to the monitoring of waterbirds gives cost-effective identification of the reasons for waterbird population changes. There are good examples of the collection of demographic information and its integration with census data. Further such national and especially international schemes should be strongly encouraged and funded.
  - Systematic analyses for atlases confirm the value of ringing studies in assessing the conservation status of breeding, wintering and stop-over sites within flyways. To this end, there should be integration of data from conventional ringing and colour-marking, telemetry, stable isotope analyses and genetic markers.
- Conservation of pelagic waterbirds in the open oceans gives a range of unique challenges. The entry into force of the Agreement on the Conservation of Albatrosses and Petrels is a most welcome development, and its full implementation is an urgent need. Addressing issues of seabird by-catch, especially by illegal and unregulated fisheries remains a critical need to reverse the poor conservation status of many species, as is the general need to achieve sustainable marine fisheries.
  - Most of the world's known flyways originate in the Arctic. The recent development of international co-operation between arctic countries is welcome, as is the recognition of the crucial need to involve local communities and their traditional local knowledge in waterbird management. Austro-tropical Flyways also require research.
  - Climate changes are already affecting waterbirds. The consequences of climate change for waterbirds will be multiple, and will greatly exacerbate current negative impacts such as habitat loss and degradation. There is a need for wide-scale planning, at landscape and flyway scales, to reduce or mitigate the impacts on waterbird populations and their habitats. Research that explores a range of potential future scenarios will be required to underpin this planning and will need data from long-term monitoring and surveillance.
  - The conservation status of non-migrant waterbird populations around the world in many cases is poorer than that of migrants, and these waterbirds generally have less focused international attention than migrants. Addressing conservation requirements of non-migrant waterbirds should also be given national and international priority.
  - On a densely populated planet it is crucial that waterbird conservationists focus on their relationships with communities and governments as the means both of reversing the causes of poor conservation status, and of resolving conflicts with protected species. Adequately funded programmes of communication, education and public awareness need to be the core of all waterbird conservation initiatives.

## Déclaration d'Edimbourg

*Une conférence internationale sur les oiseaux d'eau, leur conservation et leur utilisation rationnelle, s'est déroulée à Edimbourg, en Ecosse, du 3 au 8 avril 2004. Cette conférence a réuni 456 participants venus de 90 pays.*

**Conscients** que les voies de migration des oiseaux d'eau sont des systèmes biologiques qui relient directement des sites et des écosystèmes de différents pays et continents;

**Rappelant** que la conservation et l'utilisation rationnelle des oiseaux d'eau est une responsabilité commune des nations et des peuples, et une préoccupation de l'ensemble de l'humanité;

**Rappelant en outre** la longue histoire de la coopération internationale pour la conservation des oiseaux d'eau, développée sur une centaine d'années avec des traités comme celui de 1916 entre les Etats-Unis et le Royaume-Uni (au nom du Canada) concernant les oiseaux migrateurs; et que, il y a plus de 40 ans, la première Réunion Européenne sur la Conservation des Oiseaux Sauvages, qui s'est tenue en 1963 à St. Andrews, en Ecosse, a marqué le démarrage d'un processus qui a abouti à la création en 1971 à Ramsar, en Iran, de la Convention sur les Zones Humides, en particulier en tant qu'habitat pour les oiseaux d'eau;

**Notant** que les grandes conférences internationales qui se sont tenues à Noordwijk aan Zee, aux Pays-Bas (1966), à Leningrad, en URSS (1968), à Ramsar, en Iran (1971), à Astrakhan, en URSS (1989), à St. Petersburg Beach, en Floride, aux Etats-Unis (1992), à Kushiro, au Japon et à Strasbourg, en France (1994), ont développé davantage les échanges techniques internationaux sur la conservation des oiseaux d'eau;

**Ayant connaissance** du développement d'une coopération intergouvernementale plus poussée, à travers l'élaboration et la mise en oeuvre d'autres traités, accords, stratégies et programmes; ainsi que du développement d'une importante coopération non gouvernementale, nationale et internationale, en matière de conservation et de suivi des oiseaux d'eau;

**Conscients** qu'au Sommet mondial sur le développement durable qui s'est tenu en 2002 à Johannesburg, en Afrique du Sud, les dirigeants du monde ont exprimé leur désir d'atteindre « une importante réduction du taux actuel de perte de diversité biologique » d'ici à 2010, et qu'en février 2004, cette cible a été élaborée davantage par la Septième Conférence des Parties à la Convention sur la Biodiversité; **sachant** que l'atteinte de cette cible nécessitera d'importants investissements ainsi qu'une activité de conservation très focalisée et coordonnée sur l'ensemble des continents; et **reconnaissant** que la communication, l'éducation et la sensibilisation du public, ainsi que le renforcement des capacités, joueront un rôle crucial dans l'atteinte de cette cible;

**Conscients en outre** de l'urgente nécessité de renforcer la coopération internationale ainsi que les partenariats entre les organisations gouvernementales, intergouvernementales et non-gouvernementales, les communautés locales et le secteur privé;

**Alarmés** par l'état périlleux dans lequel se trouvent de nombreuses populations d'oiseaux d'eau vivant dans les écosystèmes terrestre et marin, ainsi que par la baisse constante de la qualité et de l'étendue des zones humides partout dans le monde;

**Notant** les conclusions et les priorités pour d'autres actions identifiées par les multiples ateliers et présentations techniques au cours de cette conférence, et rapportées par la suite dans cette Déclaration.

**Saluant** l'initiative conjointe de Wetlands International et des autorités gouvernementales du Royaume-Uni et des Pays-Bas, également appuyée par l'Australie, le Danemark, les Etats-Unis, le Japon, l'Allemagne, la Suède, l'Irlande, la Belgique, la Suisse, le PNUE/CMS, le PNUE/AEWA, FACE et CIC, ainsi que la contribution de nombreux autres individus et organisations qui a consisté à convoquer la conférence sur le thème des *Oiseaux d'Eau du Monde* à Edimbourg, aux fins d'examiner l'état actuel des oiseaux d'eau du monde;

### *Les Participants à la Conférence, réunis à Edimbourg –*

**Considèrent** que, malgré les avancées notables en matière de conservation des oiseaux d'eau et de leurs habitats de zones humides, qui ont débouché sur quelques succès majeurs, il reste dans l'ensemble d'importants défis qui, avec les incertitudes concernant les implications des futurs changements, nécessitent des efforts plus poussés et des actions ciblées;

**Réaffirment** que, selon les termes de la Convention de Ramsar, « au cours de leurs migrations saisonnières, les oiseaux d'eau peuvent transcender les frontières; par conséquent, ils doivent être considérés comme une ressource internationale » et que « la conservation des zones humides, ainsi que de leur flore et de leur faune, peut être assurée par la combinaison de politiques nationales clairvoyantes avec une action internationale coordonnée »; par conséquent, **recommandent** de multiplier les efforts inter-étatiques de conservation des populations d'oiseaux d'eau et de leurs habitats de zones humides, non seulement pour les valeurs des oiseaux d'eau pour l'alimentation des populations humaines, mais aussi pour leur propre bien;

**Considèrent** que la conservation des voies de migration devrait combiner les approches basées sur les espèces et les écosystèmes, coordonnées au niveau international sur toute l'étendue des aires de migration;

**Reconnaissent** que la conservation et l'utilisation rationnelle des oiseaux d'eau et des ressources des zones humides requièrent une action coordonnée par les secteurs public et privé, les communautés locales ainsi que les autres parties prenantes qui en dépendent;

**Appellent en particulier** à une action urgente pour:

- Faire cesser et inverser les pertes et la dégradation de zones humides;
- Achever les inventaires des zones humides, aux niveaux national et international, et promouvoir la conservation des zones humides d'importance vitale pour les oiseaux d'eau, dans le contexte des aires environnantes, en particulier par la participation des communautés locales;
- Développer et renforcer les réseaux internationaux de sites-clés pour les oiseaux d'eau, le long de toutes les voies de migration;
- Etablir et développer des accords formels et autres accords de coopération entre les pays pour la conservation des espèces, si possible dans les cadres fournis par les Conventions sur les Espèces Migratrices, la Diversité Biologique et les Zones Humides;
- Financer et mettre en oeuvre des plans de rétablissement pour toutes les espèces d'oiseaux d'eau menacées dans le monde;
- Faire cesser et inverser les récentes baisses des effectifs d'oiseaux de plage migrant sur de longues distances, grâce à une gestion durable, par les gouvernements et d'autres, des activités anthropiques dans les sites d'importance unique pour ces oiseaux;
- Restaurer les populations d'albatros et de pétrels pour les amener à un état de conservation satisfaisant, par des actions de conservation coordonnées au niveau international, notamment à travers le cadre offert par l'Accord sur la Conservation des Albatros et des Pétrels;
- Réduire considérablement la pollution en milieu marin et instaurer le prélèvement durable des ressources marines;
- Appuyer les futures décisions en matière de conservation par des conseils scientifiques de haute qualité, tirés des programmes de recherche et de suivi coordonnés et adéquatement financés, notamment le Dénombrement International d'Oiseaux d'Eau, et à cette fin, exhorter les gouvernements et autres partenaires à travailler ensemble, de façon collaborative et positive;
- Développer des indicateurs politiques de l'état des zones humides dans le monde, en particulier dans le contexte du cap 2010, en utilisant les données sur les oiseaux d'eau et d'autres données produites par des programmes de suivi solides et durables;
- Investir dans les activités de communication, d'éducation et de sensibilisation du public, en tant qu'élément clé de la conservation des oiseaux d'eau et des zones humides;
- Evaluer les risques de maladies et mettre en place des programmes de suivi concernant les mouvements migra-

toires des oiseaux d'eau, le commerce d'oiseaux sauvages et leurs implications pour la santé de l'homme.

**Incitent** à accorder une priorité particulière au renforcement des capacités pour la conservation des voies de migration dans les pays et territoires dotés d'institutions et de ressources limitées, étant donné que l'utilisation rationnelle des oiseaux d'eau et des zones humides est importante pour le développement durable et la réduction de la pauvreté;

**Engagent fortement** les pays à ratifier et à mettre en oeuvre les conventions, accords et traités pertinents, afin de promouvoir une coopération internationale plus poussée, et à utiliser les ressources dont ils disposent, notamment le Fonds mondial pour l'environnement, pour financer les actions requises dans le cadre de cette Déclaration;

**Considèrent** qu'avec la longue histoire des évaluations internationales coopératives, les oiseaux d'eau offrent d'excellents indicateurs qui permettent de mesurer les progrès vers l'atteinte du cap 2010 fixé par les dirigeants mondiaux en 2002, et à cet effet,

**Invitent** les Conventions sur les Espèces Migratrices, sur la Diversité Biologique et sur les Zones Humides, ainsi que d'autres accords internationaux, à travailler ensemble et avec d'autres partenaires sur ce genre d'évaluations, en particulier avec Wetlands International, pour élaborer davantage le contenu analytique et l'utilisation de la publication triennale *Estimations des Populations d'Oiseaux d'Eau*;

**Insistent** sur la nécessité d'une large dissémination internationale de cette Déclaration ainsi que des produits techniques de cette Conférence; et

**Convienent** de convoquer de nouveau la conférence dans dix ans, pour examiner les progrès.

Edimbourg  
7 Avril 2004

**En appui aux recommandations ci-dessus, la Conférence a conclu ce qui suit:**

- Pour les voies de migration des Amériques, la collaboration se développe entre l'Amérique du Nord, l'Amérique centrale et l'Amérique du Sud, et les états caribéens, selon les conclusions de la conférence des nations pour examiner l'état des oiseaux migrants, qui s'est tenue lors du VIII<sup>ème</sup> Congrès néo-tropical au Chili, et le Plan de conservation des oiseaux d'eau pour les Amériques, récemment achevé. Malgré plus d'un siècle d'efforts de conservation en Amérique du Nord et l'émergence d'une vision partagée pour des partenariats biologiques, axés sur l'environnement, il est évident que la coopération internationale entre les pays panaméricains ayant en commun les oiseaux migrants devrait s'intensifier.
- Dans les voies de migration Afrique-Eurasie, les connaissances généralement bonnes des oiseaux d'eau ne sont pas effectivement traduites en des actions nationales et locales

nécessaires. Pas plus que les efforts de conservation n'ont abouti au maintien ou à la restauration de la santé de nombreuses populations d'oiseaux d'eau, y compris les espèces menacées dans le monde. Il urge d'intégrer la conservation des oiseaux d'eau dans le cadre du développement durable, pour le plus grand bien des communautés locales et autres parties prenantes dépendant des zones humides, mais aussi, pour le bien de la biodiversité. L'Accord sur les Oiseaux d'Eau Migrateurs d'Afrique-Eurasie (PNUE/AEWA) offre une base adéquate pour réaliser cet objectif.

- Les voies de migration interafricaines sont fort mal connues et tireraient profit d'une plus grande attention.
- Bon nombre des oiseaux d'eau de la voie de migration de l'Asie centrale semblent en déclin, bien que les informations concernant leur état et leurs tendances soient maigres dans l'ensemble. Dans la plupart des pays, il y a eu très peu d'investissement préalable dans la conservation, et une faible participation des acteurs locaux à la gestion durable des zones humides. Il urge de créer un cadre international pour l'élaboration d'initiatives de conservation des oiseaux migrateurs en Asie centrale, en vue de promouvoir l'action coopérative. De meilleures informations sont requises pour identifier les questions de conservation prioritaires et leurs réponses.
- Les oiseaux d'eau des voies de migration Asie-Australasie sont les plus mal connus, et pourtant, c'est là qu'on trouve le plus grand nombre d'oiseaux d'eau menacés dans le monde. Cette voie de migration s'étend à travers la région du monde la plus densément peuplée, où non seulement les zones humides non protégées, mais aussi les sites protégés, sont soumises à des pressions extrêmes. La protection réelle des zones humides d'importance majeure est un besoin vital, ici comme dans les autres régions du monde. Assurer l'utilisation rationnelle effective des sites-clés, ainsi que la consommation durable des oiseaux d'eau, est une rude bataille.
- La conservation des oiseaux d'eau pélagiques en pleine mer présente un éventail de défis uniques. L'entrée en vigueur de l'Accord sur la Conservation des Albatros et des Pétrels est une évolution à saluer, et sa mise en application un besoin urgent. Traiter les questions de captures accessoires d'oiseaux marins, en particulier par des pêches illégales et non-réglées, demeure un besoin crucial pour inverser le mauvais état de conservation de nombreuses espèces, comme l'est le besoin général de réaliser des pêches maritimes durables.
- La plupart des voies de migration connues dans le monde ont leur origine dans l'Arctique. Le récent développement de la coopération internationale entre les pays de l'Arctique est à saluer, tout comme la reconnaissance du besoin crucial d'impliquer les communautés locales et leurs connaissances traditionnelles locales dans la gestion des oiseaux d'eau. Les voies de migration austro-tropicales nécessitent, elles aussi, de la recherche.
- Les changements climatiques affectent déjà les oiseaux d'eau. Leurs conséquences pour ces oiseaux seront multiples et vont fortement exacerber les impacts négatifs actuels,

tels que la perte d'habitats et la dégradation. Il faut une planification en grand, à l'échelle de l'environnement et de la voie de migration, pour réduire ou modérer les impacts sur les populations d'oiseaux d'eau et leurs habitats. Il faudra de la recherche qui explore toute une gamme de scénarios futurs possibles pour soutenir cette planification, ainsi que des données émanant d'un suivi et d'une surveillance à long terme.

- Les populations d'oiseaux d'eau non-migrants partout dans le monde ont, dans bien des cas, un état de conservation plus mauvais que celui des migrants, et en général, focalisent moins l'attention internationale que ces derniers. Il faudra donc également accorder la priorité au traitement des besoins de conservation des oiseaux d'eau non-migrants, au niveau national comme international.
- Sur une planète à forte densité de population, il est crucial que les partisans de la conservation des oiseaux d'eau se focalisent sur leurs rapports avec les communautés et les gouvernements, comme un moyen à la fois de renverser les causes du mauvais état de conservation et de résoudre les conflits avec les espèces protégées. Des programmes de communication, éducation et sensibilisation du public adéquatement financés doivent être au cœur de toutes les initiatives en matière de conservation des oiseaux d'eau.
- La science a identifié l'importance vitale d'une poignée de sites-clés pour les oiseaux de plage migrant sur de longues distances; elle a également déterminé que dans certains de ces sites, l'activité anthropique est responsable des récentes baisses spectaculaires de certaines populations d'oiseaux de plage.
- Les dernières recherches ont mis en évidence les risques génétiques et démographiques encourus par les espèces à faibles populations. Ces découvertes ont des implications pour la conception des programmes de rétablissement de ces espèces.
- La fréquence et l'ampleur des pertes dues aux maladies chez les oiseaux d'eau (provoquées par des agents pathologiques naissants ou faisant leur réapparition) se sont intensifiées, au point de requérir l'attention. Ces maladies non seulement affectent les oiseaux d'eau, mais ont aussi des impacts sur les êtres humains. Les solutions nécessitent une approche multidisciplinaire.
- Une approche intégrée du suivi des oiseaux d'eau produit une identification économique des raisons des variations des populations d'oiseaux d'eau. Il existe de bons exemples de collecte d'informations démographiques et de leur intégration dans les données des dénombrements. D'autres programmes nationaux et surtout internationaux de ce genre doivent être fortement encouragés et financés.
- Des analyses systématiques des atlas confirment la valeur des études du baguage dans l'évaluation de l'état de conservation des sites de reproduction, des quartiers d'hiver et des aires de repos à l'intérieur des voies de migration. A cette fin, les données provenant des classiques baguages et marquages par teinture, de la télémétrie, des analyses d'isotopes stables et des marqueurs génétiques doivent être intégrées.

## Declaración de Edimburgo

*La conferencia internacional sobre aves acuáticas, su conservación y uso sostenible se celebró en Edimburgo, Escocia, del 3 al 8 de abril de 2004. En ella participaron 456 personas provenientes de 90 países.*

**Conscientes** de que los corredores migratorios de las aves acuáticas son sistemas biológicos de trayectos de migración que relacionan sitios y ecosistemas en distintos países y continentes;

**Recordando** que la conservación y uso racional de las aves acuáticas es una responsabilidad compartida entre distintas naciones y pueblos y es una preocupación común del género humano;

**Recordando también** la larga historia de colaboración internacional para la conservación de aves acuáticas desarrollada hace más de cien años en tratados como aquél relativo a las aves migratorias, firmado en 1916 entre los Estados Unidos de América y el Reino Unido (en nombre de Canadá); y que hace más de cuarenta años, la primera Reunión Europea sobre Conservación de Anátidos llevada a cabo en 1963 en San Andrés, Escocia, empezó un proceso que llevó a la creación de la Convención sobre los Humedales, especialmente como hábitat de aves acuáticas; en Ramsar, Irán, en 1971;

**Tomando en cuenta** que importantes conferencias internacionales en Noordwijk aan Zee, Los Países Bajos (1996), Leningrado, Unión Soviética (1968), Ramsar, Irán (1971), Astracán, Unión Soviética (1989), Playa de San Petersburgo (Estados Unidos de América), Kushiro, Japón y Estrasburgo, Francia (1994) han promovido el desarrollo de intercambios técnicos sobre conservación de aves acuáticas;

**Conscientes** del progreso de la cooperación intergubernamental a través del establecimiento e implementación de más tratados, convenios, estrategias y programas, y del desarrollo de importantes esquemas de cooperación no gubernamental a escala nacional e internacional para el monitoreo y conservación de aves acuáticas;

**Conscientes** de que en la Cumbre Mundial sobre Desarrollo Sostenible llevada a cabo en Johannesburgo, Sudáfrica en 2002, los líderes mundiales expresaron su deseo de alcanzar “una reducción significativa en la tasa de pérdida de biodiversidad” para el 2020, y de que en febrero del 2004 este objetivo se amplió aún más en la Séptima Conferencia de las Partes de la Convención sobre Diversidad Biológica; y **conscientes** de que alcanzar este objetivo requerirá inversiones significativas y actividades específicas de conservación enfocadas en todos los continentes; y **reconociendo** que la comunicación, la educación, la concienciación y la capacitación jugarán un papel importante en lograr este objetivo;

**Conscientes** de que se necesita fortalecer la cooperación internacional y las asociaciones entre los gobiernos, las organizaciones intergubernamentales y no gubernamentales, las comunidades locales, y el sector privado;

**Alarmados** por la delicada situación de muchas de las poblaciones de aves acuáticas tanto en ecosistemas marinos como terrestres, y del continuo descenso en la calidad y extensión de los humedales del mundo;

**Tomando en cuenta** las conclusiones y prioridades para la acción identificadas por la mayoría de los talleres y presentaciones realizadas en esta conferencia y documentadas subsecuentemente en la presente Declaración;

**Recibiendo** la iniciativa conjunta de Wetlands International y de las autoridades de los gobiernos del Reino Unido y de los Países Bajos, con el apoyo de Australia, Dinamarca, Estados Unidos de América, Japón, Alemania, Suecia, Irlanda, Bélgica, Suiza, PNUMA/CMS, PNUMA/AEWA, FACE y CIC, con el aporte de muchas otras organizaciones e individuos, y **acordando** la conferencia “Aves Acuáticas Alrededor del Mundo” en Edimburgo para revisar el estado actual de las aves acuáticas del planeta;

### *Los participantes de la Conferencia reunidos en Edimburgo*

**Consideran** que a pesar de que se ha hecho un progreso significativo para conservar las aves acuáticas y los humedales donde éstas habitan, aún existen desafíos que, junto con las incertidumbres sobre las implicancias de los cambios que puedan ocurrir en el futuro, requieren aún más esfuerzos y acciones específicas;

**Reafirman** que, en palabras de la Convención Ramsar, “las aves acuáticas, en sus migraciones estacionales trascienden fronteras y deben ser consideradas como un recurso internacional” y “que la conservación de los humedales, junto con su flora y su fauna puede lograrse combinando políticas visionarias con acciones coordinadas internacionalmente”, por lo tanto **exigen** que se extiendan los esfuerzos entre los países para conservar las poblaciones de aves acuáticas y los humedales donde éstas habitan, no sólo por el valor que las aves acuáticas tienen para sostener las poblaciones humanas sino también para su propio beneficio;

**Consideran** que la conservación de los corredores migratorios debe encararse con enfoques que combinen tanto las especies como los ecosistemas, y que sean coordinados internacionalmente en todo el rango de migración;

**Reconocen** que la conservación y uso sostenible de las aves acuáticas y los recursos provenientes de los humedales requiere acciones coordinadas de los sectores público y privado, las comunidades locales y otras partes interesadas;

**Hacen un llamado** de acción urgente para:

- Detener y revertir la pérdida y degradación de humedales;
- Completar inventarios de humedales a escala nacional e internacional, y promover la conservación de los humedales de importancia para las aves acuáticas, especialmente a través de la participación de las comunidades locales;
- Extender y fortalecer las redes internacionales de sitios claves para las aves acuáticas a lo largo de los corredores migratorios;
- Establecer y extender los acuerdos formales y otros acuerdos de cooperación entre los países, y de ser posible dentro del esquema provisto por las convenciones sobre Especies Migratorias, de Diversidad Biológica y de los Humedales;
- Implementar y financiar planes de recuperación para todas las especies de aves acuáticas amenazadas;
- Detener y revertir la disminución reciente de las aves playeras migratorias de larga distancia a través de planes de manejo sostenible de los gobiernos y de las actividades humanas que se lleven a cabo en sitios de importancia única para estas especies;
- Restablecer las poblaciones de albatros y petreles a niveles favorables para su conservación a través de acciones urgentes coordinadas internacionalmente especialmente a través del marco establecido por el Acuerdo sobre la Conservación de Albatros y Petreles;
- Reducir la contaminación de los ambientes marinos y establecer un sistema de cosecha sostenible de los mismos;
- Respaldar y fortalecer las decisiones futuras de conservación haciendo uso de asesoría científica altamente calificada y especializada proveniente de programas de investigación y monitoreo coordinados y financiados adecuadamente, en particular, del Censo Internacional de Aves Acuáticas, y para ello insta a los gobiernos y otras partes interesadas a trabajar de forma conjunta;
- Desarrollar indicadores relevantes para las políticas en relación con el estado de los humedales del mundo, en particular en el contexto de la meta para el año 2010, haciendo uso de datos generados por sistemas de monitoreo sostenibles y robustos;
- Invertir en actividades de comunicación, educación y concienciación como un elemento primordial para la conservación de las aves acuáticas y los humedales;
- Estudiar los riesgos de enfermedades y establecer programas de monitoreo de los movimientos de las aves acuáticas y del comercio de aves silvestres y sus implicaciones para la salud humana.

**Exhortan** que se debe dar especial prioridad a la formación de capacidades para la conservación de los corredores migratorios en países y territorios con recursos e instituciones limitadas, dado que el uso racional de los humedales y las aves acuáticas es de suma importancia para el desarrollo sostenible y la reducción de la pobreza;

**Alientan** a los países a ratificar e implementar las convenciones, acuerdos y tratados relevantes para estimular la cooperación

internacional y hacer uso de los recursos disponibles en el Fondo para el Medio Ambiente Mundial de forma de financiar las acciones necesarias establecidas en esta Declaración;

**Consideran** que, dada la larga historia de estudios de cooperación internacionales, las aves acuáticas proveen indicadores excelentes para evaluar los progresos para alcanzar las metas del 2010 establecidas por los líderes mundiales en el 2002, y **hacen un llamado** a las Convenciones sobre Especies Migratorias, Diversidad Biológica y de los Humedales y otros acuerdos internacionales a trabajar de manera conjunta y con otras partes en estos estudios, y en particular con Wetlands International, para desarrollar aún más el contenido analítico de la publicación trienal *Estimaciones de las Poblaciones de Aves Acuáticas* y sus utilidades;

**Enfatizan** la necesidad de la diseminación a escala internacional de esta Declaración y de los resultados técnicos de esta Conferencia, y

**Acuerdan** reunirse de nuevo dentro de diez años para revisar los progresos realizados.

Edimburgo

7 de abril de 2004

#### En apoyo a las recomendaciones mencionadas anteriormente, la Conferencia concluye lo siguiente:

- Para los corredores migratorios de las Américas se están desarrollando colaboraciones entre las naciones del Norte, Centro y Suramérica y el Caribe, basadas en las conclusiones de la conferencia de naciones sobre el estado de las aves migratorias que se llevó a cabo durante el Octavo Congreso Neotropical en Chile, y la reciente culminación del Plan de Conservación de Aves Acuáticas para las Américas. A pesar de los esfuerzos de conservación en Norte América llevados a cabo hace más de un siglo y del surgimiento de una visión compartida para la cooperación basada en aspectos biológicos y paisajísticos, está claro que la cooperación internacional debe aumentar y mejorar entre los países Pan-Americanos que comparten aves migratorias.
- En los corredores migratorios de África y Eurasia, el conocimiento de las aves acuáticas no está siendo transferido de forma adecuada en acciones a escala local o nacional. De igual manera, los esfuerzos de conservación tampoco han contribuido a mantener o restaurar la salud de muchas de las poblaciones de aves acuáticas, incluyendo especies amenazadas a escala global. Es por ello urgente integrar la conservación de las aves acuáticas como una parte integral del desarrollo sostenible y el beneficio de las comunidades locales y otras partes interesadas o dependientes de los recursos de los humedales y de la biodiversidad. El Acuerdo Afro-Euroasiático sobre Aves Acuáticas (PNUMA/AEWA) provee una base apropiada para alcanzar esta meta.
- Muchas de las poblaciones de aves acuáticas del corredor migratorio del Asia Central parecen estar disminuyendo. En la mayoría de los países ha habido poca inversión en conservación y muy poca participación de los actores locales en el

manejo sostenible de los humedales. Se requiere por lo tanto de un marco internacional que promueva acciones para la cooperación y el desarrollo de iniciativas de conservación de las aves migratorias en Asia Central. Se necesita de mejor información para identificar las prioridades de conservación en esta región.

- Las aves acuáticas del corredor migratorio de Asia y Australasia son las menos conocidas y el mayor número de aves migratorias amenazadas a nivel mundial se encuentran en este grupo. Esta ruta migratoria se extiende a lo largo de las áreas más pobladas del planeta, donde existen presiones muy fuertes no sólo en humedales no protegidos sino también en humedales protegidos legalmente. Se necesita urgentemente una protección efectiva de los humedales de mayor importancia tanto en esta zona, como en otras regiones del mundo. Los desafíos tanto para asegurar el uso racional efectivo de sitios claves como para asegurar el consumo sostenible de aves acuáticas son muy grandes.
- La mayoría de las rutas migratorias conocidas se originan en el Ártico. El reciente desarrollo de cooperación internacional entre los países árticos es bienvenida, al igual que el reconocimiento de la necesidad de involucrar a las comunidades locales y su conocimiento tradicional en el manejo de aves acuáticas. Las vías migratorias Austro-Tropicales requieren mayor investigación.
- La conservación de las aves acuáticas pelágicas en los océanos abiertos ofrece desafíos únicos. La entrada en vigor del Acuerdo sobre Conservación de Albatros y Petreles es bienvenido y su implementación es una necesidad imperiosa. La necesidad de tomar en cuenta el problema de la captura incidental de aves acuáticas debido a la pesca ilegal es un asunto crucial para revertir el estado de conservación de muchas especies, y es una necesidad para lograr pesca marina sostenible.
- Los cambios climáticos han afectado a las aves acuáticas, y sus consecuencias pueden ser múltiples y pueden exacerbar los impactos negativos como la pérdida y degradación de hábitat. Se necesita una amplia planificación a escala paisajística y de las vías migratorias de forma de reducir o mitigar los impactos en las poblaciones de aves acuáticas y sus hábitats. Se requiere de investigaciones que exploren escenarios potenciales a futuro para revertir esta situación y de datos de monitoreo a largo plazo.
- El estado de conservación de las poblaciones de aves acuáticas no migratorias es, en muchos casos, muy pobre, inclusive más que el de las especies migratorias. Estas aves no migratorias reciben menos atención que las migratorias. Se necesita dar prioridad a las necesidades de conservación de las especies no migratorias a nivel nacional e internacional.
- Las acciones de conservación en las áreas más pobladas del planeta necesitan enfocarse en las relaciones entre las comunidades y los gobiernos locales como estrategia para revertir las causas que van en contra de la conservación, y para resolver los conflictos de uso de especies protegidas. La capacitación, educación y concienciación son las actividades clave en las que centrar las iniciativas de conservación en estas zonas.

- La ciencia ha identificado la importancia de un reducido número de sitios claves para las especies de aves playeras migratorias de larga distancia. También ha identificado a las actividades humanas como las responsables del reciente declive en las poblaciones de determinadas especies de aves playeras.
- Investigaciones recientes han enfatizado los riesgos genéticos y demográficos que sufren algunas especies que tienen pequeñas poblaciones. Estos riesgos tienen implicaciones en el diseño de los programas de recuperación de especies.
- La frecuencia y magnitud de muertes por enfermedades entre las aves acuáticas (tanto de agentes infecciosos emergentes como re-emergentes) ha incrementado al punto de requerir especial atención. Estas enfermedades no sólo afectan las aves acuáticas sino también a los humanos y requieren soluciones de orden multidisciplinario.
- Un monitoreo integrado de las poblaciones de aves acuáticas da como resultado una identificación eficiente de las razones que explican los cambios observados en las poblaciones de estas aves. Existen ejemplos magníficos de recolección de información demográfica y su integración en los datos de censos. Se requiere mayor financiamiento para esquemas de integración de este tipo a escala nacional e internacional.
- El análisis sistemático de los atlas confirma el valor de los estudios de anillado de aves para evaluar los corredores migratorios en cuanto al estado de conservación de los sitios de reproducción, de parada y de invernada de aves acuáticas migratorias.

## Address by His Royal Highness The Prince of Wales

Wednesday 7 April 2004

His Royal Highness The Prince of Wales. 2006. Address to the Waterbirds around the world conference, 7 April 2004. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 16-18.

Ladies and gentlemen, I am conscious that I am appearing very much at the tail end of your conference and, by the look of the programme, you have clearly had a full and varied few days. So you are probably beginning to calculate how quickly you can join your own personal 'flyway' back home. But I am delighted that so many of you are still here and that, by all accounts, you have had such a successful conference. I am just relieved that I arrived in time to hear Dr John Cooper's riveting presentation.

Now, ladies and gentlemen, I am very far from being an expert on either albatrosses or petrels but, like many other one-time mariners, I have a very special affection for these remarkable birds. I remember so well standing on the deck of a fast-moving warship in one of the Southern oceans, watching an albatross maintaining perfect position alongside for hour after hour, and apparently day after day. It is a sight I will never forget, and I find it hard (no, I find it impossible) to accept that it might one day be lost for ever. Yet that does now seem to be a real possibility – unless we, and others around the world, can make a sufficient fuss to prevent it. In 1996, three of the twenty-one species of albatross were officially listed as threatened. Four years later, when I sat down to write an article expressing my concerns about the decline of these magnificent birds, the total of threatened species had risen to sixteen. Another four years on, and all twenty-one species are threatened. The albatross family is now the biggest single bird family with every one of its members under threat.

I don't need to tell this audience that the most potent force driving the members of the albatross family to extinction is indiscriminate longline fishing, which is estimated to kill 100 000 albatrosses every year. One fishing boat reported more than 300 killed in a single day. But before I talk a bit more about that problem, I just want to say some thoroughly positive things.

First, this seems an entirely appropriate time and place to draw attention to the years of dedicated work by research scientists and their support crews, without whom we would know next to nothing about these most nomadic and elusive of birds. It must be hard and lonely work, carried out in cold, wet and thoroughly difficult conditions, and a very long way from home. But without the knowledge and data you take such pains to obtain there can be no coherent evaluation of either the scale of the problem, or the potential for solutions.

This scientific effort has been matched by BirdLife International and other non-governmental organizations, bringing these issues to the attention of a wider public. That is certainly how I first learnt of the scale of the problem and I suspect the same is true for many other people. There is, of course, a huge amount more to be done in terms of awareness-raising and advocacy.

Gaining awareness of the plight of a group of birds most people have never seen, and probably never will see, is a huge challenge. So I also want to mention the efforts of one remarkable man, who has – in his own inimitable fashion – taken up

His Royal Highness The Prince of Wales. Photo: Dougie Barnett.

that challenge and is drawing attention to the issue of albatrosses and longline fishing. John Ridgway, who may or may not like me to tell you that he is now sixty-five, has sailed with his wife, Marie Christine, and a small crew from their home in northern Scotland to the Southern Ocean, following the circumpolar track of the Wandering Albatross. John and Marie Christine and their crew are having great success in engaging with all sorts of different audiences at each landfall, and generating remarkable publicity, most recently in New Zealand and the Falkland Islands. Their yacht, *English Rose VI*, is now headed for home. They expect to berth in London in June, where there will be further opportunities to raise the profile of this issue.

In view of all the scientific and voluntary efforts I have just mentioned, I am pleased to be able to say that at least some Governments are also alive to the situation and willing to commit to taking effective action.

An international Agreement on the conservation of albatrosses and petrels (known as ACAP) came into force just two months ago. This was a huge achievement – especially as it has taken a very long time to materialize... ACAP is particularly important because it is legally binding on the countries that ratify it, and its emphasis on international co-operation is an essential first step to tackling the multiple threats to such a wide-ranging group of birds. The UK played a leading role in drawing up this key international treaty and was among the first to sign it. But ratification is the essential step. So I couldn't have been more

pleased to hear that Mr Elliot Morley, who has been a passionate fighter for the albatross, had announced, earlier in this conference, that the Government has now ratified the Agreement, without reservations and to a tight timescale. And I also want to draw attention to Elliot Morley's personal leadership on this topic, as someone with a deep understanding and concern for the issues.

Well, that was the good news. The bad news is that many countries with fishing interests in the Southern Ocean still need to ratify the ACAP, and some of the most important appear unlikely to do so – for reasons which can only be guessed at. At the same time, the problem of illegal, unregulated and unreported fishing appears to be getting worse. There are believed to be more than a thousand of these substantial pirate vessels, operating under 'flags of convenience', recognizing no rules and – with few exceptions – evading every sort of sanction and penalty available under international law.

Fishermen operating in responsible and well-regulated fisheries have adopted measures that almost entirely eliminate the deaths of albatrosses from longlining. Setting lines under water, or only at night, trailing a bird-scaring line and prohibiting offal discharge while fishing have all proved effective. Many fisheries also insist on the presence of observers on board to monitor results. The pirate vessels in the illegal fisheries, of course, take none of these measures. No-one knows how many albatrosses and petrels they kill every year, but the best estimate is that they are responsible for about one third of the total of around 100 000 deaths. But that is not the total of the environmental havoc they are causing.

One of the principal targets of the pirate ships is the Patagonian Toothfish. Sold under many 'consumer-friendly' aliases, such as Chilean Sea Bass in the USA and Mero in Japan, this valuable species is also very much under threat from over-fishing. Indeed, the Australian government has said that if fishing continues at current levels, the species faces commercial extinction. Living up to fifty years, and taking ten years to reach breeding age, it is a slow-growing creature which is being killed faster than it can reproduce. Just like the albatross, in fact, though even less visible.

Of course, it is much easier to be angry about the awful dual threat posed by the pirate fishing boats than to take effective action against them. I rather think that the Greenpeace report on this subject, which is based on intense investigation, is right when

it concludes that the only way to prevent continued pirate fishing is to close ports to these ships, close markets to the fish they catch and penalize the companies that are their true owners and operators. I know that Elliot Morley now leads an OECD Task Force on Pirate Fishing and I wish him every possible success in finding ways to do all those things. I certainly don't think that any single measure is going to succeed when the economic incentives for illegal action are so high and the chances of being detected and prosecuted are so low. It also has to be said that political willingness to act is notably absent in some countries.

Agreements on vessel monitoring and catch documentation do exist for Patagonian Toothfish, and appear to be having some positive effects. But there always seems to be a hard core of countries that want to do as little as possible and as late as possible – and preferably nothing at all. When an International Plan of Action to tackle the problem of pirate fishing was being negotiated under the auspices of the United Nations, several countries made strenuous efforts to water down the draft provisions. In particular, the opportunity to take effective measures against the use of chartered vessels in illegal, unreported and unregulated fisheries was missed. I just wonder how many of those countries claim to be committed to 'sustainable development' at the same time?

Ladies and gentlemen, it would be hard to find a more direct impact of fisheries, whether legal or illegal, on seabirds than the losses the albatross family suffers at the hands of indiscriminate longlining. But there are many examples of less direct effects all round the world.

Not far from here, in the North Sea, there is a sandeel fishery. It is now by far the largest single-species fishery in the North Sea, though not for human consumption – the sandeels are processed into fishmeal and oil, to feed livestock and farmed fish. Whether this so-called industrial fishing, targeting the bottom of the food chain, represents a sensible use of natural resources or not is a subject for another day. The point for now is that the Total Allowable Catch for sandeels for 2004 is 826 000 tonnes, despite the fact that last year the fleet was only able to catch around 300 000 tonnes (one third of its target). The fishing boat skippers simply couldn't find the fish to catch.

The seabirds evidently had the same problem. Kittiwakes are especially dependent on sandeels and last year the massive colony

His Royal Highness The Prince of Wales viewing Northern Royal Albatross *Diomedea sanfordi* at Taiaroa Head, New Zealand. Photo: Press Association.

at the RSPB reserve at Bempton in Lincolnshire had the worst breeding season in eighteen years of records. Many birds failed to nest at all and adults and chicks were clearly suffering from food shortage. Similar effects have, I know, been seen in the Shetland Isles. Here, seabirds had their worst breeding season for twenty-five years, with some Kittiwake colonies disappearing entirely and Puffins and Razorbills also seriously affected.

It is well known that the sandeel population has good and bad years, but there seem to be many more bad years than good. And there is growing evidence that the ecology of the North Sea is changing dramatically. The Sir Alister Hardy Foundation for Ocean Science, which has been monitoring plankton in the North Sea for more than seventy years, has established that higher sea temperatures have driven cold-water species of plankton much further north. They are being replaced by smaller, warm-water species that are less nutritious. Whether or not this is the cause of the dramatic fall in sandeel populations is not certain, but most recent studies show that rising sea temperatures, as a result of the changing global climate, will directly affect marine productivity – with as yet unknown impacts on fisheries and seabirds.

In the case of the sandeel fishery, there is little evidence of direct competition with seabirds. Indeed, one area where competition might have been a particular problem, known as the Wee Bankie and actually just offshore from here, has been closed to fishing for the last three years, to protect nesting seabirds – and this will clearly have to continue. In general, the fishermen and the birds seem to be suffering equally from the absence of their prey. But the sandeel is part of the food chain for other species too, including cod. I am told that at present cod stocks are so low that they are probably making little impact on the sandeels. But drastic measures are being taken to get cod stocks back to the levels of twenty or thirty years ago, and those measures should surely include ensuring that there will be enough sandeels in the North Sea for a recovered cod stock to eat.

There are plenty of complicating factors, but I find it difficult to believe that the sandeel populations of the North Sea will be able to support recovered stocks of cod and mackerel, a major industrial fishery and thriving seabird populations. In those circumstances it would be hard to argue that the industrial fishery should take precedence over human consumption fisheries and the needs of marine wildlife. Surely an ‘ecosystem approach’ to fisheries management requires fisheries to adapt to the marine environment, not the other way round?

I think the lesson to be drawn from all of this is that we live in an increasingly inter-connected world, in which actions have consequences – and huge actions have huge consequences. Before you point out that this has always been the case, let me explain what I mean – and I have tried to say this on various occasions in the past. It is simply that we now have unprecedented technological capacity to change ecosystems, very directly and very quickly, but also to monitor many of the detailed consequences of our actions. Man has always been able to change his environment, but has only comparatively recently gained the capacity to do so with such speed and finality. I would argue that this means that the need for wisdom and restraint in our actions has never been greater. I would also argue that the need has never been clearer for all the talk (dare I say “hot air”?) about sustainability to be translated into action and not just the repetition of “business as usual with little brass, sustainable knobs on”.

Our ancestors were able to hunt many species of whales to the edge of extinction and they did make the Great Auk extinct. But they did so over hundreds of years and without a fraction of our capacity to know – simultaneously – precisely what was happening. To give just one example, nylon longlines eighty miles long, containing thousands of baited hooks, are doing unprecedented damage, at unprecedented speed, to albatross populations. And, as Dr Cooper pointed out just now, satellite monitors enable us to know a great deal about what is happening.

In many ways the albatross may be the ultimate test of whether or not, as a species ourselves, we are serious about conservation: capable of co-existing on this planet with other species. Or are we going to sacrifice what’s left of wisdom on the altar of short-term gain? None of the short cuts and quick fixes that might help some other species will help the albatross. No nature reserve will ever be big enough to encompass more than a fraction of such a nomadic bird’s total requirements. Captive breeding and stock enhancement have no conceivable part to play. No corporate sponsor or private philanthropist can do any more than raise awareness of the problems. And no single nation state can take any effective unilateral action. Nor is there much time left – the clock is ticking very, very fast. Even if mortality from long-lining were, somehow, to be stopped overnight, the rate of decline in the populations and the exceptionally slow rate at which albatross species breed are such that recovery would take many decades.

To me, the plight of the albatross is a symbol of the emptiness of the rhetoric surrounding so-called ‘sustainable development’. Will it take the complete dodo-like disappearance of this noble winged creature to bring us to our senses? Or are we to remain blind and deaf to the appalling tragedy unfolding, out of sight and out of mind, in the vast foam-flecked spaces of the Southern Ocean?

Whatever the case, it would be a shameful travesty of our duty as stewards of this increasingly fragile globe if we couldn’t find a way of living our lives in such a manner that these magnificent birds can continue to share the same planet with us. Ratification of ACAP is an important step in that process, but the reality is that in the current dangerously critical situation the only effective actions will be those that are implemented immediately, and continued indefinitely.

Ladies and gentlemen, I am sorry to have dwelt so much on a single group of birds, and on just one issue. I know that you have covered a huge range of subjects relating to waterbirds during this week, and that some of you will be experts in species that are just as desperately threatened as the albatross.

If there had been time, I would have welcomed the opportunity to talk about subjects such as the importance of wetland habitats and the many adverse consequences of intensive agriculture around the world. Indeed, some people who have heard me speak before may be surprised at my ability to resist that particular temptation!

Forty years after one of the very first gatherings of waterbird specialists took place at St. Andrews, here in Scotland, your work remains hugely important. Reviewing past efforts, considering key questions for future research and co-ordinating future conservation actions are all essential tasks. I hope you feel this particular conference has been worthwhile. I applaud your efforts and I look forward to seeing the implementation of your thinking in years to come.

## Address by Elliot Morley MP, UK Minister for Environment and Agri-Environment

Sunday 4 April 2004

Morley, E. 2006. Address to the Waterbirds around the world conference, 4 April 2004. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 19-20.

Ladies and Gentlemen, it is an enormous pleasure to be here. Thank you to John Markland, Chairman of Scottish Natural Heritage, for extending such a warm welcome to Scotland. On behalf of the UK Government, I'd like to say that we have been delighted to play our part in the organisation of this conference and to welcome you to our shores. I'd like to extend a particular welcome to the Dutch Minister, Professor Cees Veerman.

It is quite extraordinary that this conference has attracted 456 people from 90 different countries round the world - as such it is certainly the largest assemblage of waterbird experts ever seen in the UK. When the first European Meeting on Wildfowl Conservation took place just up the coast from here, in St Andrews in 1963, there were just 81 participants from 17 countries. The increase in numbers, and the representation here from right around the world, is a real measure of how our international concern for waterbirds and their wetland habitats has grown over the last 40 years.

I must also say how especially honoured we are by the presence of some of the participants of that meeting in St. Andrew's, here today, continuing to give their support and expertise.

The UK is critically important for migratory waterbirds in the overall pattern of flyways. This is why we believe that it's vital to participate fully in the Bonn Convention and its African-Eurasian Waterbird Agreement. The potential strength of that Agreement is manifested in the fact that it has no fewer than 117 Range States and is growing fast with already 46 Contracting Parties.

We were honoured to host a meeting of the Technical Committee of the African-Eurasian Waterbirds Agreement in North Berwick last week and are committed to the implementation and review of international action plans for species that are specially important to us in the UK, such as the Bittern, the Corncrake, the Roseate Tern and, - for rather different reasons, - the globally-threatened White-headed Duck which is threatened in Europe by the invasive Ruddy Duck, introduced by accident in the UK many years ago. We are implementing a strategy to deal with the Ruddy Duck, which could be seen as the opposite of conservation!

I am especially pleased that UK expertise is helping to assess the habitat priorities for waterbirds in Africa and South-East Asia, including the identification of sites of international importance, and applying restoration and rehabilitation techniques for waterbird habitats - especially those affected by invasive aquatic weeds, a big problem internationally and in the UK. In addition, funding from the UK's Darwin Initiative has been able to help develop waterbird monitoring in eastern Africa. This project stands to make major contributions to wetland and waterbird conservation in that part of the AEWA region.

The Ramsar Convention is also very dear to our hearts in the UK. We have 243 Ramsar sites covering 6% of the land surface. These sites, and others of European importance, are home to

Elliot Morley MP. Photo: Dougie Barnett.

85% of our breeding seabirds, and about half of all the waterbirds over-wintering in the UK. As you will no doubt hear in some of the presentations to come, the UK has many different types of wetlands, from peatlands to estuaries, and from rivers to artificial reservoirs, and each of these habitats is important for different assemblages of waterbirds. We have examples of most of these wetland types within our national Ramsar network, and the UK is currently undertaking a strategic review to identify gaps in network coverage through a detailed audit of all the wetlands in the UK.

The designation of such sites is, of course, just the first step in ensuring their long-term wise-use. In a densely populated and highly developed country such as ours, protected areas face many habitat management challenges. In common with the Netherlands we find that our wetlands are under a whole range of threats. The precise issues may be slightly different from those in other parts of the world, but they are no less acute. The value of international conferences such as this one is the opportunity to share experiences and solutions, and so to learn from each other. I do urge you all to make the most of the opportunities presented in the next few days for such exchanges. This will undoubtedly help us all to deliver better, and more focused conservation.

Elliot Morley MP counting waterbirds on the Humber Estuary Ramsar site. Photo: Gareth Harford.

Throughout your conference, over the next few days you will hear a great deal about the problems faced by migratory waterbirds and the serious conflicts arising from human activities in many parts of the world. Amongst the most serious are of course the threats to some of our especially extraordinary and spectacular migratory seabirds - the albatrosses and petrels of the southern oceans. Only international action can help to address the issues of longline and illegal fishing, which are the principal threats to them.

So I am delighted to be able to announce today that the UK Government has just become the 6th state to ratify the Bonn Convention's Agreement on the Conservation of Albatrosses and Petrels. Our instrument of ratification was deposited with the Australian Government on Friday 2 April. By happy coincidence the Secretary of State for the Environment, Food and Rural Affairs, Margaret Beckett, was on a visit to Australia at the time and was able, during her visit, to reinforce our commitment to this treaty - the UK having played a key role in drafting the Agreement and was amongst the first to sign it. Our ratification covers the UK and three Overseas Territories - the Falkland Islands, South Georgia and the South Sandwich Islands, and the British Antarctic Territory. We will be working hard to extend the ratification to a fourth Overseas Territory, Tristan da Cunha as soon as possible. We also look forward to participating in the first Conference of the Parties when it is convened in the coming year. Our aim, together, must be to make real changes to the fortunes of these amazing birds.

We must bring more and more people to an understanding of the challenges for biodiversity that we face. The plight of the mythical albatross connects peoples across oceans and between continents and captures the poetic imagination. But it can also generate more down-to-earth instincts! I was very interested to discover that the Conservation Foundation is working with Ladbrokes the bookmakers to help raise money for albatross research through what is called 'The Big Bird Race'. This is a serious scientific satellite tracking project based in Tasmania to find out where the Tasmanian Shy Albatrosses migrate. But it's combined with an innovative approach to betting, in which on-line clients back an albatross to win the migration race. This gives a whole new meaning to 'having a flutter'.

This idea could bring a whole new section of society to an interest in biodiversity and to research and data collection. We have come to call the mass involvement of people in research as

'citizen- science' - and the more of this we can encourage the better! Only by engaging the understanding and involvement of people at large can we hope to make the large-scale changes needed to slow the progressive loss of biodiversity worldwide. There are now many tools that we can use - with the Internet, web cams and satellite tracking - to bring these issues to a wider public.

Many of you will know what a strong tradition we have in the UK of using volunteer effort to collect biodiversity information. I'm pleased to say that I myself am a volunteer and have been involved in making low-tide counts on a monthly basis. This helps me to get out on the first Sunday in the month and talk to other enthusiasts and landowners and makes a contribution to the database. Time-series data is essential to monitor population trends and to try and establish what the influences are - and here we have had volunteers collecting data for over 50 years and there are between three and four thousand of them now who collect regularly. For example, we have discovered through our Wetland Bird Survey (or WeBS) monitoring data an early real manifestation of climate change. With increasingly mild winters, it seems that many waders and other waterbirds are not having to fly so far west to find mild winter feeding conditions. Our volunteers are discovering declines in the numbers of waterbirds on estuaries on the west coast of the UK, and commensurate increases on the east. Perhaps in the future - with climate change - these migrants will increasingly over-winter in Denmark and the Baltic. We can see these changes going on, and must consider their implications for conservation management.

I am sure that every one of you is aware of the immediacy of the challenge we face on global biodiversity loss - potentially as a result of long-term climate change - but also of course from the direct and pervasive influences that are apparent here and now. The global community has set itself the target of substantially reducing the rate of biodiversity loss by 2010. Conferences like this one are vital in exchanging ideas, understanding the problems and galvanising initiatives as we strive to achieve that objective. But we must not deceive ourselves into thinking that conferences themselves are a substitute for real action on the ground. I urge you, as you listen to the speakers this week, to consider how their messages can be translated into new, concerted activity that makes a real difference. It is the task of all of us, politicians, scientists and the research community and NGOs to make sure that our work engenders real conservation activity.

I hope that, - just as we look back on the first European wild-fowl conference, 40 years ago, as a key point when Governments and NGOs began to work seriously together in partnership internationally to address the conservation problems of waterbirds and wetlands - so we will reflect on this truly 'Global' Flyway Conference as a defining moment when the 2010 target came clearly into sight and became realisable.

The role of migratory waterbirds as indicators of wider ecological change is clear and important. They can be signals of broader environmental threats. Let us make sure that our data is robust and our actions are effective to serve the wider biodiversity community and, most importantly, the people we represent.

Whilst it is absolutely essential for national governments to make decisions in their own national contexts, they must not forget that action in one country impacts on conservation in another. It is wonderful to see so many countries gathered here, so I wish you a very successful conference - one that will help and guide our decision-making.

## Address by Cees Veerman, The Netherlands' Minister for Agriculture, Nature and Food Quality

Sunday 4 April 2004

Veerman, C. 2006. Address to the Waterbirds around the world conference, 4 April 2004. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 21-22.

Ladies and gentlemen, recently, on a farm in Southwestern France, I heard the high-pitched wail of dozens of Common Cranes as they made their way, far up in the early spring sky, from their wintering sites in North Africa to their Siberian breeding grounds.

As I watched the birds fly steadily North, I stood once again in awe about the unfathomable phenomenon of bird migration. What makes these birds fly thousands of miles along well-defined routes, using the same wetlands as stop-over points for many decades? What moves the Arctic Tern each year to make the 35 000 kilometer round trip from the Arctic to the South Pole and back?

As we gaze deeper and deeper into the Universe, observing galaxies and stars billions of miles away, we haven't even begun to understand the mechanisms that cause bird migration. That is a humbling thought, teaching us profound respect not only for the tiny Arctic Tern on its epic annual journey, but for nature as a whole.

Over the past decades, we have witnessed a remarkable shift in the relationship between nature and man. Even 40 years ago, mankind was ruling the roost, viewing nature as an inexhaustible wellspring of resources that man could mine as he saw fit.

At the dawn of the 21st century, much of man's self-instilled authority over all things living has evaporated. Mankind has learned to see itself not as nature's supreme ruler, but as part of it. A vulnerable part, for there are limits to the extent that we can exploit our natural resources. If we exceed those limits, we now understand, our very existence on this planet may well be in jeopardy. We have discovered the principle of sustainability.

So we have a duty to take care of nature in all its richness and variety. For in my view, taking care of nature equals taking care of mankind itself. If you think this sounds as if I'm talking about nature conservation as an act of self-interest, you are partly right. But taking care of our natural environment is also an intrinsic duty. We are, after all, responsible for husbanding the resources that have been entrusted to us.

This is where biodiversity kicks in. Preserving and protecting it is of the utmost importance, because it is the measure of the richness and variety I was talking about only a minute ago. And it is well understood these days that the richness and variety of nature is the very cornerstone of it. Without biodiversity, our natural environment would not be functioning, or at least not be functioning that well.

Preserving and protecting biodiversity is the common responsibility of mankind. National governments play an important role, to be sure. They may reflect, in the words of Jean-Jacques Rousseau, the *volonté générale*, or popular will. But governments also have an important trailblazing role. They must stir up popular support for policies that may seem tough or far-fetched at first sight. This is why governments around the globe have a direct responsibility in the quest to save biodiversity.

Cees Veerman. Photo: Dougie Barnett.

However, governments cannot go it alone. We need the cooperation of international bodies, regional and local authorities, non-governmental organizations, the business world and individual citizens. Only then will we succeed in tackling the global problem of the loss of biodiversity.

The growing effort to protect migratory birds is part of the worldwide struggle to halt the loss of biodiversity. It perfectly illustrates the necessity of cooperation: it makes no sense for one single nation to protect and preserve wetlands and other staging posts if the same is not done in other countries further up and down the line.

Co-operation, I am pleased to say, has become the norm in migratory bird conservation. It is one of the pillars of the 1971 Ramsar Convention. The Bonn Convention, whose 25th anniversary we celebrate this year, is exclusively dedicated to migratory species, birds figuring prominently among them. And then there are the broader frameworks such as the Convention on Biological Diversity and the Millennium Goals we all agreed upon during the 2002 World Summit on Sustainable Development in Johannesburg.

I referred earlier to the mysterious and fascinating forces that trigger bird migration. But all this mystery and fascination

should not cause a kind of awestruck paralysis. For despite our lack of understanding, there is a lot we can do to let the Common Crane, the Arctic Tern and many hundreds of other species to travel the skies unhindered.

We know, for instance, that strings of connected sanctuaries, such as wetlands, are of the utmost importance to migratory birds. In the Netherlands, creation of a National Ecological Network is one of our priorities - a long slog indeed, for work on it began in the early 1990s and is due for completion in 2018.

Work on an analogous Global Ecological Network - presumably an even longer slog - is underway. International flyways, the routes that migratory birds follow, are an important part of this network. The Dutch government strongly supports the creation of this global network and its concomitant flyways.

One Dutch initiative has ensured the protection of the East Atlantic Flyway from the vast tundra in northern Siberia to the wetlands in the Netherlands and from there on to Africa. This flyway has official status since the African-Eurasian Waterbird Agreement came into force in November 1999.

But we also support flyways that are far from our doorstep: we are participating in the development of the Central Asian Flyway and the Flyways of the Americas. We do this inspired by the spirit of cooperation and by a strong conviction that we carry a global, if shared, responsibility.

So far, I have been stressing preservation and protection, conspicuously avoiding the words 'sustainable use'. But since one of the objectives of this conference is the presentation of an 'update on the harvest and sustainable use of migratory waterbirds', I feel I must briefly address the issue.

Words like 'harvest' would make any true-blue environmentalist shudder. And indeed, the hunt on most migratory water birds is forever closed in the Netherlands. But I stress that we understand and respect the needs of other peoples, whose livelihoods depend, for instance, on duck and goose hunting. As I

said before, man is part of nature and that implies us making use of its 'products'. The vital point is to emphasize the sustainability of such harvesting activities.

At the outset of this talk, I spoke about the past, when man was lording it over nature. I discussed the relatively recent shift in mankind's attitude towards its fellow creatures. In conclusion, let me give one example of that changed relationship.

As you may know, my country has been seriously hit by Avian Influenza last year. There are strong suspicions of a link between bird migration and outbreaks of the disease. In the past, we might have opened the hunt on migrating birds in order to curb Avian Influenza.

Nowadays, we employ monitoring and early warning systems. Simultaneously, we are studying ways to adapt the management of our chicken and duck farms. The simile is probably inappropriate here, but this way we are killing two birds with one stone: the migratory birds fly on, while our farms are protected from Avian Influenza.

It has been a pleasure speaking to you in Edinburgh, a city 'Crowded with Genius', to quote the title of a recent book on the Scottish Enlightenment of the 18th century.

It has also been a pleasure for my ministry to be involved in the preparation of this important conference, in close cooperation with Her Majesty's Government, the Scottish Executive, and Wetlands International, where the idea of this conference was originally conceived.

I particularly want to thank Professor Colin Galbraith, the chair of the Conference Steering Committee, for his unstinting efforts to make this conference a success.

I wish Professor Galbraith and all other participants a fruitful conference, whose outcomes will help migratory birds, after all our fellow creatures, to continue their age-old journeys along the flyways of the world.

Thank you.

## Address by Max Finlayson, President, Wetlands International

Sunday 4 April 2004

Finlayson, M. 2006. Address to the Waterbirds around the world conference, 4 April 2004. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 23-26.

Ladies and gentlemen, I am pleased to be welcoming you here on behalf of Wetlands International. It's a pleasure to be in Scotland at this conference and to have the opportunity to make a few comments about why we are here. First let me record my pride at being able to represent Wetlands International – as we have been around for a long time many of you know a lot about us and I am confident that during this conference you will see further evidence of the ongoing value of our work. We have a long history – our first office opened its doors in 1954 – some 50 years ago – and we have developed many long-lasting partnerships that will come to the fore during this Conference.

We have a great interest in this conference. In collaboration with our partners in the organising group we have made a major effort to ensure that you have a successful conference. By this I mean that we have worked to ensure that you have a conference that should both educate and entertain you, and set the scene for ongoing outcomes for the conservation and wise use of wetlands and waterbirds worldwide. Let me record my gratitude to the organisers – they have worked long and hard to make this conference a reality – thank-you for your efforts.

I would now like to focus on the globally important concept of flyways – the networks of sites that support waterbirds around the world. Flyways have for a long time been central to the work of Wetlands International. The term 'flyway' refers to a concept for waterbird conservation that encompasses conservation and wise use of wetlands and waterbirds across multiple sites across very large areas – it is global and it is important.

Max Finlayson. Photo: Dougie Barnett.

Stalwarts of waterbird conservation - Hugh Boyd, Geoffrey Matthews, Harvey Nelson and Eckhart Kuijken. Photo: Dougie Barnett.

Important Bird Areas – Birdlife International’s global inventory of key sites for bird conservation.

Asia-Pacific waterbird counts - Wetlands International’s Asian Waterbird Census: part of the International Waterbird Census.

I doubt that any other concept has the same immediate meaning and value for global waterbird conservation and wise use. It can also provide valuable lessons for other conservation planners and managers.

We are keen through the flyway approach to promote concepts and actions that ensure connection between sites, species and the ecological interactions that support these. It is about linkages – both those in the environment and those between people and institutions that support our common goals of conservation and wise use. The concept of linkages is also not new, but recently we have been hearing more and more about interlinkages between conservation efforts globally and locally. Through this conference we can support these efforts – waterbird conservation has long focussed on linkages between sites and between concerned and erudite people. The formation of the Ramsar Convention in 1971 is one example where interlinkages and common purpose came together through the efforts of dedicated and erudite scientists.

This conference presents an opportunity to discuss the science that is needed to conserve our waterbirds – our global waterbirds. Monitoring of waterbirds has been formally undertaken for many decades. The International Waterbird Census was started by Wetlands International (through the component of our organisation that was known as IWRB) in the 1960s and we now have a long time series of data for many species and sites. This dataset and associated products, such as the Waterbird Population Estimates are key resources for the Ramsar Convention. Birdlife International also provides an invaluable data resource through its Important Bird Area program. Many national and international organisations now rely on these datasets. We are pleased to welcome to this conference some of the stalwarts of waterbird conservation and monitoring.

# AEWA

African-Eurasian Waterbird Agreement

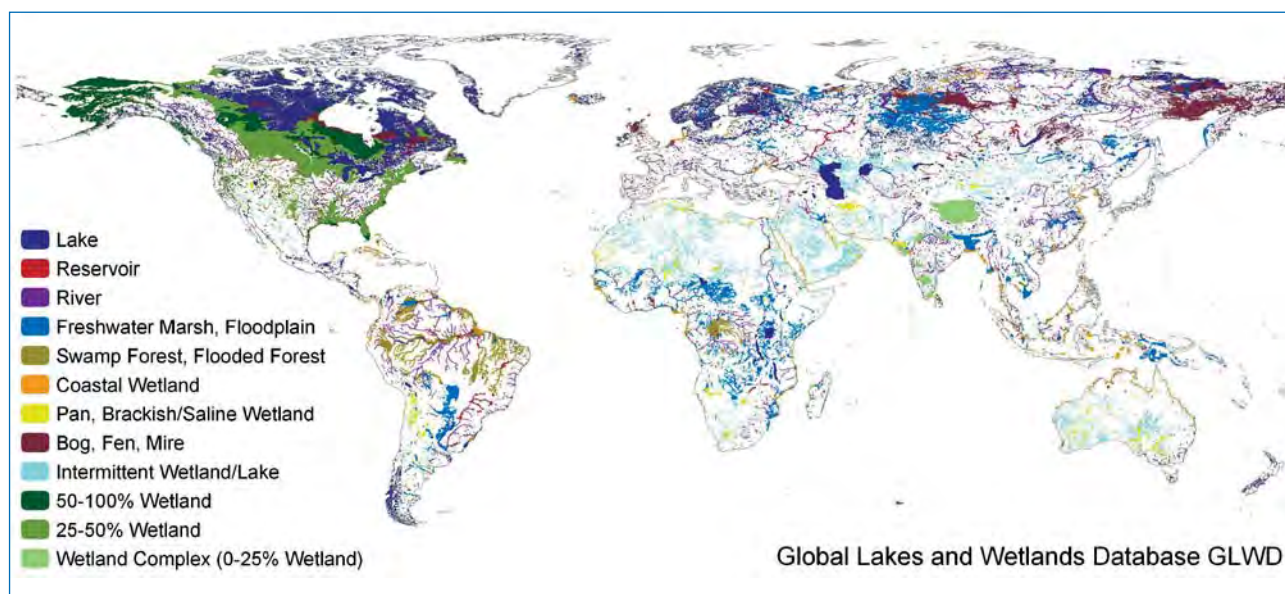

The importance of the datasets that have built up over many years will be well illustrated in this conference. I would also like to draw your attention to the launch of another product from this work, namely, the report of the Asian Wetland Census 1997-2001. This report complements others reporting results from the International Waterbird Census and the *Waterbird Population Estimates*, with the third edition of the latter being launched at the Ramsar Conference (CoP8) in Spain in November 2002, and again demonstrates our commitment to supporting waterbird conservation worldwide.

During this conference we have presentations covering activities across all major waterbird flyways. Through these we will cross the globe and we will enjoy it – it will be fun and exciting, and as we do this we will consider the ecology and future of our waterbirds and their wetland habitats from many important perspectives. Wetlands International sees formal flyway agreements as a powerful way of developing cooperation for the conservation of migratory birds. We strongly support the efforts of the Convention on Migratory Species and others involved in these formal agreements. We would like to see them extended wherever possible.

Asia-Pacific Migratory Waterbird Conservation Strategy.

I am also very aware of major issues that still need to be tackled if we are to conserve our waterbirds. The continued destruction of many important waterbird habitats is well known, as is the decline of many waterbird populations. We are broadly aware of the distribution of wetlands around the globe; however, the global wetland mapping and inventory resource is inadequate for many if not most purposes. The Ramsar Convention has been at the forefront of efforts to close these gaps, but there is a long way to go.

Global distribution of wetlands.

Percentage of Globally Threatened waterbirds, including seabirds, in different threat categories. Each waterbird family is allocated as either depending on only inland wetlands, depending on only coastal/marine systems, or depending on both inland and coastal/marine systems (Millennium Ecosystem Assessment & BirdLife International).

We are also aware that many waterbird populations are in decline with many threatened at a global level by a litany of problems that are all too familiar. We are also aware that our data resources and management both need improving if we are to stop and reverse recent trends. The issue of adequate data is one that recurs regularly. I would like to reinforce Wetlands International's

International Waterbird Census sites in Europe and northern Africa.

The Grado Strategy – the forerunner of MedWet.

support for a statement that I first heard at a wetland conference held in Italy in 1991. A now deceased British hydrologist, Dr Ted Hollis, was metaphorically pounding his fist and loudly seeking support for holistic and concerted action to “halt and reverse wetland loss and degradation” in the Mediterranean. He did not obtain universal support from the assembled scientists and managers who were stumbling over the concepts of halting and reversing loss and degradation – was it possible?

But times have changed and we recognise that we need to both halt further destruction and to restore or rehabilitate what has already been lost or degraded. To achieve this we need political commitment and support for meaningful outcomes. We need capacity in all parts of the world. We also need science, and we need *quality* science. I cannot emphasise enough the importance of that last point – the rigour of our data is paramount if we are to make our points and be believed and influence managers and policy-makers. Wetlands International is a science-based organisation and our much lauded global monitoring programs must provide the type of data that we require for effective management actions. For this to occur these monitoring programs must be scientifically rigorous and supported fully by the users.

On that closing note – a note that emphasises the importance of basing our work on sound science - I welcome you to this conference and implore you (if this is needed) to enjoy yourselves as you devote your time to this scientific forum. Thank you and welcome on behalf of Wetlands International.

## Address by John Markland, Chairman of Scottish Natural Heritage

Sunday 4 April 2004

Markland, J. 2006. Address to the Waterbirds around the world conference, 4 April 2004. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 27.

Ladies and gentlemen, welcome to Scotland, and to our capital city, Edinburgh. As the Chairman of Scottish Natural Heritage I am delighted to welcome all of you to Heriot-Watt University to participate in this vitally important, international conference.

Looking across this auditorium I am hugely impressed by the exceptional turnout – I gather we have more than 450 delegates from 90 countries throughout the world. You will be aware of the slogan ‘think globally and act locally’. Well, I think it’s fair to say that we will be working locally to act globally.

Behind the logos and fliers for this event there has been a huge amount of collaborative work. I congratulate the organising Committee, Government officials of the United Kingdom and the Netherlands, along with the Board and officials of Wetlands International, for working together so brilliantly to bring us here today. In fact, more than thirty organisations and countries have contributed to this event, and I note the leading contributions from the USA, Australia, Denmark and Japan and from global organisations such as the Ramsar Convention, Birdlife International, United Nations Environment Programme, Pacific Seabird Group, The Waterbird Society, and many, many others. We are so pleased to hold this event in Edinburgh, and so proud to be able to point to the splendid partnership approaches being developed in this work.

Effective partnerships are critical if we are to see global impacts from this conference. We have lost vast areas of wetland habitat, and many of our waterbird species now have critically endangered populations in different parts of the world. We are dealing with a unique biological issue, because what brings us here today are the flyways, the connections between where birds nest, rest, feed, stop-off when in transit to moult or over-winter. We get a sense of the vast range of problems facing these birds as they make their way north, south, east and west, some of them travelling immense distances across the globe. We have to find ways of building on the research work, the conservation and management techniques, and the partnership forged between individuals, bodies and countries, to ensure that the globe is a

John Markland. Photo: Dougie Barnett.

safer, better and healthier place for waterbirds, and for the people who love to watch them.

Finally, and on a domestic note, I hope you enjoy the field visits on Tuesday. You have a wonderful choice of locations, including the Clyde, Forth, and Solway Estuaries, Scotland’s first recently-established National Park, Loch Lomond & Trossachs, Loch Leven (to be even more local, this is where I live), the River Tay, Blair Atholl and even the Bass Rock. Each of these is a jewel in our nature conservation crown of wetland Scotland. Enjoy these areas and I do hope that you leave the conference with a special memory of your visit to Scotland.

Thank you very much.

## Address by Allan Wilson MSP, Deputy Minister for Environment and Rural Development, Scotland

Wednesday 7 April 2004

Wilson, A. 2006. Address to the Waterbirds around the world conference, 7 April 2004. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 28.

Your Royal Highness, Conference Chairman, Delegates, I must open my short address by expressing our gratitude and appreciation to His Royal Highness. Not only for being here today but for sharing with us his expectations as to what this Conference might deliver. In closing this Conference, I offer delegates my two challenges for them to take home, to all parts of the globe.

Everyone here today has been charged with the common duty to care for the natural world. We will do that, not for our benefit but for the generations who will follow us.

We leave here today with the Edinburgh Declaration and the clearest of messages that we all have a common responsibility to protect and conserve our waterbirds. To do that, we must be open with our technical knowledge and expertise. The sharing of knowledge is not an optional extra: information and expertise must be exchanged to help preserve the world's waterbirds.

Ninety countries are represented here today – what of the other countries elsewhere in the world who either couldn't be here or who may not have the resources to take forward the achievements of this Conference? Will you give them the support they need? That is a further challenge laid down by this Conference.

The first challenge I offer is one that only those here can achieve. I ask you to create the opportunity when you go home, and are speaking with your colleagues about your week in Scotland, to consider how YOU are going to make the Declaration work. The Edinburgh Declaration is an important step but at the end of the day, it is only a bit of paper or the text on the screen of a computer monitor. Your task is to turn the words of the Declaration into action.

Conservation is about engaging with others. And not just those who share your views on what nature conservation is and why it is important. Some outside this Conference may see your discussions this week as a threat to them. Don't ignore them. Engage them. Your Conference has focused on the links between people and nature, and has looked at issues such as over-crowding and development and how they can affect both man and species.

We cannot ignore the inter-relationship between man and the other species which inhabit the planet. We need to work with others, many of whom do not share our nature conservation objectives, if we are to ensure that biodiversity is maintained throughout the world. That is the second challenge I set before you and I recognise that it will not be easy to achieve. It is one which we in Scotland have to tackle and we still have much to do to demonstrate the benefits which nature conservation brings, in ecological and in economic terms. That effort must be made and I know that Scotland is not alone in facing that issue.

There has been some very positive press coverage of this Conference. The Scottish Executive too has a positive message to convey in relation to Scotland's contribution to conservation at a national, European and international level, not least through

Allan Wilson MSP. Photo: Dougie Barnett.

our achievements in the Nature Conservation (Scotland) Bill. This Bill is making good progress through our Scottish Parliament and I expect the measures will be law later this year.

The Bill introduces a wide range of initiatives which are good for the natural environment and for water birds. New protective measures for both species and protected habitats are core elements of the Bill. Above all, the Bill recognises the significance of conserving the biodiversity of our planet.

In drawing to a close, I'd like to repeat the pleasure I had to meet you all on Sunday and welcome you to Scotland. I know for many of you it was your first visit to the United Kingdom and I thank you for your contribution to the Conference.

Like the migratory birds you have come to Scotland to discuss, I hope that your flyway route home is safe and secure, and that the habitat to which you are returning is warm and welcoming!

The Conference is now over. Let its ideas, its creativity, its links continue. I wish you all the very best for the future and wish you a safe journey home.

Thank you.

## Waterbird conservation in a new millennium – where from and where to?

David A. Stroud<sup>1</sup>, Gerard C. Boere<sup>2</sup>, Colin A. Galbraith<sup>3</sup> & Des Thompson<sup>3</sup>

Stroud, D.A., Boere, G.C., Galbraith, C.A., Thompson, D.B.A. 2006. Waterbird conservation in a new millennium – where from and where to? *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 29-30.

The *Waterbirds around the world* conference held in Edinburgh in April 2004 was a major milestone for waterbird conservation. There has long been recognition of the need for international perspectives in the conservation of migratory birds, and especially waterbirds. Indeed, 90 years ago the USA and Great Britain, on behalf of Canada, formally agreed the first of the modern international conservation treaties related to migratory birds.

The development of the International Waterfowl Research Bureau (IWRB) in the years following the Second World War is outlined by Kuijken (this volume). On the European continent, IWRB has been highly effective in progressively stimulating a range of collaborative international actions for waterbird and wetland conservation. Major IWRB conferences – more fully described by Kuijken – were held at Noordwijk aan Zee, The Netherlands (1966), Leningrad, USSR (1968), Ramsar, Iran (1971), Astrakhan, USSR (1989), St. Petersburg Beach, Florida, USA (1992), Kushiro, Japan (1994), Strasbourg, France (1994), Kuala Lumpur, Malaysia (1995), and Dakar, Senegal (1998).

Participation in these meetings has grown steeply to the present, in terms of numbers of participants and countries represented, as well as in numbers of represented international organisations (Figs. 1 & 2). It is striking to see such an upsurge of interest since 1989.

In introducing these proceedings and noting that *Waterbirds around the world* was the first major international conference specifically concerning waterbirds of the twenty-first century, we first consider the historical context of international waterbird conferences, and then move on to look beyond the Edinburgh conference. Table 1 summarises the main themes of some of the previous international meetings and conferences on the conservation of waterbirds and their wetland habitats.

### DEVELOPMENT OF MAJOR THEMES IN WATERBIRD CONSERVATION

#### Mechanisms and means of international co-operation

The main themes of some of the previous international meetings and conferences on the conservation of waterbirds and their wetland habitats are summarised in Table 1. In North America there has been a very long history of international collaboration in the conservation of waterbirds at continental scales. This was established early through the 1916 Migratory Birds Treaty between the USA and the UK (on behalf of Canada), developed in 1936 through a further treaty between the USA and Mexico (more fully outlined by Schmidt, this volume). The signing of the North American Waterfowl Management Plan in 1985 gave a mechanism for collaboration between governments and a wide range of

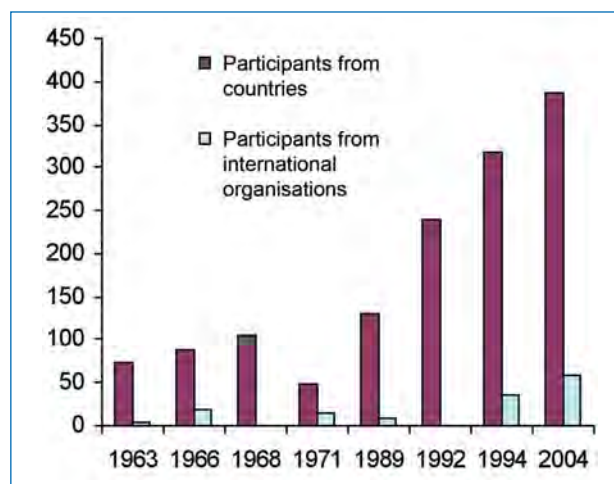

Fig. 1. Increasing numbers of participants at international conferences on waterbirds, 1963-2004.

Fig. 2. The increasing geographic and international institutional participation in international conferences on waterbirds, 1963-2004.

non-governmental stakeholders and has been particularly effective (Wheeler, this volume). In the 1990s, the Western Hemisphere Shorebird Reserve Network (WHSRN) gave an informal mechanism for site-twinning and thus the building of links between waterbird conservationists in North and South America (Hunter *et al.* 1991). More recently, two international conferences have developed the Western Hemisphere Migratory Species Initiative as a means of promoting international co-operation at continental scales (Schmidt, this volume, Ralph & Rich 2005).

**Fig. 3.** The seventy-eight participants at the First European Meeting on Wildfowl Conservation held in St. Andrews, Scotland, 1963. Photo: Colin Galbraith, from an original by the Nature Conservancy.

The establishment and progressive development of the International Wildfowl Research Bureau (IWRB) by Luc Hoffman and others in the years following the Second World War was a major step forward (see Kuijken, this volume). From the outset, IWRB provided an organisational means of promoting international collaboration and co-operation in wildfowl conservation and research. Its initial activities, however, were largely restricted to NW Europe and parts of North Africa, and largely focussed on understanding the size, distribution and trends of wildfowl populations. However, an important early aim was also to develop a good insight in harvest pressure on species, and the creation of an IWRB Hunting Rationalisation Research Group in 1969 pioneered international assessments of waterbird harvests (Lampio 1974, 1977). Whilst IWRB's initial activity was focussed on Anatidae, the scope of interest and activity progressively broadened to encompass waders (Lippens 1967, Prater 1974) and to other waterbird taxa.

IWRB, in close collaboration with the UK Nature Conservancy, provided the impetus for the convening of a First European Meeting on Wildfowl Conservation in St. Andrews, Scotland. This conference was held in October 1963 and attracted 73 participants from 17 countries (Fig. 3). Much discussion related to the need to create mechanisms of collaboration (Table 1), and one of the key conclusions was that "all delegations [were] unanimously of the opinion that such European meetings should be held at regular intervals in the future..."

A major topic for consideration in St. Andrews was the possibility of establishing an international legal treaty related to the conservation of the wetland habitat of wildfowl. As described in detail by Matthews (1993) and Kuijken (this volume), this was a major theme of the subsequent international conferences leading to the formal agreement of the Convention on Wetlands of International Importance, especially as waterfowl habitat at Ramsar, in Iran 1971 (Carp 1973). The ensuing Ramsar Convention has increasingly broadened its activities and remits from its original focus on wildfowl into a more holistic

international instrument concerned with all aspects of wetland conservation, especially in recent years, and now with issues of sustainable development through wetland conservation to the fore.

As the implementation and activities of the Ramsar Convention has developed, other international mechanisms for waterbird conservation and international co-operation have been established. The Convention on Migratory Species (CMS) was established in 1979, in turn leading to the formal agreement of the Agreement on the conservation of Africa-Eurasian migratory waterbirds in 1995 (Boere unpublished; see Lenten, this volume).

The development of formal multilateral treaties in Asia and Oceania have taken somewhat longer to achieve, although a range of formal bilateral agreements on the conservation of migratory waterbirds have been established, mainly between Japan, Russia, USA and Australia (Lane & Parish 1991). The Asia-Pacific Migratory Waterbird Conservation Strategy — more fully described by Mundkur (this volume) has been very influential since 1996 in building not only site-networks but also encouraging informal processes of collaboration research and conservation (Long & Watkins 2005a,b, Straw 1997, 2005). The development in recent decades of a comprehensive environmental protection regime in Antarctica through the 1991 Protocol on Environmental Protection to the Antarctic Treaty has been of huge global significance on constraining potential human impacts on this unspoilt 'continent of science'. Similarly, the adoption in 1982 of the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR) and its subsequent implementation has been a major step forward in moving, internationally, to regulate man's impact in the marine environment — not withstanding the greatly problematic illegal, unregulated and unreported fishing highlighted by HRH the Prince of Wales in his address to the conference (this volume). Most recently, the coming into force of the Agreement on the Conservation of Albatrosses and Petrels (ACAP) seeks, inter alia, to address the cause of impacts and threats to these species

**Fig. 4.** The publication of an international species action plan (inset) for Lesser White-fronted Goose *Anser erythropus* (Heredia *et al.* 1996) was an important stimulus for a range of conservation initiatives as reported by several authors elsewhere in this volume. An update of the action plan was discussed at an international conference in Lammi, Finland in April 2005. Photo: Ingar Jostein Øien.

on the international high seas – of crucial importance in reversing current negative population trends. The establishment and implementation of such international regulatory regimes for the environment are a major achievement for proponents of conservation and sustainable use, although they tend often to be overlooked by those whose outlooks are either terrestrial or more orientated to the northern hemisphere.

In the Americas, the Migratory Birds Act 1936 is restricted to Canada, USA and Mexico and does not formally include other Central or South American countries. Potentially the Western Hemisphere Convention could act as multilateral instrument; the recent adopted USA/Neotropical Migratory Bird Conservation Act provides a framework for support to migratory birds projects and programmes, including waterbirds, in the Neotropics, but is not a formal flyway conservation instrument; see also Boere & Rubec (2002) and Boere (2003) for a more detailed overview of relevant bilateral and multilateral instruments.

The Waterbirds around the world Conference in Edinburgh was an opportunity to compare and contrast the different institutional approaches being adopted around the world concerned with the processes of international collaboration for waterbird conservation. One of these, the development of national and international single species action plans for threatened waterbirds, has been an important means of cost-effectively directing conservation activity. Conservation action plans were first discussed at the St. Petersburg conference in 1992, and were an important element of discussions at the Anatidae 2000 Conference in Strasbourg in 1994. In the years since, they have become increasingly adopted as a central means of delivery of conservation actions (e.g. Heredia *et al.* 1996). Whilst early

discussions concentrated on format and structure of action plans, discussions in Edinburgh highlighted that many plans remain largely unimplemented. If action plans are to be effective, they must be adequately resourced, and be sufficiently ‘owned’ by the interested parties in order for them to be effectively implemented (see Flyway management for species of conservation concern, this volume).

Stroud *et al.* (2004, and this volume) in their review of the status of migratory waders in Africa and Western Eurasia, showed that that area has the greatest number of declining wader populations (12 of 22 populations - 55%). Effectively, this region

**Fig. 5.** Political changes in the early 1990s aided the undertaking of international research programmes in the Russian arctic. International expedition arriving at the island of Izvestia Tronoy, Taimyr, 1993 to assess numbers of Ivory Gulls *Pagophila eburnea*. Photo: Gerard Boere.

embraces the European Union (EU15), which also has the greatest extent of species-orientated international legislation specifically requiring countries to maintain a favourable conservation status of waders (and other birds). Both the European Union's Directive on the Conservation of Wild Birds (the so called EC Birds Directive) and the Council of Europe's Convention on the Conservation of European Wildlife and Natural Habitats (Bern Convention) have been in force since 1979 suggesting that additional delivery and implementation mechanisms are needed to address the fundamental drivers of population declines. Stroud *et al.* (this volume) stress that whilst national and international strategies and legal conservation instruments have scope to help, they need to be much more penetrating in their implementation so as to address root causes of population declines.

The major political changes in eastern Europe in the late 1980s and early 1990s led to unprecedented new opportunities for international co-operation, not least the organisation of major meetings which brought together waterbird researchers from western Europe with those from the former USSR. A notable example was the International Wader Study Group's conference in Odessa, Ukraine in April 1992, which involved 79 participants from 13 countries, and developed The Odessa Protocol on international co-operation on migratory flyway research and conservation (Hötter *et al.* 1998). The Odessa Proceedings contained a wealth of previously unpublished information on wader research and survey from central and eastern Europe, and Asia. The political changes also facilitated the development of joint research programmes in the Russian arctic, notably through a series of joint expeditions involving, variously, Russian, Dutch and German waterbird researchers (Fig. 5).

### Habitat protection

The need to promote the conservation of wetland habitats in the face of habitat loss and degradation has been a central theme for international conferences. Human impacts on wetlands were clearly the major motivation for initial conservation measure in North America (Schmidt, this volume), and especially the creation of the Ramsar Convention which drew from initial European evaluations in 1962 by Project MAR (Kuijken, this volume, Matthews 1993). Whilst initial conferences focussed on the need to stem habitat loss, more recent conferences (since the 1990s) have increasingly also focussed on the exchange of information regarding means of restoration and rehabilitation of degraded habitats, as well as the appropriate management of wetlands to enhance their carrying capacity (Table 1). The important topic of wetland restoration has increasingly been addressed through targeted meetings (e.g. Moller 1995 in Denmark) and a growing specialist literature has developed especially aimed at practitioners (e.g. Eiseltová 1994, RSPB, NRA & RSNC 1994, Hertzman & Larsson 1999).

Interestingly, as early as the 1968 Leningrad meeting, habitat and predator management as a means of increasing site-carrying capacity was under discussion. Although the impact of non-native species is now recognised as one of the principal causes of biodiversity loss world-wide (Millennium Ecosystem Assessment 2005a), previously there was discussion of the introduction of non-native waterbirds for hunting (most recently at the 1989 Astrakhan conference which heard of proposals to introduce

Canada Geese *Branta canadensis* to the USSR: Gabuzov 1990).

Workshops at Edinburgh considered the need for holistic approaches to conservation which need to include elements related both to site-based protection and wider countryside policies (Building effective ecological networks; and integrating waterbird conservation, populations, habitats and landscapes, this volume).

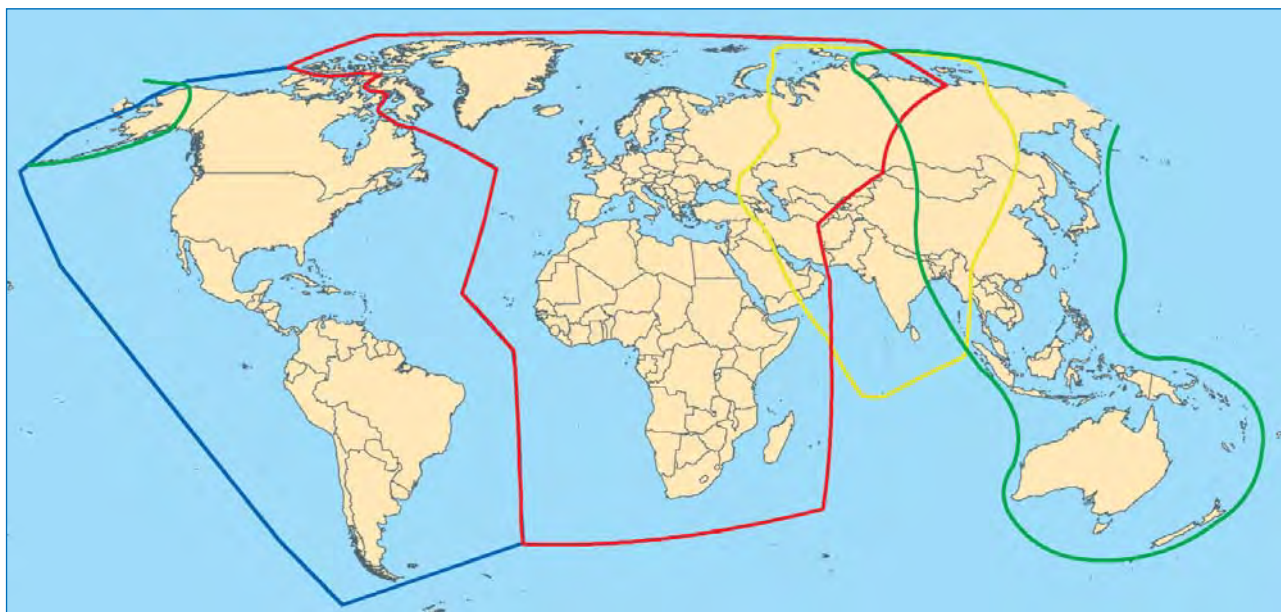

In spite of modern techniques to analyse habitat losses and the increasingly global coverage of the International Waterfowl Census and other monitoring schemes, it is still almost impossible to determine the consequences of some large scale habitat losses for waterbird populations. Indeed, habitat loss and fragmentation remains a major threat to many waterbird populations. A topical example is the lack of information concerning the fate of the immense waterbird populations formerly present in the Mesopotamian marshes of Iraq (Evans 1994). Although parts of the marshes are now being restored and 're-wetted', the understanding and monitoring of the accompanying ecological changes are limited. Such knowledge limitations typically are the consequence of political instability and/or lack of resources constraining an ability to undertake relevant surveys and monitoring.

### Developing issues

Edinburgh saw substantive discussions on a number of new issues. Climate change has emerged in the last decade as one of the central challenges for the long-term conservation, not only of waterbirds but for the world's biodiversity. It has the potential to further and markedly exacerbate the negative impacts of other current and principal drivers of ecosystem changes such habitat change, the impacts of invasive species, over-exploitation and pollution (Millennium Ecosystem Assessment 2005a, Finlayson *et al.*, this volume; The implications of climate change for waterbirds, this volume). Possible consequences of climate change for the implementation of multilateral treaties in relation to waterbirds are discussed by Boere & Taylor (2004).

Whilst the recent spread of Asian lineage Highly Pathogenic Avian Influenza H5N1 westwards across Eurasia occurred after the Edinburgh Conference, the holding of a workshop on avian disease issues in Edinburgh (Disease emergence and impacts in migratory waterbirds, this volume) underlined the importance of this issue which has not previously been considered as an integral part of any previous international conference on waterbird conservation. The need to better develop links between veterinarians and the ornithological research and conservation communities was emphasised.

Possibly the most significant element in the Edinburgh programme which contrasted with earlier conference programmes, was recognition of the increasing need to promote the 'mainstreaming' of waterbird conservation within other governmental policies. In other words, how to ensure full and effective integration of conservation objectives in the policies and programmes of others – and not just of the traditional conservation 'sector' itself. This was manifest through discussion of the importance of communication, education and public awareness (Let the waterbirds do the talking, this volume); reviews of conflict resolution and reduction (Conflict resolution, this volume); assessments of the opportunities that modification of wider land-use policies provide for the promotion of waterbird conservation (Integrating waterbird conservation, populations,

**Fig. 6.** The possible global scope of multilateral agreements for the conservation of migratory waterbirds.

habitats and landscapes, this volume); the need to build human capacity for conservation and research, especially in developing countries (Building and sustaining capacity for waterbird conservation and research, this volume); and finally discussion of a central issue, how to develop sustainable programmes of funding to support conservation initiatives (Financing global conservation: innovation, linkages, options, this volume).

At the beginning of the twenty-first century, and in a world which faces increasing acute pressures not only on ecosystems but also on human communities and societies across most of the less-developed world (Millennium Ecosystem Assessment 2005a,b,c), the cross-sectoral approach to ecosystem conservation and management is taking the centre stage of attention.

### Beyond Edinburgh...

The Conference conclusions were formalised as *The Edinburgh Declaration*. We highlight below several key issues for the future, stressed not only in the Declaration but also in many of the papers included in this volume:

- **Making more effective use of existing legal and policy instruments.** In many parts of the world a wide range of legal and policy instruments relevant to the conservation of waterbirds and their habitats exist, not least, being the Convention on Biological Diversity (CBD) to which 188 countries are currently Contracting Parties. Whilst CBD is essentially a framework Convention, the Ramsar and Bonn Conventions are more specific regarding waterbird and wetland conservation whilst also having global scope and relevance. Such international legislation, supported by national laws and policies already gives considerable opportunity for the promotion of waterbird conservation and the achievement of sustainable use. The immediate challenge is to ensure the effective *implementation* of the provisions of these existing treaties. In doing this the continued sharing of national experiences will continue to be important. However, the development of further multilateral flyway agreements similar in conceptual scope to AEWA could

provide global coverage of migratory flyways and focus for international waterbird conservation (Fig. 6).

- **Enhancing resourcing and human capacity.** There are few, if any, countries, where there is adequate capacity to address the multiple challenges posed by the current ever degrading environmental conditions. World leaders at the World Summit on Sustainable Development, Johannesburg, in 2002, established a target of “*a significant reduction in the current rate of loss of biological diversity*” by 2010, but noted that to achieve this target “*will require the provision of new and additional financial and technical resources to developing countries*”. This need remains as urgent as ever, and the Edinburgh workshops on ‘Financing global flyway conservation’, and ‘Building and sustaining capacity for waterbird conservation and research’ specifically addressed these issues (Castro, this volume).
- **Responding with urgency.** The planet is currently facing an extinction crisis. The conclusions of the Millennium Ecosystem Assessment (Millennium Ecosystem Assessment 2005a,b,c) have served as a wake-up call to the severity of the issues and the urgency of necessary responses at all levels. The Millennium Ecosystem Assessment found that “*The degradation and loss of wetlands is more rapid than that for other ecosystems. The status of freshwater dependent species (in both inland and coastal areas) is deteriorating faster than those of other ecosystems. Wetland-dependent biodiversity in many parts of the world is in continuing and accelerating decline.*” More detailed assessments that re-enforce this conclusion are reported in this volume (Declining waterbirds: problems, processes and sites, this volume). We need to promote early conservation actions: later may be *too* late — patients are typically easier (and certainly cheaper) to treat *before* they reach the Intensive Care Ward!
- **Demonstrating relevance of waterbird conservation in a pressured world.** Governments and others face many priorities in delivering Millennium Development Goals concerning food and water security, sanitation, and poverty

reduction. In a world with much extreme human poverty, those concerned for waterbirds will need increasingly to be prepared to justify the relevance of this activity. However, the role of healthy wetlands in providing ecosystem services to human populations across the world (Finlayson, this volume; Millennium Ecosystem Assessment 2005c) provides this rationale. *“Species-focused arguments are unlikely to have significant influence on decision-making on trade-offs between the maintenance of wetland ecosystems and sustain-*

- **Better engagement with the public and stakeholders.** Sustainable development on the one hand, and achieving conservation goals through the resolution of management-conflicts requires close engagement with multiple ‘stakeholders’ – those people whose lives are affected or influenced by decisions taken or policies adopted. The Conference heard of many examples of successful conflict resolution (Conflict resolution, this volume) as well as specifically considering linked communication, education

**Fig. 7.** Children celebrating waterbirds dance at the launch of World Migratory Birds Day at Laikipia, Kenya, 9 April 2006. Photo: David Stroud.

able development, and more potent arguments are likely to involve the importance of maintaining and enhancing ecosystem services so that they continue to support human livelihood. To achieve this requires the maintenance of wetland biodiversity and processes, which in turn will help maintain the ecosystems upon which waterbirds depend. Using waterbirds as flagship indicators of the health of wetland ecosystems can help to secure adequate trade-offs to ensure that these ecosystems can continue to deliver their services. However, more clearly articulating these arguments for continued research and monitoring of waterbirds for the benefit of decision-makers is much needed.” (Davidson & Stroud, this volume). Accordingly, waterbird conservationists will need to become more adept at justifying ‘traditional’ conservation of biodiversity in the context of human sustainable development. As an example, the role of sustainably managed waterbird populations in providing a valuable source of protein source for human populations in developing countries and elsewhere could be stressed (Kanstrup, this volume).

and public awareness issues (Let the waterbirds do the talking, this volume). These are crucial activities and need to be considered as essential element for any conservation programme to be successful. Initiatives such as the recently established World Migratory Birds Day, on 9 April 2006, provide opportunities to allow the threats faced by migratory waterbirds to be highlighted with a wide range of audiences, as well as giving opportunity to celebrate the cultural importance of waterbirds communication (Fig. 7).

- **Combating negative images of waterbirds.** A consequence of the spread of Asian lineage Highly Pathogenic Avian Influenza H5N1 across Eurasia since the Conference has been that increasingly, the media have portrayed waterbirds in a very negative context and there remains widespread public misunderstanding of the issue in many countries, including circulation of misinformation. Indeed, in the UK, visitor numbers to waterbird conservation centres have fallen in a significant and sustained manner. Such negative portrayal has the potential to undo decades of work by conservation communicators such as Sir Peter Scott and

others. Misinformation leading to unnecessary fear creates political pressure for ill-advised and disproportionate policies such as the culling of wild birds and the destruction of wetland habitats. There is an urgent need for conservation scientists and veterinary services to pro-actively work with media to enhance the accuracy of reporting on this issue. As recently stressed by the CMS, AEWa & UNEP International Seminar on avian influenza (2006), this should include the development of much more effective communication strategies to give policy makers, stakeholders and the general public more balanced information on real levels of risk and appropriate responses.

- **Focussing conservation actions where they are most effective.** This volume outlines the wide range of conservation 'tools' that are available in the twenty-first century. However, it is increasingly important that scarce and possibly diminishing resources for waterbird conservation are cost-effectively used to the greatest effect. The development of conservation action plans (Flyway management for species of conservation concern, this volume) provides a means of objectively determining priority actions. These should be informed by integrated population monitoring which identifies critical demographic processes or life-history stages driving population declines (Pienkowski & Galbraith 1993, Piersma, this volume, Blohm *et al.*, this volume).
- **Resourcing monitoring activity.** There is a long history of waterbird monitoring at national and international scales notably through the International Waterbird Census (IWC), yet resourcing for this essential activity remains *ad hoc* and grossly inadequate. Given that monitoring provides us with the most fundamental of information on the status of waterbirds and their trends, it is essential that there is adequate and sustained funding for such monitoring. AEWa (2005) has recently called for an international partnership to support international waterbird monitoring and this should be strongly supported. Compared to the budgets of 'Big Science' projects, the absolute amounts allocated to annually maintain the IWC are tiny – almost trivial. Yet, as stressed throughout this volume, waterbirds are powerful indicators of environmental quality, with birds often integrating environmental information at continental scales (Piersma & Lindström 2004, Piersma, this volume). Data and information derived from the IWC can provide a powerful indication of the status not just directly of waterbirds themselves, but also of many other aspects of wetland biodiversity.
- **Access to data and information for decision makers.** Many governments and others have undertaken risk assessments related to the spread of highly pathogenic avian influenza H5N1. Yet, the process of undertaking these highlighted how poorly organised much data and information on waterbirds is to rapidly inform government and other decision makers. This is no organisational criticism, but is another aspect of the inadequacy of long-term financing for much waterbird conservation. There is an urgent need to synthesize the huge volume of data which exist on individual bird movements into flyway atlases and other information products in order to inform decision makers (Migration and flyway atlases, this volume, Wernham *et al.* 2002, Veen *et al.* 2005). If we are to *really* underpin governmental decisions and policies, our data and information has to be readily and rapidly accessible.

## CONCLUSIONS

We conclude with three reflections on cross-cutting needs highlighted by *Waterbirds around the world*:

- First, we need a **clear understanding of the key issues which are currently affecting waterbird status and trends**. This means establishing and maintaining international monitoring and reporting processes so that we have regularly updated summaries of the status and trends of waterbirds: we need to know what is actually happening out there!
- Second, we need to **establish clear and strategic priorities for action**. There is much, indeed *too* much, to do, and we need to guide actions to where they will be most effective for the greatest good. A sharp focus on the real priorities is paramount.
- Finally, we need to **continue to work co-operatively**, across national borders, both formally and informally, to put in place solutions to the increasingly complex and challenging problems. Working together, we have a chance of tackling these issues; individually, we do not.

Yet we should not end on too pessimistic a note. The *Waterbirds around the world* conference was attended by His Royal Highness, The Prince of Wales and by three Government Ministers with environmental responsibilities. All have demonstrated their commitment to the conservation of wetlands and waterbirds through inspired and spirited presentations – we earnestly hope that such statements will inspire others to act.

Boere, G.C. & Stroud, D.A. 2006. The flyway concept: what it is and what it isn't. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 40-47.

### INTRODUCTION

Bird migration has always fascinated man although it is only recently that details of international migratory routes have become known. Whilst modern technology such as satellite tracking has given, for some species, huge insights into the details of migration and stopover places used, this has built on a broad body of knowledge derived from over 100 years of bird-ringing using inscribed metal rings and individual colour-marks (Davidson *et al.* 1999) – largely the result of volunteer efforts.

Reviewing this body of information highlights the complexities of migration (Alerstam 1990, Owen 1996, Bairlein *et al.* 2002, Rees *et al.* 2005). Migration routes and schedules can vary by species (and by population within species – Fig. 2) and the extent of any migratory route can vary, both by the total length of flight-path, and the number and duration of stops along the flight-path (Fig. 1). It can also vary according to the age and/or sex of the bird, by season, and with weather (*e.g.* unfavourable headwinds can increase number of stops used). Further, there can be considerable variation between individuals in the same population, reflecting the fact that such variation in migration schedules (timing of migration or routes taken) is adaptive and central to differential evolutionary fitness (Ens *et al.* 1994).

Such individual variation relates to trade-offs between the eco-physiological costs and benefits of arriving earlier or later at different locations along a migratory route (Piersma 1994). A migration strategy that is successful in a season, say, when the arctic summer comes early may be less successful in a year when the arctic thaw on breeding areas comes later. Any population will contain individuals migrating at different times and possibly using different routes, which may in any case vary between years according to a range of environmental conditions such as wind-speed and direction. Indeed, studies of the timing of passerine migration in relation to changing climate provide indications that this variation helps change migratory behaviour at the scale of populations.

**Fig. 1.** Different types of migratory strategy shown by waders moving from coastal west Africa to sub-arctic breeding grounds: (from left to right) by Turnstone *Arenaria interpres* ('hop'), Dunlin *Calidris alpina* and Redshank *Tringa totanus* ('skip'); and Red Knot *Calidris canutus* and Bar-tailed Godwit *Limosa lapponica* ('jump'). Source: Piersma 1987.

Yet despite all this complexity, many waterbird species are highly faithful to the sites they use throughout their annual cycle (both within and between years). Such site fidelity can be explained as a result of various selective pressures that favour individuals which have an intimate knowledge of their environment. Its consequence is that certain locations not only hold large concentrations of waterbirds year after year, but that these sites are repeatedly visited by the same birds. Further, despite variation, migration to breeding areas is often highly synchronised, especially in those species which breed in the high arctic, where the short breeding season makes time a critical commodity.

In terms of the practicalities of implementing conservation policies for migratory species there has been a clear need to simplify the real-world complexities of migration so as to assist consistent international cooperation between governments and non-governmental organisations. This has been successfully achieved through the flyway concept, defined broadly as the biological systems of migration paths that directly link sites and ecosystems in different countries and continents.

This short review provides some background to the flyway concept and the various ways this has been developed over time and has been applied in various parts of the world and for different groups of waterbirds.

### DEFINITION OF A FLYWAY

The *Waterbirds around the world* conference, in many of its sessions, reviewed waterbird migration at many levels of detail: from the long migration routes of many waders to the relative short distance movements of, for example, intra-African migrants such as flamingos (this volume). In almost all cases the word "flyway" has been used to indicate the geographical region along which the species has moved.

In line with the above, a general definition of a flyway, applicable not only for waterbirds, could be:

"A flyway is the entire range of a migratory bird species (or groups of related species or distinct populations of a single species) through which it moves on an annual basis from the breeding grounds to non-breeding areas, including intermediate resting and feeding places as well as the area within which the birds migrate."

We emphasize that we prefer the term 'non-breeding areas'. The term "wintering areas" is clearly confusing in the case of cross-equatorial migrants as well as being unsuitable for regions where regular migration is the result of unpredictable events such as rainfall in parts of Africa and Australia. Moreover in such cases the movements often do not follow the same route but can be very different from year to year pending the weather conditions.

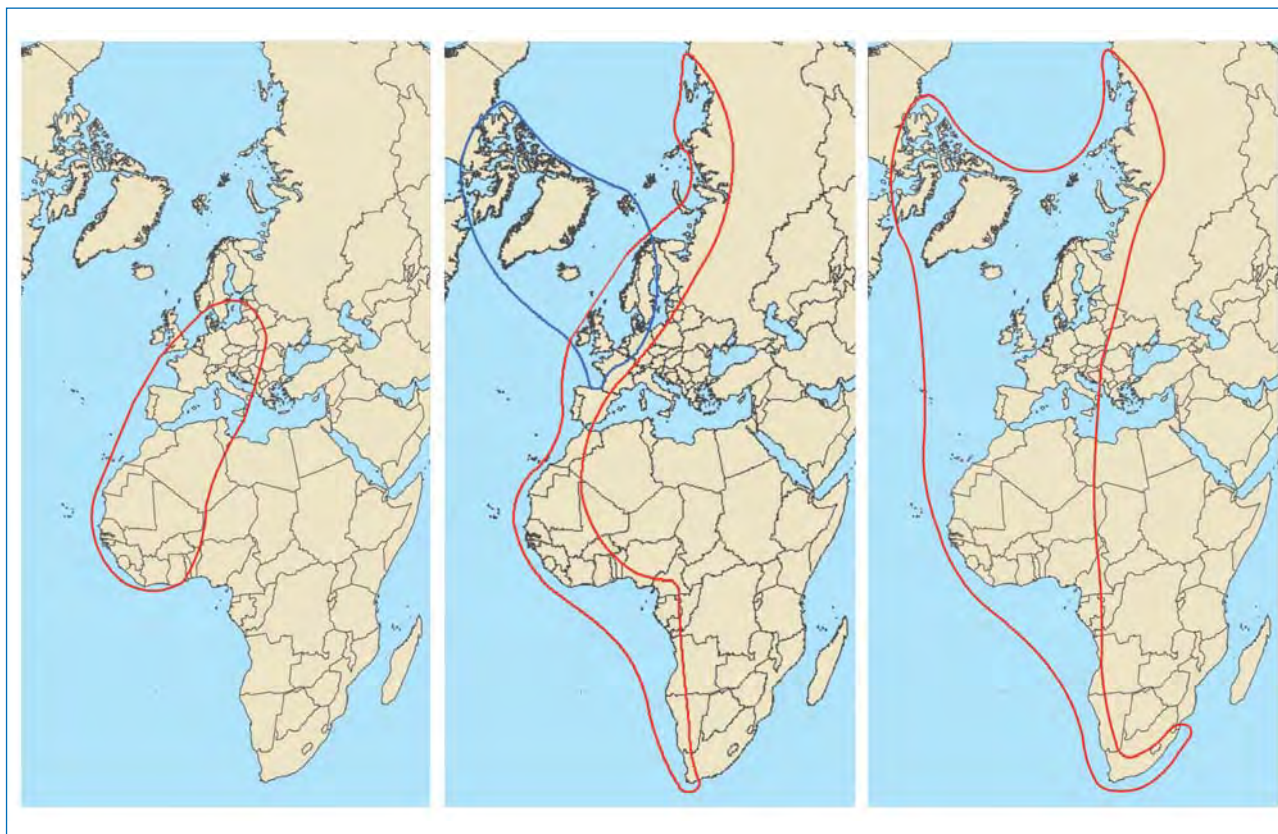

Flyways can be considered at different scales:

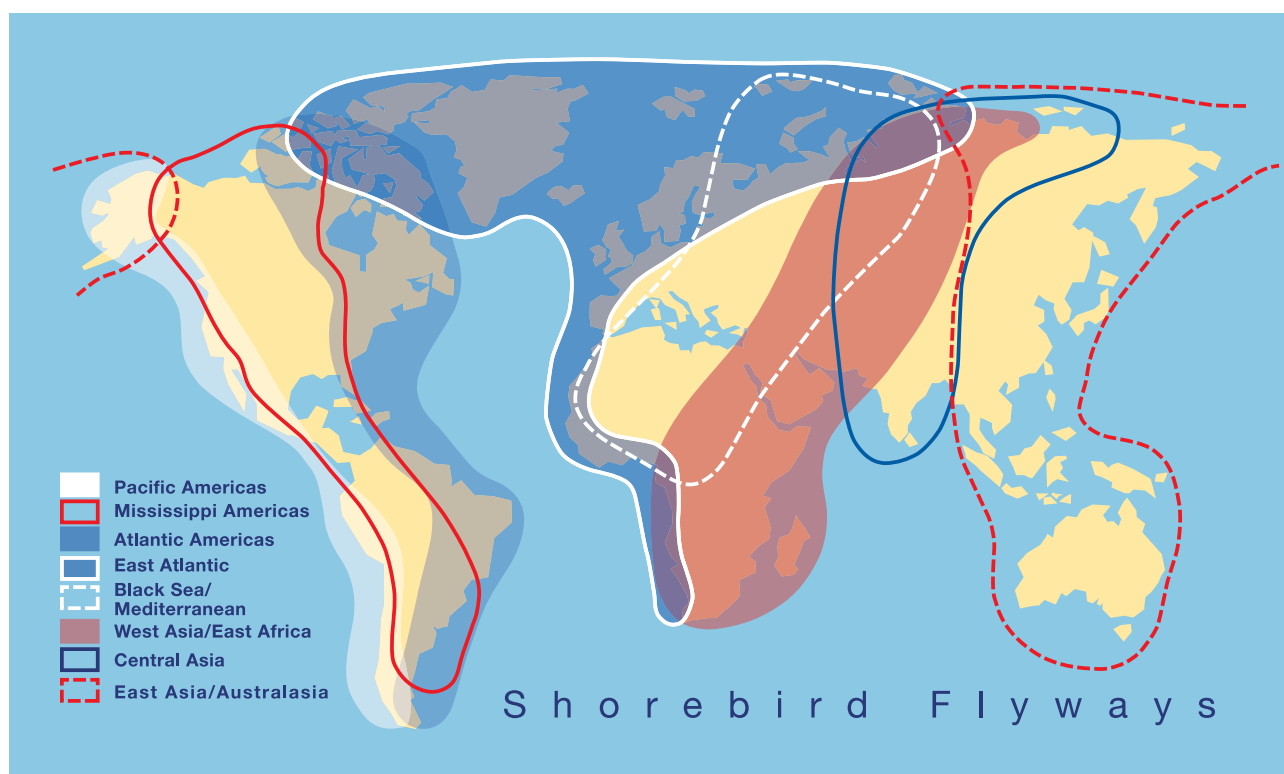

**Fig. 2.** The migration systems of three populations of Brent Goose *Branta bernicla* occurring in Europe. Source: after Scott & Rose 1996.

- **Single species migration systems.** The distributional extent of the annual migration of a species, or population within a species, encompassing breeding staging and non-breeding areas. Examples are given in Figs. 2 and 3. Whilst often described as the flyways of the species concerned, such annual distributional ranges are better described as the migration system of the species concerned.
- **Multi-species flyway** are defined by the Ramsar Convention (1999) as follows: “A single flyway is composed of many overlapping migration systems of individual waterbird populations and species, each of which has different habitat preferences and migration strategies. From knowledge of these various migration systems it is possible to group the migration routes used by waterbirds into broad flyways, each of which is used by many species, often in a similar way, during their annual migrations. Recent research into the migrations of many wader or shorebird species, for example, indicates that the migrations of waders can broadly be grouped into eight flyways: the East Atlantic Flyway, the Mediterranean/Black Sea Flyway, the West Asia/Africa flyway, the Central Asia/Indian sub-continent Flyway, the East Asia/Australasia Flyway, and three flyways in the Americas and the Neotropics” - (Fig. 4).
- **Global regions for waterbird conservation management.** At a larger scale still are global regions containing species with similar migration systems that are the subject (actual or potential) of shared international conservation activity – what Hagemeijer (this volume) describes as ‘political flyways’. Thus, the Agreement area for the African-Eurasian Agreement on the conservation of migratory water-

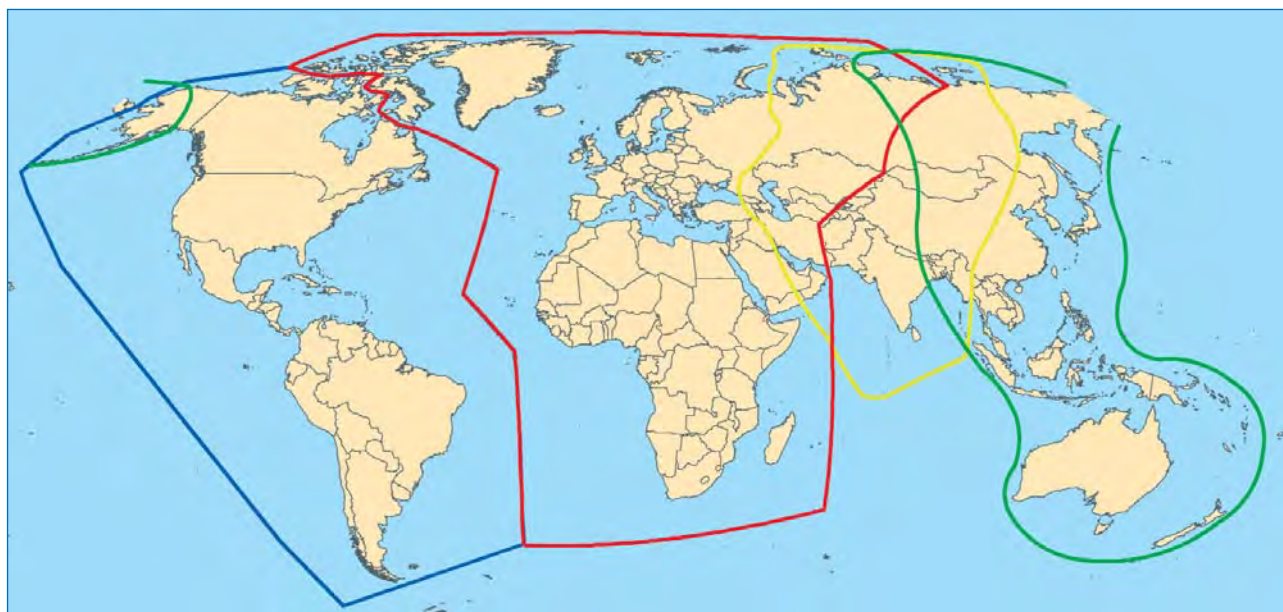

**Fig. 3.** Examples of three different species’ migration systems within the East Atlantic Flyway for waders, showing broad migration routes from northern breeding areas to over-wintering sites in Europe and Africa. Left to right, Kentish Plover *Charadrius alexandrinus*, Red Knot *Calidris canutus* and Sanderling *Calidris alba*. Source: after Smit & Piersma 1998.

**Fig. 4.** The eight broad flyways of waders/shorebirds. Source: International Wader Study Group. A more detailed evaluation by Brown *et al.* 2001 distinguishes five shorebird flyways in North America: Pacific-Asiatic, Intermountain West, Central, Mississippi, and Atlantic.

**Fig. 5.** Regions of the world subject to either actual or potential multilateral agreements for the conservation of migratory waterbirds.

birds (AEWA, Fig. 5) is the area that contains the migration systems of all migratory waterbirds that occur in Africa and western Eurasia. A similar approach has been applied to the main flyway systems of the Asia-Pacific region (Fig. 5). It contains multiple flyways of different waterbird taxa, and its value is in terms of the political and governmental processes of international co-operation (e.g. Biber-Klemm 1991). Accordingly, it has rather little descriptive value related to the exact movements of any bird.

#### THE HISTORY OF THE FLYWAY CONCEPT

Previous descriptive terminology related to bird migrations have used terms such as 'Route of Migration' in the context of describing bird movements following post glacial range expansions (Dixon 1895). However, the flyway concept has become widely used in the twentieth century because it helps to understand the problems a migratory waterbird encounters throughout its life cycle and identifies those countries that should co-operate to protect and sustainably manage populations.

**Fig. 6.** North American flyways used for the management of migratory waterbirds – especially as related to the regulation of hunting.

The basic multi-species flyway concept was developed in North America in the 1930–40s to provide a spatial management framework for waterbirds (Lincoln 1950, Hochbaum 1955). The system of four flyways, each with its own Council and Technical Committee, was established between 1947–1952 to provide a framework for co-operative management of waterfowl between the federal government, states, provinces and non-governmental organisations (US Department of the Interior 1959, Hawkins *et al.* 1984, Linduska 1964, Nelson & Bartonek 1990, Fig. 6).

Although in Eurasia and northern Africa, a sustained programme of international co-operation for waterbird conservation commenced in post-war years (Kuijken this volume, Stroud *et al.* this volume), coherent planning for the conservation of migratory waterbirds at a flyway level started in the 1960s (Boere 2006). In the Asia-Pacific region, it effectively commenced in the mid-1990s (Wells & Mundkur 1996).

The first flyway maps for waterbirds for western Eurasia were published by the International Waterfowl Research Bureau (IWRB; now Wetlands International) and Prof. Isakov of the USSR Academy of Sciences (Isakov 1970). These maps of the main ‘geographical’ populations of Anatidae in the western part of the former USSR and Europe were published against the background of ongoing discussions in the 1960s about an international legal instrument for the conservation of wetlands and migratory waterfowl, which later turned into the Ramsar Convention. Isakov (1967) recognised four major flyways for Anatidae in western Eurasia (Fig. 7). IWRB further developed

**Fig. 7.** Isakov’s (1967) main geographical populations of Anatidae in western Eurasia. Flyway coding: 1. Northern White Sea/North Sea population; 2. European/Siberia/Black Sea-Mediterranean population; 3. West Siberian/Caspian/Nile population; and 4. Siberian-Kazakhstan/Pakistan-India population.

the concept, organising a specific symposium in 1976 on the mapping of waterfowl distributions and habitats (Matthews & Isakov 1981).

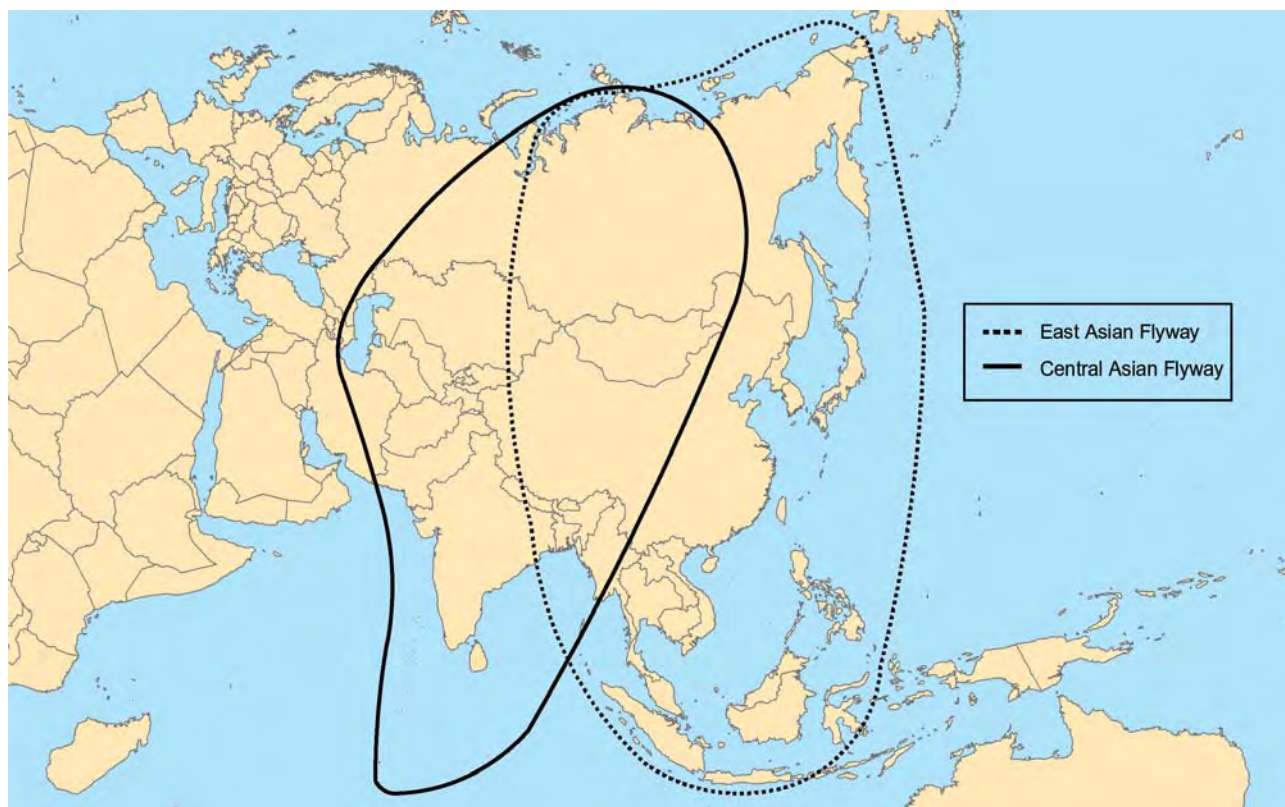

With the advent of legally binding multilateral treaties such as the Bonn Convention on Migratory Species in 1979 and the African Eurasian Migratory Waterbird Agreement in 1999, as well as the more informal Asia-Pacific Migratory Bird Conservation Strategy in 1996, the concept has proved valuable in focusing attention on strategic needs for waterbirds migrating within defined geographical regions. Similarly, the concept has underpinned the rationale for many bilateral treaties (for example Memoranda of Cooperation) between governments focusing on the conservation of shared migratory species (see Boere & Rubec 2002 and Boere 2003 for more details).

Different groups of waterbirds show broadly similar migration systems, although the extent to which these have all been described – or attempted to be consolidated into broader, multi-

**Table 1.** Main published sources of information on the flyways of different taxa of waterbirds.

Waterbird taxa	Americas	Europe, Africa and western Eurasia	East Asia - Pacific

**Fig 8.** Generalised flyways of Anatidae in eastern Eurasia. Source: after Miyabayashi & Mundkur 1999.

species flyways – is quite varied. Table 1 summarizes main information sources related to different flyway systems.

Flyways illustrated on different map projections can appear quite different, and the use of different projections can in themselves give useful messages – thus a polar projection highlights the fact that all the world's flyways converge in the arctic.

#### LIMITATIONS TO THE FLYWAY CONCEPT

The complexity of the migration strategies and systems of individual waterbird species was noted above. Attempts to simplify will, necessarily, lose information. For example, whilst in Eurasia (although less so in the Americas), most waterbirds migrate in more or less north-south directions there is an impor-

**Fig. 9.** Ringing recoveries of Pochard *Aythya ferina* showing predominantly east-west movements across Eurasia. Source: Wernham *et al.* 2002.

**Fig. 10.** Recoveries of Lapwings *Vanellus vanellus* ringed or recovered in Central Siberia; showing a strong east-west migration pattern. Red symbols refer to birds ringed in Central Siberia. Source: Veen *et al.* 2005.

tant component of east-west migration (see for instance Fig. 9 & 10, (Veen *et al.* 2005 and recovery maps in Fransson & Pettersson 2001, Bakken *et al.* 2003 and Wernham *et al.* 2002). Such elements are not well captured in traditional flyway models.

Further, maps of generalised flyway systems conceal the considerable between-species variation in individual migration systems. Thus Fig. 3 highlights three quite different migration systems for different wader species which all use the East Atlantic Flyway.

Such limitations should not detract from the application of the concept, although they give the scope for considerable confusion, much of which has been apparent in the use of inappropriate flyway maps by the media and others in attempts to describe and predict the possible spread of highly pathogenic avian influenza by migratory waterbirds across Eurasia in late 2005. Thus the global map of wader flyways (Fig. 4) has been widely reproduced as variously relating to all waterbirds, and even more erroneously, as describing the movements of *all* migratory birds (e.g. FAO 2005, Normile 2006, Olsen *et al.* 2006). Such confusion is unhelpful, especially in contexts where potentially important policy formulation can be influenced by such misinformation, although the limitations of the concept are recognised in the EU (Pfeiffer *et al.* 2006).

Thus there needs to be caution in applying the flyway concept to other migratory birds, given that ringing recoveries of passerines indicate widespread broad front migration across continental land-masses (e.g. Wernham *et al.* 2002, Zink 1973, 1975, 1981 & 1985).

## FUTURE DEVELOPMENTS TO THE CONCEPT

The flyway concept directly and valuably supports the 'ecosystem approach' promoted under the Convention on Biological Diversity (CBD) as a framework to help integrate conservation activities and policies.

CBD describes the ecosystem approach as: "...based on the application of appropriate scientific methodologies focused on levels of biological organization, which encompass the essential structure, processes, functions and interactions among organisms and their environment. ... This focus on structure, processes, functions and interactions is consistent with the definition of "ecosystem" provided in Article 2 of the Convention on Biological Diversity: "Ecosystem" means a dynamic complex of plant, animal and micro-organism communities and their non-living environment interacting as a functional unit." This definition does not specify any particular spatial unit or scale, in contrast to the Convention definition of "habitat". Thus, the term "ecosystem" does not, necessarily, correspond to the terms "biome" or "ecological zone", but can refer to any functioning unit at any scale. Indeed, the scale of analysis and action should be determined by the problem being addressed. It could, for example, be a grain of soil, a pond, a forest, a biome or the entire biosphere." (CBD Decision V/6).

A flyway is in fact the totality of the ecological systems that are necessary to enable a migratory waterbird to survive and fulfil its annual cycle. In this sense such bird movements link sites and ecosystem into a single functional unit, the loss of any part of which (for example, a staging area) may jeopardise the long-term viability of the species. Whilst some do not consider

that flyways should be seen as ecosystems as defined by CBD (van der Zon pers. communication), we note that the concept has been used within the context of recent decisions of the Global Environment Facility, notably its support for African/Eurasian Migratory Waterbird Flyways project. Further, CBD Decision V/6 (above) explicitly notes the potential inclusion of wide-scale approaches such as are provided by international waterbird flyways.

## ACKNOWLEDGEMENTS

We are very grateful to Greg Conway and the British Trust for Ornithology for the preparation of the flyway maps presented here.

## 2.0 Plenary presentations. Introduction

David A. Stroud

Joint Nature Conservation Committee, Monkstone House, City Road, Peterborough, PE1 1JY, UK. (email: David.Stroud@jncc.gov.uk)

Stroud, D.A. 2006. Plenary presentations. Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 50-51.

Throughout the world, much monitoring and surveillance of waterbirds is undertaken by amateur birdwatchers, with financial support of co-ordination provided by governments or state institutions. This has proved to be an extremely cost-effective model. The maintenance of such annual monitoring programmes is of critical importance to give conservation managers the data and information they need to respond to a rapidly changing world. Photo: Meinte Engelmoer.

The plenary presentations gave time to review the major themes that would be touched on throughout the conference programme. The topics covered in the plenaries were all subject to further discussion in the programme of parallel workshops. These gave the opportunity to further discussion of the issues involved.

One strand of the conference programme related to geographical regions and was structured around the world's main waterbird flyway systems. The presentations by Schmidt (2.2, Americas), Davidson & Stroud (2.3, Africa and western Eurasia) and Mundkur (2.5, East Asia and Australasia) provided contrasting reviews of knowledge and conservation activity of these flyways. Of particular note was the contrasting periods during which formal (and informal) international conservation structures have been in place in different parts of the world in order to support and encourage waterbird conservation (a theme further elaborated upon by Kuijken - 2.1). Thus, whilst the 1916 Convention for the Protection of Migratory Birds provided the early and initial stimulus for international co-oper-

ation between the two countries of Canada and USA, structures for international co-operation have only more recently been established in other parts of the world, most recently in the Neotropics through the informal Western Hemisphere Migratory Species Initiative. Whilst formal multilateral inter-governmental conservation treaties have still to be established in some regions, Schmidt and Mundkur both outlined the bilateral treaties involving USA, Russia, Japan and Australia in the East Asia-Australasian flyway. The development of the Agreement on the conservation of migratory African-Eurasian Waterbirds (AEWA) potentially includes 117 countries, and is the most ambitious multilateral treaty related to waterbirds yet to be developed (Lenten, 3.7.1).

Finlayson and colleagues (2.6) gave a stark assessment of the range and complexity of the potential impacts of changing climate on waterbirds and their wetland habitats. Evidence for these impacts is increasingly becoming apparent. Many such effects are predicted first to impact upon arctic environments,

and Wohl (2.10) summarised the global significance of this region as the ultimate source of most waterbird flyways, outlining also several recent initiatives to develop pan-arctic environmental co-operation.

The conservation of seabirds, especially whilst they are on the high seas, is an issue of major recent conservation concern. Indeed, nearly all the world's albatross species are now listed as globally threatened. Cooper (2.9) outlined the main approaches being undertaken to address these problems so as to reverse current negative trends.

The impact of fisheries on albatrosses is an example of bycatch or an unintentional harvest. Kanstrup (2.7) reviewed the other deliberate harvests of waterbirds and the basis through which some of these might be made more sustainable.

The critical role of science in understanding and deriving solutions for conservation issues was outlined by Piersma (2.4), and Lank & Nebel (2.8). They stressed the need for evidence-based approaches to the development and implementation of conservation policy.

Considering the wide range of material presented by the plenary speakers, it is clear that recent decades have given waterbird conservationists a wide range of tools with which to address

issues and problems. These range from formal inter-governmental treaties, to practical conservation responses such as species action plans (section 4.1), management planning processes to maintain the ecological character of protected areas, as well as wider-scale catchment/water-basin management planning, Integrated Coastal Zone Management and other land-use policies (5.4).

Despite the existence of these tools (notably the wide range of guidances and handbooks developed and published by international conventions such as Ramsar, AEWA and the Convention on Biological Diversity, waterbirds populations and the ecological quality of the wetlands on which they depend continue to decline markedly throughout most of the world. This is a reflection of the massive, unsustainable environmental impacts generated by increasing human populations and their economic demands.

Important though current responses are, the stark findings of the Millennium Ecosystem Assessment in 2005 stress the urgent need for conservation responses to be urgently pro-active in engaging with the primary drivers of environmental degradation. This will take committed waterbird conservationists into increasingly unfamiliar territories.

Seasonal wetlands, such as the floodplain of East Alligator River, Kakadu, Australia are important habitats for many waterbirds. Photo: Nick Davidson.

## A short history of waterbird conservation

Eckhart Kuijken

Kuijken, E. 2006. A short history of waterbird conservation. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 52-59.

### ABSTRACT

For over a century, pioneering naturalists have determined the way in which waterbird conservation has evolved around the world and have been instrumental in the establishment of international organizations such as IUCN. Following declines in North American waterfowl in the 1930s, ICBP launched an International Wildfowl Inquiry and created IWRB, later to become a founding organization of Wetlands International. The inspiring MAR Conference, organized by IUCN, ICBP and IWRB in 1962, was a turning point in the development of conservation strategies. A series of “waterfowl conferences” followed during the 1960s and culminated in the adoption of the Convention on the Conservation of Wetlands of International Importance especially as Waterfowl Habitat in Ramsar, Iran, in 1971. This Convention launched the concept of “wise use”. At the United Nations Conference on Environment and Development in Rio de Janeiro in 1992, this concept was translated as “sustainable use”. The Convention on Biological Diversity (CBD) was adopted during this world summit and gave wide recognition to the intrinsic value of biodiversity. The recent “Countdown 2010” initiative gives a strong signal to intensify efforts if the CBD conservation goals are to be achieved. Monitoring is a fundamental conservation tool and has remained a central focus of IWRB and subsequently Wetlands International since the 1960s. The International Waterbird Census represents one of the most valuable global data sets. International conservation strategies based on waterbirds as bio-indicators are being developed (e.g. AEWA), but global threats such as climate change are ever-increasing. We should therefore strive to improve land-use policies, increase public awareness and achieve common acceptance of the principles of conservation. Based on an understanding of ecological, economic and social mechanisms including culture, we must now communicate with decision makers and local people about the essentials of “wise use”.

### INTRODUCTION

This presentation on the history of waterbird conservation is not a thorough analysis of all existing information, but rather a brief review of some of the relevant initiatives that have served as “stepping stones” in the past. It reflects a mainly personal approach, and has been prepared from a biased point of view, as my own experience is mostly limited to activities in the field of goose research in the Western Palearctic region, inspired to a large extent by the papers of Hugh Boyd at Slimbridge in the early 1950s (e.g. Boyd 1959). Initially based on ornithology, my conservation actions and expertise were subsequently developed within a broader ecological landscape dimension. Active participation at a number of conferences enabled me to have discussions with many of the early pioneers and to witness the changes in views and methods, priorities and actions of research and

**Fig. 1.** “Waterfowl shall come to you in their thousands” (from a tomb at Thebes, XVIII Dynasty, about BC 1580-1350; now in the British Museum).

conservation. The many meetings also offered me an opportunity to visit some famous wetland habitats in the hosting countries. Finally, my position for the past two decades has trained me to function mainly as an interface between science and policy planning, while at the same time stimulating my growing awareness from local to international level.

The history of waterbird conservation has always been strongly linked with catching and hunting for food or sport, as already illustrated in early Egyptian periods with drawings of wildfowl netting, paintings of goose catching, and many written sources, some of which mention that “Waterfowl shall come to you in their thousands” (Fig. 1). This could be our *leitmotiv* of today, when we consider the Red-breasted Geese *Branta ruficollis* in ancient Egypt and the most recent meeting of Wetlands International’s Goose Specialist Group in Odessa in March 2004, which admired the same species along the Black Sea coast.

Throughout history, philosophers, scientists and artists have paid attention to nature, often as a background rather than a subject on its own. Colonialism, following the famous travels of Baerents, Cook, Columbus, Marco Polo and many others, began the exploration – and later exploitation – of the fast shrinking wildernesses, and caused growing interest in exotic species as collectable items or objects for study (from botanical gardens and zoos to Darwin’s theory). Natural history books with highly valuable illustrations (Dodonaeus, Buffon and so many others) were well known sources for an increasing scientific approach for half a millennium.

Since the Romanticism at the end of the eighteenth century (J.J. Rousseau: “retour à la nature”), the first concern for nature arose with the industrial revolution, and gradually some real conservation thinking was developed from the mid-1800s

<sup>1</sup> Renamed the Research Institute for Nature and Forest in 2006.

onwards (e.g. the creation of the first National Park at Yellowstone in 1872). This was still a rather elitist movement based on mainly sentimental and aesthetic feelings towards specific plants and animals or scenic landscapes, often combined with hunting activities. When Lenin awarded the status of National Park to the Volga Delta in the early 1900s, this was still an exceptional event, but this prophetic action revealed the Soviet interest in conserving nature.

### FIRST INTERNATIONAL ACTIONS AND ORGANIZATIONS

Stimulated by such isolated initiatives, international dimensions and joint actions for nature protection became organized from the beginning of the last century, with institutions such as the International Council for Bird Preservation (ICBP), International Union for the Conservation of Nature (IUCN), International Wildfowl Research Bureau (IWRB), World Wildlife Fund (WWF) and others eventually taking the lead. The spiritual and social values of conservation were also gradually recognized and received broader public support, especially after World War II.

Ornithological interests have frequently stimulated the first nature protection initiatives, and in this context waterbirds often received special attention. This was a result of the growing concern amongst both wildfowlers and naturalists about the rapid decline in waterfowl populations in the first decades of the twentieth century. Restrictions on hunting seasons, the commercial harvesting of eggs and the use of duck decoys became the subject of much debate. In the USA, the severe drought in the 1930s combined with land reclamation caused a sharp decline in waterfowl populations, and various actions were taken (Linduska 1964, Hawkins *et al.* 1984). This cry of alarm reached Europe, and the Royal Society for the Protection of Birds (RSPB) in the UK and similar bodies in several other countries obtained increasing support to press for the adoption of legal instruments preventing excessive harvesting of waterfowl (Lowe 1941). As in the USA, this was a joint effort of ornithologists and traditional wildfowlers, both with an interest in abundant duck and goose populations and in protecting suitable habitat for breeding and wintering birds.

Gradually, the basic concerns of conservation became separated from hunting considerations. Illustrative of this are the consecutive changes in name and aims of the former IWRB reflecting the newly developing aspirations, needs and opportunities (see Box 1). Concepts and terminology changed from “protection” to “conservation”. The International Union for the Conservation of Nature (founded in 1946) was first called the

International Union for the Protection of Nature (IUPN); nowadays it is known as the World Conservation Union, although it has retained the acronym IUCN. The word “wildfowl” became “waterfowl” in the 1980s, and has more recently been replaced by “waterbirds”; in addition, the term “wetlands” appeared in the name of some organizations. These changes were inspired by an increasing ecological awareness that an integrated and scientifically based approach was needed, not only to accommodate hunting interests (“wildfowl” is very much the language of sportsmen), but also to maintain viable populations of endangered species and their often threatened habitats.

In a similar way, the Severn Wildfowl Trust, established in the UK by Sir Peter Scott in 1946, was later (1989) renamed the Wildfowl and Wetlands Trust (WWT). In Belgium, Les Réserves Ornithologiques de Belgique (co-founder Count Léon Lippens, 1951) became Les Réserves Naturelles et Ornithologiques de Belgique and later simply Réserves Naturelles. WWF also changed its name from World Wildlife Fund to Worldwide Fund for Nature, indicating a broader range of interests.

### VISIONARY PIONEERS

The names of some of the pioneers in waterbird conservation have already been mentioned; many more should be added, but this goes beyond the aim of this contribution. Still it is important to remember the efforts of these pioneers, some of whom are still alive today and, in their youth, were active in the period between the two World Wars. Many are remembered from their publications or activities that often represent the very basis of our common conservation goals today. The ornithologists P. Lowe, A. Landsborough Thomson, R. Coombes and C.T. Dalgety were some of the members of the ICBP Wildfowl Inquiry Sub-Committee, while Miss Phyllis Barclay Smith acted as its secretary. She still participated at Executive Board Meetings of IWRB until the early 1970s, ensuring the bridge with the generations to come.

The International Wildfowl Inquiry was organized by ICBP after a meeting in 1937. The results were reported under the title “Factors affecting the general status of wild geese and wild duck” (ICBP 1941). The introductory chapter, “The history of events leading to the formation of the Wildfowl Inquiry sub-committee” by Percy R. Lowe, is worth mentioning as it illustrates how visionary these pioneers were. It also illustrates how conservationists and hunters worked closely together for their common interest. Lowe referred to a report from Sweden presented at the International Ornithological Congress in Copenhagen in 1926, as a result of which “the diminution in the numerical status of wildfowl was brought to the notice of ornithologists and preservationists, followed by official proposals to European Governments which had for their object the establishment of international regulations aimed at a more effective protection of wildfowl on migration”. In 1934–36, ICBP received “profoundly shocking news” from the USA (Audubon Society) about the decline of duck and goose populations. This was the combined result of extreme drought in 1930, shrinking wetland habitats due to land claim and large-scale drainage, and excessive shooting. After some political interventions, a temporary shooting ban was declared.

In his personal contribution to the Wildfowl Inquiry, Lowe analysed the situation in European countries and presented the results under the heading “Some Factors Responsible for a

International Waterfowl & Wetlands Research Bureau  
Wetlands International (1995)

Revolutionary Diminution in the World's Stock of Wildfowl" (Lowe 1941; see Box 2). Many of the factors listed by Lowe have now altered landscapes and nature world-wide, and thus influenced the breeding and wintering of waterbirds in most countries. Furthermore, it is really striking that some problems still need to be solved, despite all the discussions and activities over the past 80 years (e.g. spring shooting, impact of drainage, agriculture, urbanization, etc.). It is certain that ICBP members in the 1930s could not have imagined how incredibly fast "development" would occur, and how natural values in general would suffer from the resulting and ever-increasing environmental pressures at global scale.

In an excellent overview of early pioneering work in North

**Box 2. "Some Factors Responsible for a Revolutionary Diminution in the World's Stock of Wildfowl" (Lowe 1941). The examples given in parenthesis are only a selection of those given by Lowe.**

**1. Increased facilities of travel and transport**

(steam engines, railways, steamships, internal combustion engine and motor-cars, motor-boats, etc. opening up inaccessible resources, also enabling weekend trips to estuaries; driving ducks together for hunting on the Nile...)

**2. Cold storage and commercialization**

(commercialization of wildfowl hunting seen as the most serious factor; importation of frozen wildfowl even during the close season...)

**3. Conditions in the far north**

(depredations by egg collecting in Iceland, Spitsbergen, Greenland)

**4. Ill-considered reclamation of unsuitable areas of land**

(drainage of marsh lands, swamps and fens destroys breeding haunts and winter quarters of wildfowl and causes a disastrous chain of events, e.g. in USA)

**5. Other agricultural factors**

(cessation of irrigation of water meadows, new industry of potato farming; growth of villages into towns in Russian Siberia and over-hunting of ducks for commerce)

**6. Siltation in estuaries, inlets and old harbours**

(caused by the introduction of the exotic *Spartina townsendii* and subsequent spread by swans, and decrease of *Zostera* as a result of disease)

**7. Punt-gunning and shooting from mechanically propelled boats**

(there is a great need for shortening the open season for punting; ducks becoming shyer, bags becoming smaller, etc.)

**8. Disturbance by aeroplanes**

(sometimes needless; often deliberate and systematic driving of ducks together for shooting; forbidden from military aeroplanes)

**9. Long hunting seasons**

(hunting legislation needs scientific background; in most cases, the hunting season opens too early and goes on too long; proposed opening on 1 September; there is an internal dispute in sportsmen's associations on this issue)

America, Hawkins *et al.* (1984) came to the same alarming conclusions.

## IWRB AND THE SERIES OF WATERFOWL CONFERENCES

The pioneering work of IWRB (in close co-operation with IUCN and ICBP) has been crucial in waterbird and wetland conservation. In western Europe, two groups of dedicated specialists were extremely active: Sir Peter Scott with G.L. Atkinson-Willes, H. Boyd, J. Harrison, J. Kear, G.V.T. Matthews and others at the Wildfowl Trust at Slimbridge (UK); and Dr Luc Hoffmann with his staff (J. Blondel, H. Hafner, A. Johnson and others) at the Station Biologique de la Tour du Valat (founded in 1954) in the Camargue (France). Many of today's leading conservationists obtained their first training and experience at one of these two centres. In addition, specialized groups and field stations were set up by a number of universities and natural history museums, and were active in waterbird research all over Europe and the former USSR. Well-known correspondents from many countries became active members of the early IWRB network of waterbird conservationists.

One particularly significant initiative was the MAR Conference, jointly organized by IUCN, ICBP and IWRB in 1962. Again, it is worthwhile to remember the basic aims and ideals of this conference, as some of the considerations are still extremely relevant today. The introduction to the proceedings of the conference stated that: "Alarmed by the progressive loss of marshes, bogs and other wetlands through drainage and 'improvement', IUCN's Executive Board and scientific advisory body, the Commission on Ecology, proposed early in 1961 that IUCN, in close co-operation with ICBP and IWRB, develop a programme on conservation and management of temperate marshes, bogs and other wetlands, to be called 'Project MAR'...". The main goals of this project are summarized in Box 3.

The MAR Conference was a real turning point in the development of strategies and practices for the conservation of waterbirds and wetlands. Many of the participants in that meeting

**Box 3. The main goals of Project MAR, as given in the Introductory Statement in the Proceedings of the MAR Conference, 1964.**

The final goals of the MAR programme are:

- 1 to prepare a broad statement on the importance of marshes and wetlands to modern mankind and to give the widest publicity to this statement;
- 2 to assemble all important data on means of conserving wetlands, to keep or improve them for wildlife through proper management, to restore them when debilitated and to make man-made aquatic habitats useful for wildlife: to make this information known and available to all those in a position to take action to advance the conservation of wetlands;
- 3 to make an inventory and classification of all European and north-west African marshes, bogs and other wetlands of international importance; and
- 4 to offer technical assistance for establishment of reserves in marshes, bogs and other wetlands classified as of international importance.

**Box 4.** The series of IWRB conferences on waterbirds and wetlands from St Andrews in 1963 to the first Conference of the Parties to the Ramsar Convention in 1974. The editor and year of publication of the proceedings are given in brackets.

- 1st European Meeting on the Conservation of Wildfowl, St. Andrews, UK, 1963. (J.J. Swift, 1964)
- 2nd European Meeting on the Conservation of Wildfowl, Noordwijk-aan-Zee, The Netherlands, 1966. (Z. Salverda, 1967)
- 3rd International Regional Meeting on Conservation of Wildfowl Resources, Leningrad, USSR, 1968. (Yu.A. Isakov, 1970)
- International Conference on the Conservation of Wetlands and Waterfowl, Ramsar, Iran, 1971. (E. Carp, 1972)
- International Conference on the Conservation of Wetlands and Waterfowl, Heiligenhafen, Germany, 1974. (M. Smart, 1976)

remained active until the 1980s or 1990s and supported the fast growing impact of IWRB which became the real engine of waterbird research and conservation. Initially based at the Museum of Natural History in London, IWRB moved its headquarters to the Tour du Valat in the Camargue where it remained until 1968, and then to the Wildfowl Trust in Slimbridge (UK) where it remained until 1995. Since then, its work has been continued by Wetlands International.

From the very beginning, IWRB was responsible for a number of scientific publications as well as booklets on the threatened status of waterbirds and wetlands. One of the first booklets, “Liquid assets”, appeared in 1964 with the support of UNESCO (Atkinson-Willes 1964) and was reprinted in 1979. This stressed that wetlands are not wastelands, and drew attention to their importance for recreation, science and education, the costs and dangers of drainage, the problems of pollution, and the desirability of restoring wetlands and managing them wisely.

An impressive amount of knowledge became available thanks to a series of international conferences convened by IWRB and the resulting Proceedings which were published in a similar and recognizable layout (Box 4). In addition to these conferences, IWRB organized most of its Annual Executive Board Meetings in combination with scientific symposia in various parts of the world. This brought national delegates and other active people together on a regular, structured basis, thanks especially to highly professional pioneers working for IWRB, such as E. Carp, G.L. Atkinson-Willes, G.V.T. Matthews, D.A. Scott, M. Smart, M. Moser and many others. The dedicated IWRB secretariat, with M. Moser (successor to G.V.T. Matthews) as Director, moved from Slimbridge to Wageningen (The Netherlands) in 1995. Here, the new headquarters could build up a growing staff with several departments, especially after the XXXVIth Executive Board Meeting in Kuala Lumpur, Malaysia, in 1995 when IWRB merged with Wetlands for the Americas and the Asian Wetland Bureau and became Wetlands International (with Chris Kalden as President).

The first Meeting of the Board of Members of Wetlands International was held during the famous Second Conference on Wetlands and Development in Dakar, Senegal, in 1998, replacing the traditional Executive Board Meetings of IWRB after 36 sessions: quite a change for those of us who had participated in so many earlier meetings.

## THE MASTERPIECE: THE RAMSAR CONVENTION

The above-mentioned meetings during the 1960s were focussed on the development of an international convention specifically related to the conservation of wetlands. This process culminated in a conference held in the Caspian coastal town of Ramsar, Iran, in early 1971. Delegates of 18 countries signed the final text of the Convention on the Conservation of Wetlands of International Importance especially as Waterfowl Habitat on 2 February 1971 (Fig. 2). This date is now known as “World Wetlands Day”. The Ramsar Convention is considered to be the first of the modern global environment treaties and is well structured, thanks to a strong secretariat based at IUCN Headquarters in Gland (Switzerland). As part of the evolution of concepts mentioned above, the working title of the Convention (Ramsar Convention on Wetlands) no longer recalls its relationship with waterfowl habitat. There is no need to present the full history of this convention here, as Geoffrey Matthews, former Director of IWRB, has published an excellent overview: “The Ramsar Convention on Wetlands: its History and Development” (Matthews 1993).

**Fig. 2.** Signing ceremony of the Ramsar Convention, 2 February 1971. From left to right: USSR delegate; E. Firouz (Conference Chair); South African delegate; M.F. Mörzer-Brujns (The Netherlands, Vice-Chair), G.V.T. Matthews (IWRB Director); and E. Carp (IWRB Secretariat, Conference Rapporteur). Photo: E. Kuijken.

One of the most original and handsome contributions of the Ramsar Convention has been the introduction of the 1% criterion (of waterbird populations at flyway level) for designating internationally important wetland sites. Linked with the waterbird databases of IWRB and its successor Wetlands International, a regular update of 1% thresholds at flyway level has offered an objective and attractive tool. Several sessions at IWRB meetings before 1971 gave considerable attention to the required level of waterbird numbers before a site could be considered as being of “international importance” (Sziij 1972). After studying models with 5% and 2% levels, it was concluded that at these levels the number of outstanding sites would be too low to establish a dense enough network to create a functional series of stepping stones or “fuelling stations” for long-distance migrants. The 1% criterion was therefore adopted and has since become a widely used tool in ecological evaluations, not only in waterbird conservation. Later Conferences of the Parties to the Ramsar Convention have gradually added more criteria for assessing the international importance of wetlands, based on functions, habitats, educational values, importance for fish, etc. In 2005, the ninth Conference of the Parties, formally adopted a

1% criterion for non-avian taxa. This further developed the concept by seeking its application to aquatic fauna for which good population data exist (such as river dolphins, hippos, turtles, crocodiles etc.; Stroud unpublished).

Even more significant during the Ramsar Conference in 1971 was the launch of the “wise use” concept by the pioneering architects of the Ramsar Convention. Although also adopted in the Bern Convention (1979), it was 20 years before this approach became more widespread. The Convention on Biological Diversity (CBD), adopted at the United Nations Conference on Environment and Development in Rio de Janeiro in 1992, included “sustainable development” and “sustainable use” almost as synonyms of “wise use”. In its Preamble, the CBD also recognizes the intrinsic value of biodiversity, although this concept remains difficult to explain and even more difficult to bring into practice.

“Wise use”, as an anthropocentric approach, gradually became fully respected, especially when appropriate CEPA (communication, education and public awareness) strategies are carried out among local populations dependent on wetlands for their survival. Indeed, the possibilities for balanced use of the vital resources of wetlands are recognized by an increasing number of Ramsar Contracting Parties. This makes a major contribution not only to biodiversity conservation, but also to global strategies to combat poverty and provide security against natural disasters.

Some pessimism may exist as regards achieving the necessary nature conservation goals in the twenty-first century, even if economic development were to turn more to sustainability. Unfortunately, the Rio+10 Conference in Johannesburg in 2002 no longer included “environment” in its title, thus suggesting that qualitative and quantitative needs are considered to be an integral part of development (which, of course, is true in theory). There is a risk, however, that environmental issues may receive less attention. Fortunately, close links have been established between CBD, other environmental treaties and the Ramsar Convention, and must now reinforce the common conservation aims. The recent “Countdown 2010” initiative (“stop the loss of biodiversity by 2010”) is giving another strong message for real action before it is too late.

Nowadays, the Ramsar Convention is recognized as a most dynamic and functional treaty, having opened the way for wetland conservation, especially in many developing countries. In the early years, technical support was provided mainly by IWRB, and Wetlands International still plays an important role as one of the Convention’s five International Organisation Partners, e.g. in the management of the databases of waterbirds and wetlands, and in the preparation of recommendations in co-operation with the Scientific and Technical Review Panel (STRP).

The increasing efforts made by the growing number of Contracting Parties to designate wetlands of international importance is illustrative of the impact of the Ramsar Convention at global scale (Fig. 3). Since the Eighth Conference of the Parties in Valencia in 2002, a Strategic Work Plan has provided guidelines for the fulfilment of five general and 21 operational objectives. The status of the Convention by 5 July 2006 is impressive: 152 Contracting Parties, and 1 609 Wetlands of International Importance designated for the Ramsar List, covering a total surface area of 145.8 million ha. The triennial Meetings of the Parties are always stimulating and inspiring events, where

Fig. 3. The increase in the area of designated Ramsar sites (from Wetlands International Ramsar Sites Information Service web-site).

criteria are reviewed, results are discussed, and a number of recommendations for further specific actions are developed.

After ratification of the treaty, Ramsar Parties must not only designate at least one wetland, but must also agree to provide compensation when specific Ramsar sites are lost as a consequence of urgent national interest. The very first example of the strength of this Article 4 of the Convention was in relation to the Belgian Ramsar site of Galgenschuur near Antwerp, where 30 ha were lost as a result of the construction of a new container terminal. In compensation, the Flemish government designated 2 500 ha of floodplain along the River IJzer, just at the time of the Regina Conference in 1987.

The “maintenance of the ecological character” of designated wetlands is a permanent obligation. When serious threats exist and are likely to change the characteristics of a designated wetland, this site is to be put on the ‘Montreux Record’. Such sites can be the subject of a Ramsar Advisory Mission, with specialists from the Ramsar Secretariat and other Contracting Parties visiting the site and helping the local authorities to develop solutions, adequate management, etc. This controlling system reflects another (moral) impact of the Convention, as the status of sites on the Montreux Record has to be mentioned openly in the National Reports before each of the Conferences of the Parties.

## FROM WATERBIRD MONITORING TO CONSERVATION OF WETLANDS

The need to identify waterfowl species and a curiosity to learn about their fascinating behaviour inspired many authors to publish valuable handbooks, contributing significantly to our knowledge of these species (e.g. Alpheraky 1905, Delacour 1954, Scott 1965). The Wildfowl Inquiry stimulated more concerted action to collect information on the numbers and distribution of ducks, geese and swans. Traditional methods, such as the collection of wings from shot birds, were applied in order to gain better insight of population dynamics. This again illustrated the close co-operation between hunters and conservationists.

The organization of regular international counts of waterbirds (the International Waterbird Census, IWC) has been a key activity of IWRB/Wetlands International for almost four decades. The first mid-winter counts, initiated in 1967, were confined to “wildfowl” (ducks, geese, swans and coots) and were co-ordinated by G.L. Atkinson-Willes at the Wildfowl

Trust in Slimbridge, with the help of dedicated national co-ordinators, specialists and volunteers in the field. Atkinson-Willes had a long history of organizing counts in the British Isles (Atkinson-Willes 1955). The results of the IWC in the period 1967-1983 were published by Rüger *et al.* 1986. The number of co-workers has grown considerably over the years, and now comprises a network of many thousands all over the world. The counts have provided an immense amount of information, not only of scientific value, but also of strategic importance for wetland conservation. These data have enabled the publication at regular intervals of estimates of waterbird populations in each of their different flyways. The first edition of this work was published in 1994 (Rose & Scott 1994). The Specialist Groups of IWRB/Wetlands International play an important role in bringing expert data together. Reports on ducks and geese were among the first to be published (e.g. Mörzer-Bruijns *et al.* 1969), with comprehensive reviews of the status of many other taxa following in the years since. Monitoring the changes in waterbird numbers at specific wetlands of critical importance can also serve as an “early warning system” that can be used to mobilize authorities to take appropriate measures before it is too late.

The development of ecological networks is a present-day priority (e.g. the Natura 2000 networks of Special Protection Areas within the framework of the European Union’s Birds and Habitats Directives of 1979 and 1992, respectively). The establishment of a network of protected wetland areas to safeguard populations of waterbirds that migrate over long distances was already a basic goal of the Ramsar Convention, and has since been recognized as an essential functional approach in waterbird conservation, promoting the concepts of corridors and stepping stones to connect larger core areas and enhance the mobility of waterbird populations and their genes.

The African-Eurasian Waterbird Agreement (AEWA) under the Bonn Convention was launched in 1995. The Agreement covers 117 Range States in Europe, western Asia and Africa, as well as parts of Canada. Initiated by Gerard Boere, this is a real IWRB spin-off. The AEWA has been ratified by 57 countries and is currently carrying out its “International Implementation Priorities Plan 2003-2007” which includes many species protection plans and other projects (Lenten, this volume).

In North America, the concept of waterfowl “flyways” was introduced much earlier than in Europe (see “Waterfowl Tomorrow” by Linduska 1964, and “Flyways. Pioneering Waterfowl Management in North America” by Hawkins *et al.* 1984). Both these publications draw attention to the large number of dedicated naturalists who, between the late 1800s and World War II, tried to counteract the negative impacts of the earliest land developments.

In Asia, attention was initially focussed mainly on shorebird (wader) flyways, under the co-ordination of the Asian Wetland Bureau (e.g. Parish & Prentice 1989). International waterbird counts and wetland inventories stimulated many Asian countries into further conservation actions, and this was also the case in Latin America. In many biogeographical regions, specific initiatives relating to wetlands developed into powerful regional organizations (cf. MedWet). Other thematic groups worked on specific wetland types and programmes (peatlands, lakes, riverine systems, dunes and estuaries, etc.). National overviews of waterbird counts and wetlands became available in many countries; in this regard, the states of the former USSR were

**Fig. 4.** Japanese crane symbol, where waterbirds, wetlands and culture meet. Photo: Eckhart Kuijken.

often well ahead, with famous names such as Yu. Isakov, E. Kumari, E. Rutschke, E. Nowak and many others.

Not only were waterbird population estimates becoming available in a series of publications, but so too were directories of wetlands of international importance (e.g. Olney 1965, Carp 1980, Scott 1980, World Conservation Monitoring Centre 1990 and Frazier 1999, 2002), often on the occasion of the Ramsar Conferences. Such directories are now available for most continents of the world (e.g. Scott & Carbonell 1986, Scott 1989). Again, these provide an immense source of baseline information on the state of the environment in and around wetlands. In addition, interesting discussions on conservation strategies for wetlands have been presented by Moser *et al.* (1993) and Beintema & van Vessem (1999). In general, the number of publications and proceedings has increased tremendously since the 1990s, thanks to the shift in emphasis of IWRB and Wetlands International towards broader scientific disciplines and social sciences, including economics.

Various themes that have been developed in recent years include wetland management and restoration (Erwin 1996), the economics of conservation, the functions and values of wetlands (Hails 1997), and the goods and services of ecosystems in general (Constanza *et al.* 1997). IWRB, WWF and IUCN have also published valuable contributions and handbooks in these fields. Long-lasting debates, e.g. between conservation and agriculture, hunting or other exploitation, have been the subject of inspiring specialist meetings. The increasing concern about water resources is now giving a new impulse to wetland conser-

vation (European Water Framework Directive 2000, World Commission on Dams, etc.). Illustrative of this is a WWF publication (Schuyt & Brander 2004) with a table expressing the economic values of the Dutch Wadden Sea (270 000 ha), a key wetland site in Europe that is still threatened by increasing developments such as gas exploitation, mollusc fisheries and tourism that are probably not sustainable. The economic value of this tidal wetland is estimated at about US\$ 2 330 000 000 per year! (For more interesting figures, see Constanza *et al.* 1997).

After the boom in publications, proceedings of wetland meetings, inventories, waterbird atlases, directories, etc., a great variety of web-sites is now joining – if not reducing – traditional printed matter; these web-sites are supported by government offices, international bodies, NGOs or individuals, and often offer a wealth of rapidly updated information. This enables individuals and action groups to make their own conclusions about what is going on within the entire biosphere and how they must react. How far future generations will criticize us for not always storing this short-term electronic information in a useful permanent format remains to be seen. On the other hand, a large amount of knowledge would never have been so widely accessible.

### BIODIVERSITY: THREATS AND THE FUTURE

Wetlands are among the most vulnerable types of habitats. The reasons are well known and do not need to be listed here. Wetland losses have been estimated on several occasions, with alarming figures illustrating the great need to take action (Finlayson & Moser 1991, Millennium Ecosystem Assessment 2005). Hopefully, the Ramsar Convention can help to slow the rate of loss of wetlands significantly. This needs long-term strategies, including research and monitoring, site management, ecologically sound policy planning, education and communication. Without public awareness, most initiatives will fail to achieve any long-term sustainability. This is especially important if national and local authorities are to be convinced to respect wetlands in their physical planning, land-use development plans, education programmes, etc.

As to the needs of wetland and waterbird research and monitoring, the traditional bird counts by volunteers – still of crucial importance – are now increasingly being carried out with specialized equipment, additional research techniques and better financial support. The classic ringing schemes, with most recoveries coming from dead birds, have revealed the major patterns of migrations. However, the use of colour rings and satellite transmitters on individual birds has taught us much more about the various types of movements, habitat use and seasonal patterns in only a couple of decades. Earth observation programmes with satellite imagery offer ever-increasing opportunities for digital mapping and monitoring of wetland systems world-wide. More new techniques are becoming available, even allowing us to establish new migration routes by using imprinted waterbirds following light aircraft. It is up to this and the next generation to judge if such far-reaching manipulations of natural characteristics are justified. In any event, careful restoration of habitats and ecological networks, enlarging protected areas and improving habitat quality should be our first priorities and duty.

It is not surprising that our knowledge is developing very fast, but at the same time, concerns about the rapid ecological changes must serve as a warning to modern society that it is time for inte-

grated actions and ecologically based economics. Public awareness through education and training must be translated into political pressure at all decision-making levels. The mission of Wetlands International is clear enough: to sustain or restore wetlands, their resources and biodiversity for future generations through research, information exchange and conservation activities world-wide.

Wetlands play a key role in a number of global processes, from climate change to coastal protection, from eco-tourism to food and timber production, from water supply to transportation, and much more, and thus merit the full attention of all sectors in our society. Wetlands are real crossing points where nature and human culture have come together for hundreds of generations, many of whom have used and admired the wealth of waterbirds in their thousands and other living resources. A wide range of traditional skills (often practised by women) and modern techniques are now needed in joint efforts to maintain this worldly heritage, these “liquid assets” of the highest spiritual and aesthetic value.

### ACKNOWLEDGEMENTS

I wish to thank the Ramsar Convention Secretariat (Delmar Blasco, Nick Davidson and Tobias Salaté) and Wetlands International (Doug Taylor) for responding to requests for information, and give special thanks to Gerard Boere for his encouragement to finalize this contribution. I wish to express my sincere appreciation to my colleagues on the “Board of Patrons” of this Conference, H. Boyd, L. Hoffmann, G.V.T. Matthews and H. Nelson, for having accepted me as a “junior” in their stimulating company as real pioneers. I am most grateful to Derek Scott for the final revision of the manuscript.

## North American flyway management: a century of experience in the United States

Paul R. Schmidt

U.S. Fish and Wildlife Service, Migratory Birds and State Programs, 1849 C St. NW, Room 3250, Washington, D.C. 20240, USA.

Schmidt, P.R. 2006. North American Flyway Management: a century of experience in the United States. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 60-62.

There is a long history of waterbird conservation in the United States of America, with a century of cooperation and legislation. The awakening of the conservation movement dates back to 1900, and the first international agreements for migratory waterbirds were established in 1916. Through the 1920s and 1930s, legal measures for hunting and then habitat protection were introduced; the latter focused on land acquisition and was especially important for wetland conservation. In the 1940s, the first flyway-level cooperation began, incorporating administrative divisions to ensure clarity in approaches. Then in the 1950s, surveys became the focus and, enhanced by technological advances and aerial surveys, became central to understanding waterbird populations in North America. Surveys were conducted on bird populations, habitats and harvesting. Each year, tens of thousands of miles of aerial surveys are carried out. In the 1960s, the roles of management and research came to prominence, and in the 1970s, science was clearly driving management decisions. In the 1980s, the forging of partnerships led to establishment of wider agreements, such as the North American Waterfowl Management Plan, which has also been influential for other species. The 1990s saw the development of other continental partnership efforts to conserve other groups of species, such as Partners in Flight (for landbirds), Waterbird Conservation for the Americas, and the United States Shorebird Plan. Additionally, an effort to integrate population monitoring began to take root. Conservation agreements are living, evolving and dynamic measures, and in 2000 the North American Bird Conservation Initiative was developed between USA, Canada and Mexico with the aim of integrating science and partnerships in management to deliver bird conservation for the benefit of society. The National Wildlife Refuge System was begun in 1903, and birds have been a primary influence on its development. International agreements such as the Western Hemisphere Shorebird Reserve Network (WHSRN) have drawn upon this network. WHSRN is an enormous partnership combining science and voluntary participation in site-based protection. Current initiatives, such as Important Bird Areas of North America, are raising awareness further and identifying critically important sites. Successful conservation demands federal leadership in any country – this has been achieved through the United States Fish and Wildlife Service (USFWS) in the USA. Challenges facing conservation are more complex today than a century ago; there are many continued pressures, of which habitat loss remains the most significant, but there are new pressures such as disease, for example West Nile Virus in North America. The USFWS vision is to combine science and landscape-scale partnerships to deliver the full spectrum of bird conservation and, in doing so, lift human spirit and enrich human lives for generations to come.

*“Propelled by an ancient faith deep within their genes, millions of birds hurdle the globe each season... They are not*

*residents of any single place, but of the whole, and their continued survival rests almost entirely within our hands.”* (Scott Weidensaul, author).

*“Many birds are indeed a source of wonder and inspiration. They weave the nations of the globe together as neighbors.”* (John Turner, Assistant Secretary of State).

Indeed, the wonder of birds and their migrations have inspired people for generations past. The citizens of the United States of America have connected to this natural resource over the decades, and have demanded a conservation effort that considers birds an international resource not “owned” by anyone. For more than a century now, the United States government has made concerted and organized efforts to ensure that this resource is conserved for future generations of Americans and other people of the world.

Without question, migratory birds are an international shared resource, requiring cooperation among nations. This is evident around the globe with the many international agreements and treaties that have formalized what we all know intuitively. In the case of the United States, there are important and binding international partnerships in this endeavor with Canada, Mexico, Japan, and Russia. Beyond that, the United States has informal arrangements with virtually every country in Central and South America as well.

The milestone for early efforts in the United States to conserve migratory birds was the establishment of the first National Wildlife Refuge in 1903. This refuge, Pelican Island, was, not coincidentally, established for the protection of migratory birds. Federal laws were passed in the early 1900s that established the foundation of a regulatory framework for protection of wildlife. For instance, the Lacey Act in 1900 made it a Federal violation to transport wildlife across state boundaries if that wildlife had been taken in a manner that violated state law. However, without question, the most prominent and important Federal law for the protection of migratory birds was the Migratory Bird Treaty Act of 1918. This domestic legislation implemented a bilateral treaty, signed in 1916, between the United States and Great Britain (on behalf of Canada). This international treaty for the first time clearly established the authority and obligation of the Federal government to protect and conserve migratory birds. Three more bilateral treaties would follow: with Mexico in 1936, with Japan in 1972, and with the Union of Soviet Socialist Republics (later to be Russia) in 1976. The language in these conventions demonstrated the evolution or refinement of conservation science over those decades. Each subsequent treaty was more sophisticated and comprehensive in its language, building on the preceding one(s) and using the state of the art scientific thought. The bottom line is that, in order to be successful, governments must find ways to cooperate in the conservation of shared species and habitats.

The evolution of conservation in the United States over the past century can be characterized by each decade building on the scientific knowledge and customs of the previous decade. Clearly, the twentieth century was an important one for the conservation of migratory birds in the United States and indeed in North America as a whole. Incredible progress was made over that 100 years, such that there is significant hope that birds will be conserved long into the future.

In the early 1900s, there was an awakening of the conservation movement in the United States. It is during this period that governments experimented with laws and regulations as a way of stemming the obvious losses of the robust wildlife populations that the public had taken for granted for so long. Political leaders and conservationists began to realize that unless the commercialization of wildlife was regulated in some fashion, the future of the wildlife resource would be in question. Federal and state laws began to be passed that criminalized abuses that had come to be common practice. The public's interest in conserving wildlife, and in particular birds, was growing. The people were awakened to the need for sustainable use and the idea that there are limits to what the public can do and still have a future blessed with wildlife.

The legal authorities continued to expand in the 1910s, highlighted by the passage of the Weeks-McLean Law in 1913 and the Migratory Bird Treaty Act in 1918. Visionary leaders during this decade realized that this was an international resource that cried out for cooperation and coordination. There was a clear need for Federal authority.

The 1920s brought an emphasis on population management and protection. Individual populations of species of migratory birds were the focus of management efforts throughout the country. The days of unlimited commercial or market hunting were over, as people recognized that some limits had to be established to ensure species survival. The principle of sustainable use was beginning to be understood.

While the efforts in the 1920s were directed at reacting to the influences and effects of human behaviors, the 1930s brought about a response to a natural disaster: continental drought. The "dust bowl era" of the 1930s was exacerbated by poor land use practices and resulted in a significant deterioration of habitat conditions, particularly in the Midwest and West. It was most noticeable in the precipitous drop in populations of waterfowl<sup>1</sup> that relied upon the prairie pothole wetlands for breeding. The wetlands dried up, and the skies, once darkened by flocks of waterfowl, were now clear and silent. Conservationists began to realize that there must be a concerted effort to conserve habitat or these healthy populations would be no more. Conservationists identified key habitats throughout the country that needed to be protected in order to sustain future populations of birds. It was clear that just regulating the public's behavior was not enough. The birds are inextricably linked to the land and water. The passage of the Migratory Bird Hunting and Conservation Stamp Act of 1934 was the first time that a segment of the public (the migratory bird hunters) was willing to be taxed to raise funds to buy lands for wildlife. This Federal law required every hunter of waterfowl over the age of 16 to purchase a Migratory Bird Hunting and Conservation Stamp in order to hunt. The proceeds of the sale of these stamps would be used to buy waterfowl habitat throughout the country for decades to come.

Given the migratory nature of this resource, governments must coordinate their efforts in order to be most effective.

This was certainly realized in the 1940s, when all the states in the United States began acting in concert with each other to best manage the game species that migrated north-south. The "Flyway System" was borne out of this need to coordinate, and the United States was divided into four flyways: Atlantic, Mississippi, Central, and Pacific. The boundaries to these flyways balanced the biological nature of the migration with the geopolitical boundaries of the states. This system allowed for the Federal government U.S. Fish and Wildlife Service to work with the flyway councils to ensure that the biological and public issues could be openly shared and debated. This system has served the birds, the public, the states, and the U.S. Fish and Wildlife Service well.

Visionary biologists and leaders recognized the need to develop systematic surveys in order to gather current data on the status of important bird populations for supporting decisions on the "take" of migratory birds; this was particularly important in establishing hunting seasons. In the 1950s, a few of these visionaries designed the most comprehensive wildlife survey system in the world. With the availability of excess military aircraft after the end of World War II and a few biologists and pilots, the age of aerial surveys began. The waterfowl breeding population survey began in earnest in 1955 and has remained much the same over these past 50 years, providing one of the most widely used databases for migratory birds in the world. Since that time, the Fish and Wildlife Service has added survey components to collect information on habitat conditions and hunter harvest throughout North America. All of these surveys are carried out in cooperation and partnership with Canadian and state biologists. The aerial surveys cover over 80 000 linear miles (128 000 km) each year in the best waterfowl breeding areas in North America.

In the 1960s, there was an emphasis on intensive management to try to improve the status of key populations. Efforts to reduce predation and enhance production were conducted to get the most out of the natural system for the benefit of the public. Biologists experimented with management treatments. These same biologists realized it was incredibly important to use the best available science. Hence, the emphasis in the 1970s was on using science to drive management actions. It was during this decade that much progress was made in understanding the fundamental principles underlying complex biological systems.

The crisis of the decline in waterfowl populations in the 1980s gave rise to the need for a comprehensive effort to secure sufficient habitat to sustain these populations. It was clear that no single organization could make this happen on its own, and therefore formal partnerships were created. In 1986, the Secretary of the Interior for the United States and the Minister of the Environment for Canada signed the North American Waterfowl Management Plan. This Plan would form the rallying point for government and non-governmental organizations to focus work and funds toward a common goal of restoring waterfowl populations to the levels enjoyed in the 1970s. The partnerships were fuelled by new Federal funding in the North American Wetlands Conservation Act of 1989. This new funding would provide matching grants to organizations to protect or restore priority wetland habitats throughout the continent. Private fund-raising efforts were combined with government funding to produce significant results for the protection of wetlands.

The North American Waterfowl Management Plan was used as a model agreement for other partnerships to conserve other

<sup>1</sup> The term "waterfowl" is here used in the North American sense, i.e. restricted to ducks, geese and swans (Anatidae).

large groups of migratory birds. In the 1990s, organizations came together for landbirds, waterbirds, and shorebirds. Partners-in-Flight (1991) was formed to bring attention to the decline of many landbirds, particularly neotropical migrants. Waterbirds for Americas was launched in 2001 to focus efforts on waterbirds other than waterfowl. The decline of many shorebird species brought organizations together to develop plans to improve the status of these birds as well. The U.S. Shorebird Conservation Plan was completed in 2000. All of these efforts are built on the principle that science and partnerships can come together to make a significant difference for migratory birds.

As the twentieth century came to a close, partners across the continent formed the North American Bird Conservation Initiative (1999); this effort built on the four bird partnerships that had developed continental plans. The role of the Initiative was to serve as a forum in which partners could share ideas and find efficiencies among the ongoing conservation work. This Initiative includes government and other organizations in Mexico, the United States, and Canada. The hope is that this idea will spread throughout the hemisphere to bring together conservation efforts for the benefit of birds and people.

Regional partnerships called “Joint Ventures” have been formed to plan and implement regional habitat efforts toward the goals of the continental plans. Originally focused on waterfowl, they have all adopted the responsibility of delivering habitat conservation for all migratory birds. The “vision” adopted by all the major partners in bird conservation is “Biologically-based, landscape-oriented regional partnerships delivering the full spectrum of bird conservation.” This vision is being realized every day in the dozen or so “joint venture” partnerships that have formed across the USA and Canada, and are beginning to form in Mexico. Each joint venture is responsible for understanding the fundamental needs of the suite of species of migratory birds within its geographic scope, and designing a conservation program that is grounded in the goals of those species. This work entails understanding the gap that exists between a healthy sustainable habitat state and the current state of the landscape. The partners come to the joint venture with ideas and resources to work together on the goals identified.

There are a number of site networks that have been developed in North America over the years that contribute to the overall conservation of migratory birds from a flyway perspective. The National Wildlife Refuge System is a century old and covers almost 100 million acres (40 million hectares) in the United States. There are lands set aside for the conservation of America’s wildlife in every one of the 50 States. It is an incredible legacy that will provide lasting benefits to conservation in the flyways forever. The refuges are strategically placed to benefit the many species of migratory birds with which we concern ourselves.

The mission of the Western Hemisphere Shorebird Reserve Network (WHSRN; created in 1985) is to conserve shorebird species and their habitats across the Americas through a network of key sites. The guiding principles of this network are:

- International strategy for local conservation
  - Site-based action
  - Focus on collective actions that individual sites cannot do alone
- Voluntary, non-regulatory
- Science-based

- Community driven (valuing traditional knowledge and customs)
- Integration at national and regional scale

The WHSRN encompasses 57 sites in seven countries and 23 states; it has over 240 partners and affects 20 million acres (8.1 million hectares).

Last but not least, the American Bird Conservancy has been coordinating the Important Bird Areas of North America since 1995. These sites are identified because they are important for threatened, endangered and “watch-list” species, or support large concentrations of birds. The goal of the program is to raise awareness at critical sites on the continent. Over 500 areas have been identified as globally important.

The twenty-first century brings us to a crossroads in the conservation of migratory species. Conservation and management of such a highly mobile group of species requires and demands Federal leadership. The Fish and Wildlife Service is entrusted with this responsibility in the United States, with more than 25 legislative Acts of Congress authorizing the conservation and management of over 800 species. The multiple and expanding constituencies will continue to grow in their demands and expectations on this leadership.

This century will bring a varied and complex set of challenges greater than the century before, including but not limited to:

- Continued habitat loss and degradation
- Pesticides and other contaminants
- Complex harvest program for game species
- Long-line and gillnet fisheries
- Towers and other human-made structures
- Invasive species
- Over-abundant species
- West Nile Virus and other diseases

The Fish and Wildlife Service has recently adopted a new vision and plan to deal with these challenges: “A Blueprint for the Future of Migratory Birds (March 2004).” This strategic plan envisions that: “Through careful management built on solid science and diverse partnerships, the Service and its partners restore and sustain the epic sweep of bird migration and the natural systems on which it depends – fostering a world in which bird populations continue to fulfill their ecological roles while lifting the human spirit and enriching human lives in infinite ways, for generations to come.” To these ends, the goals of the Service’s Migratory Bird Program are to:

- 1 maintain and increase healthy migratory bird populations of economic or ecological importance and their associated habitats;
- 2 improve the status of migratory bird species in decline or listed as threatened or endangered;
- 3 address concerns regarding over-abundant migratory bird populations; and
- 4 improve bird-related recreational experiences and opportunities.

These goals will be pursued in a climate that endorses and supports adaptive resource management. For North America, migratory bird conservation, now and in the future, will be biologically-based, landscape-oriented partnerships, delivering the full spectrum of bird conservation.

## African-Western Eurasian Flyways: current knowledge, population status and future challenges

### ABSTRACT

This paper reviews the status of the 762 biogeographical populations of waterbirds (of 307 species in 33 families) which depend upon the African-Western Eurasian region. Fifty-four percent are inter-continental migrants and the remainder are resident or short-distance migrants, the status of which is particularly poorly known. Despite a huge wealth of long-term research and monitoring effort, especially in western Europe, population trends have been estimated for only half of the populations due largely to the dispersed nature of some populations and limited monitoring networks in Africa, the Middle East and western Asia. Many waterbird populations in Africa and Western Eurasia remain in long-term and serious decline: 45% of populations are decreasing and only 16% are increasing. Populations in decline exhibit a variety of characteristics, but it is clear that some waterbird taxa (e.g. rails, cranes, ducks and terns) are particularly threatened, as are populations dependent on some flyways (notably the Black Sea/Mediterranean and West Asian/East African), some regions (e.g. Africa, especially its islands, and West Asia/Middle East) and some key migratory staging areas (notably the Wadden Sea). However, more broad analyses (at the flyway and/or higher taxon levels) are needed to determine at which habitats, regions and key sites our resources and conservation actions should be focused. The main driver of change continues to be wetland loss and degradation, probably now being exacerbated by severe and prolonged droughts and other impacts of climate change. Despite over 30 years of inter-governmental action for waterbirds, notably through the Ramsar Convention on Wetlands and the African-Eurasian Migratory Waterbird Agreement, there remain major gaps, especially in Africa, in the envisaged comprehensive flyway-scale network of sites for waterbirds, with less than one-quarter of key sites having been designated. The future challenges of justifying more waterbird research and monitoring in the context of the African priority for sustainable development to achieve human well-being and elimination of extreme poverty are discussed.

### INTRODUCTION

Waterbirds in Africa and Western Eurasia are amongst the most well-studied animals in the world. Numbers, distributions and status have been extensively monitored and researched for the last 40 years, yielding a wealth of knowledge and understanding of migration movements and phenology, sites and habitats of importance, and leading the way in unravelling the complexities of the eco-physiology of long-distance migrations.

This paper provides a brief overview of the numbers and status of waterbird populations dependent on the African-Western Eurasian region, drawing on examples from studies

particularly on waders (shorebirds) and Anatidae (ducks, geese and swans). Whilst focusing on migratory species and populations, it also assesses the status of non-migrant populations and species, which are often less well-known and in poorer status than migratory populations. It assesses their current conservation status, the value of using waterbirds as indicators of global change, and whether the transfer of scientific knowledge to policy-relevant application of conservation measures has been effective in maintaining or restoring the health of waterbird populations. Future challenges are identified, particularly as to how, and if, waterbird science can be shown to be relevant to the key priority issues of securing biodiversity conservation in the context of sustainable development, food and water security and poverty reduction. These issues, set out by the World Summit on Sustainable Development (WSSD; Johannesburg, 2002) and the United Nation's Millennium Development Goals, are the focus of attention in the developing world, and especially Africa.

### THE INTERNATIONAL CONSERVATION FRAMEWORK FOR AFRICAN-WESTERN EURASIAN WATERBIRDS

An international conservation framework for wetlands and waterbirds has now been in place for over 30 years. The importance of maintaining the ecological character of the network of wetlands, both inland and coastal, on which these populations depend was the driving force behind the establishment of the Convention on Wetlands (Ramsar, Iran, 1971), amongst the oldest of the global multilateral environmental agreements (MEAs). More recently, these flyways have become the focus of a further regional MEA, the 1995 Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA). In addition, the 1979 EEC Directive on the Conservation of Wild Birds established a legally-binding instrument for bird conservation throughout the Member States of the European Union (EU). These international intergovernmental agreements for flyway-scale conservation set the international frameworks and context for the many national and local conservation actions designed to safeguard waterbird populations.

The Ramsar Convention delivers its mission of "the conservation and wise use of all wetlands through local, regional and national actions and international co-operation, as a contribution towards achieving sustainable development throughout the world" through three "pillars" of activity:

- the wise use of all wetlands;
- the designation and management of Wetlands of International Importance (Ramsar sites); and
- international co-operation, which includes the establishment of waterbird flyway networks.

The Convention gave an initial priority to the identification and designation of Ramsar sites for waterbirds, and has established quantitative criteria for such designations (see Ramsar Convention 1999). Since the early 1990s, the Convention has been developing so as to address fully its initially-established scope of securing the maintenance of the ecological character of all wetlands and, importantly, through safeguarding the critical role of wetlands in maintaining the global hydrological cycle, securing water supply for current and future generations. The Convention, as at July 2006, has 152 Contracting Parties, including 98 in the African-Western Eurasian region.

The African-Eurasian Migratory Waterbird Agreement (AEWA) is an agreement established in 1995 under the auspices of the Convention on Migratory Species (CMS). The Agreement has now entered into force in 54 countries in the region (as at June 2006), i.e. some 46% of the total number of eligible range states. AEWA has developed an ambitious and comprehensive range of implementation priorities for the period 2003-2007. The CMS itself, established in 1977, aims “to conserve terrestrial, marine and avian migratory species throughout their range” and (as at June 2006) has 98 Contracting Parties, of which 79 are in the African-Western Eurasian region.

In Europe, the 1979 EEC Directive on the Conservation of Wild Birds requires EU Member States to classify a national network of Special Protection Areas (SPAs) for certain listed rare and vulnerable birds, as well as for all migratory species, and urges special priority to be given to wetlands of international importance – an implicit cross-reference to the Ramsar Convention. In addition, Member States are required to maintain the favourable conservation status of bird populations, maintaining their range and distribution. SPAs, together with Special Areas for Conservation established under the subsequent EU Habitats Directive, are intended to form a comprehensive European-wide network of protected areas in the “Natura 2000” network of the European Union.

Non-European Union Contracting Parties to the “Berne” Convention on the Conservation of European Wildlife and Natural Habitats are required to establish national networks of protected sites as a contribution to the European “Emerald Network”, which is complementary to the EU’s Natura 2000 network.

## STATE OF KNOWLEDGE OF AFRICAN-WESTERN EURASIAN WATERBIRD POPULATIONS

### Number of waterbird species and populations in the African-Western Eurasian region

There is no globally definitive list of “waterbird” species and populations. The Ramsar Convention has defined “waterbirds” as “species of birds which are ecologically dependent on wetlands”. The Convention regards “waterbirds” as a term synonymous with “waterfowl” – a treatment followed in this paper – and lists 14 bird orders which especially include waterbirds (Ramsar Convention 1999). Wetlands International’s *Waterbird Population Estimates - Third edition* (WPE3; Wetlands International 2002) lists all species and populations of 33 families which have traditionally been considered as “waterbirds”, but recognizes that this listing needs expanding to cover wetland-dependent species in other taxa. In the African-Western Eurasian region, there are at least 762 biogeographical populations (including 14 extinct or probably extinct populations) of 307 species (35% of the global total) in the families covered by WPE3.

WPE3 lists 346 populations in Europe and 611 in Africa (but note that some populations occur in both continents). For migratory species, waders (28.9% by species) and Anatidae (ducks, geese and swans; 21.7%) dominate the flyways. In addition, BirdLife International (2001, 2002) has identified at least a further 61 species (including 20 seabirds) in Europe and 217 species (including 77 seabirds) in Africa which can be considered wetland-dependent.

AEWA covers only a subset of these species and populations: 497 populations (65% of African-Western Eurasian populations in these families) of 221 migratory waterbird species in 23 families, since certain migratory species which are not wetland-dependent are excluded, as are resident wetland-dependent species.

Just over half (54%) of the African-Western Eurasian populations listed in WPE3 are inter-continental migrants, with the other 46% being resident or short-distance migrants. Of these, 20% are resident on African islands and many of these are small, declining and/or threatened populations.

### Knowledge of waterbird populations in the region

Waterbirds in the African-Western Eurasian region, especially in western Europe but also increasingly in eastern Europe and Africa, are amongst the most well-studied of anywhere in the world. In some parts of the region, waterbird populations have been monitored regularly for over 50 years, and annual trend analyses for Anatidae in some countries in Western Europe are available since the mid-1950s (e.g. Atkinson-Willes 1963). This wealth of knowledge has been acquired through vast, and often informal, national and international networks of waterbird enthusiasts, usually working on a voluntary basis. The multiple sources upon which this paper is based bear witness to the multinational, and generously open, collaborations which are essential if migratory species moving along flyways are to be fully understood.

Site and national scale co-ordinated waterbird counts are compiled through Wetlands International’s International Waterbird Census (IWC) and regularly summarized for the Western Palearctic and South-west Asia (e.g. Delany *et al.* 1999, Gilissen *et al.* 2002) and Africa (e.g. Dodman *et al.* 1999). This information is supplemented by a large variety of national, regional, key site and taxonomic analyses, such as those for South Africa (Taylor *et al.* 1999), the United Kingdom (e.g. Pollitt *et al.* 2003) and the international Wadden Sea (Meltotte *et al.* 1994), the large number of WIWO (Working Group of International Wader and Waterfowl Research) site reports (summarized in WIWO 1999), and taxonomic reviews of Anatidae (Scott & Rose 1996, Madsen *et al.* 1999) and waders (Stroud *et al.* 2004, International Wader Study Group in prep.).

Underpinning this is a large volume of published research on migration routes and migration phenology (e.g. Piersma & Davidson 1992, Wernham *et al.* 2002), and the eco-physiology of waterbird migrations in the region (e.g. Ens *et al.* 1990 and Piersma 1994 amongst many others). Furthermore, these detailed research findings have been synthesized and, to some extent, have provided source material in support of waterbird conservation decision-making and implementation, at national scale (e.g. Davidson *et al.* 1991), flyway scale (e.g. Davidson & Pienkowski 1987), regional scale (e.g. Hötter *et al.* 1998), and thematically (e.g. Davidson & Rothwell 1993).

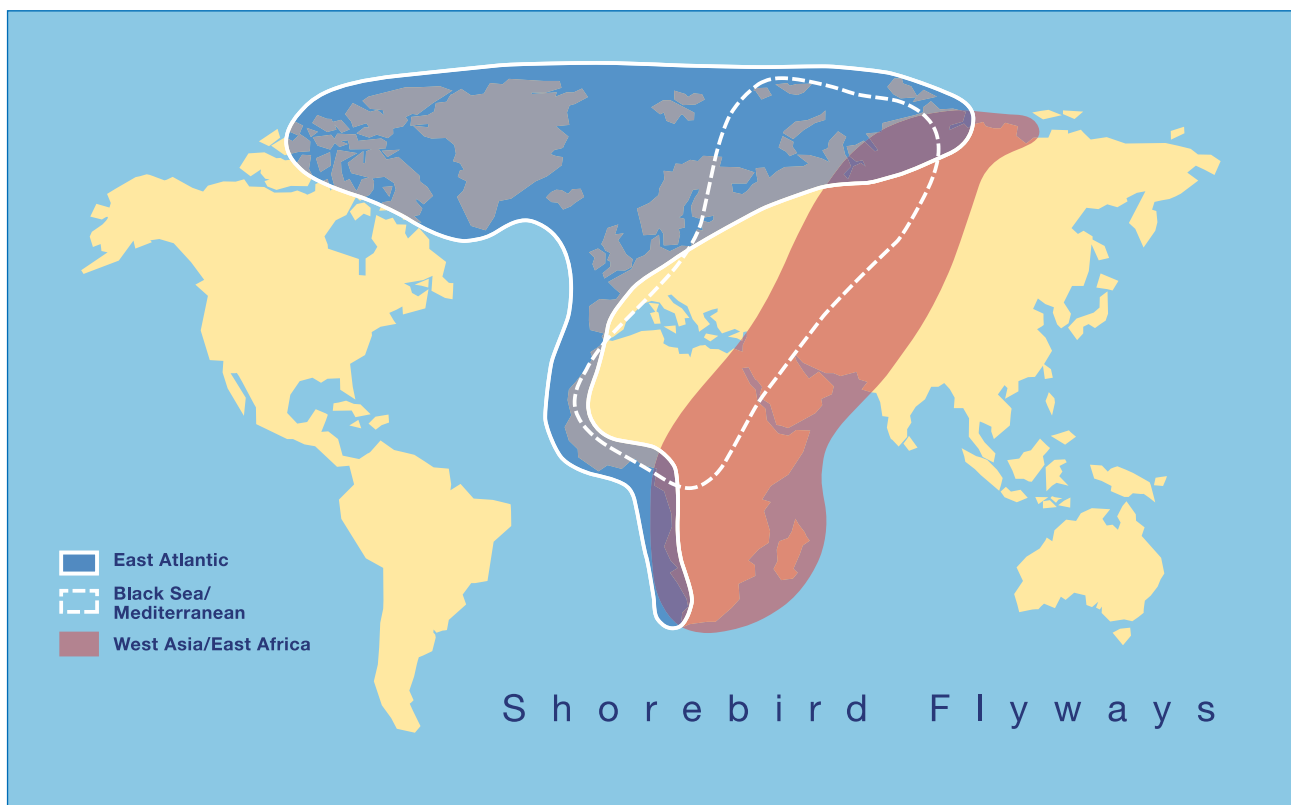

Fig. 1. The three wader flyways which cover the African-Western Eurasian region. Adapted from International Wader Study Group (1992).

Nevertheless, many of the region's waterbird species still remain remarkably poorly known. A recent global analysis of published literature on waders (Thomas *et al.* 2003) found that research has focused on species with large populations, and that one third of all publications are on just five relatively common species in the African-Western Eurasian region: Eurasian Oystercatcher *Haematopus ostralegus*, Northern Lapwing *Vanellus vanellus*, Common Redshank *Tringa totanus*, Red Knot *Calidris canutus* and Dunlin *Calidris alpina*. In contrast, there has been very little, if any, research conducted on many of the scarce and globally threatened wader species, and these should be a focus for better future attention.

#### Waterbird flyways in Africa and Western Eurasia

Within the African-Western Eurasian region, several waterbird flyways have been recognized, although it is important to recognize that flyways vary for different waterbird taxa. For example, for waders, three main flyways (East Atlantic, Black Sea/Mediterranean, and West Asian/East African) have been defined, and together these cover the region (Fig. 1). However, for many Anatidae species (especially ducks), population segregation is much less clear, with fewer birds reaching south into Africa, and more moving on a north-east/south-west axis between breeding and wintering areas within Western Eurasia (see, for example, Scott & Rose 1996). In contrast, populations of geese and swans tend to be highly segregated, moving along individual and discrete flyways between traditional breeding and non-breeding areas (Madsen *et al.* 1999). Flyways for most other waterbird taxa in the region have not yet been well established, but are in general likely to be population-specific.

#### State of knowledge of waterbird population sizes and trends

Overall, the level of knowledge of waterbird populations in the African-Western Eurasian region is better than in other parts of the world. WPE3 provides a population size estimate for 91% of populations using Africa and 97% of populations using Europe (Table 1). For other global regions, figures range from 59% to 81%. However, it is important to note that these figures include many populations for which there are only rough estimates within a broad size range, and the percentage for which population size is known to greater precision is considerably smaller. For example, for African-Western Eurasian waders (which are better known than many other waterbird taxa), some estimate of population size has been given for 95% of populations, but a more precise estimate is available for only 72% of populations (Stroud *et al.* 2004).

**Table 1.** Knowledge of waterbird population sizes and trends. Figures are the percentage of populations with a known population size or trend. Source: Wetlands International (2002).

Region <sup>1</sup>	Population size estimate (% of populations)	Population trend estimate (% of populations)
Europe	97	74
Africa	91	63
North America	81	64
Asia	79	43
Oceania	66	40
Neotropics	59	36
World-wide	76	50

<sup>1</sup> Regions are those defined by the Ramsar Convention on Wetlands

Waterbird population trends in the region are less well known than population sizes: WPE3 includes trend information for 63% of African populations and 74% of European populations. However, as for population size, this knowledge base is better than for most other regions of the world (see Table 1). Although knowledge of population trends in the region thus appears good, only for a small number of these populations (largely Anatidae in Europe) is the trend derived from a statistically sound analysis: most remain derived from “best expert assessment” of the available information, which is often derived from only one or two periodic compilations of international population size (see, for example, Stroud *et al.* 2004 for further discussion of this issue).

Furthermore, the regional-scale analysis (Table 1) masks considerable variation in the quality of information between flyways within the African-Western Eurasian region. For waders, for example, there is much better information for coastal populations in the East Atlantic Flyway (93% with trends) than for populations using the Black Sea/Mediterranean Flyway (76%) and West Asia/East Africa Flyway (35%), and particularly for populations confined to Africa (30%) (Stroud *et al.* 2004).

Similarly, there is great variation in the extent of knowledge of population trends between different waterbird taxa in the African-Western Eurasian region (Fig. 2).

**Fig. 2.** The extent of available information on biogeographic population trends in the waterbird families covered by the 3rd edition of *Waterbird Population Estimates* (Wetlands International 2002). Numbers in parenthesis after family names are the total number of populations in that family in the African-Western Eurasian region.

Information quality is generally better (<20% of populations lacking trend information) for the taxa in which species are large, often localized in distribution and so relatively easier to count, such as pelicans (Pelecanidae), cormorants (Phalacrocoracidae), storks (Ciconiidae), flamingos (Phoenicopteridae), ducks, geese and swans (Anatidae), cranes (Gruidae) and oystercatchers (Haematopodidae). Conversely, it is particularly poor for taxa in which birds are generally smaller, widely distributed and/or highly cryptic, especially for taxa occurring largely in Africa. Such families, each with >40% of populations without trend information, include divers (Gaviidae), finfoots (Heliornithidae), painted-snipes

(Rostratulidae), stone-curlews (Burhinidae), coursers and pratincoles (Glareolidae), plovers (Charadriidae), gulls (Laridae) and terns (Sternidae).

## INDICATORS OF EFFECTIVENESS OF WATERBIRD CONSERVATION IN AFRICA AND WESTERN EURASIA

Two indicators can provide useful insights into the level of success of conservation efforts to safeguard migratory waterbird populations in this region. These are:

- 1 A “process-oriented indicator” – progress in the designation of Wetlands of International Importance (Ramsar sites) under the Ramsar Convention; and
- 2 An “outcome-oriented” indicator – the current status and trends of waterbird populations in the region.

It is important to bear in mind, however, that such outcome-oriented indicators can at best generally provide evidence of correlation between the effectiveness of decision-making and conservation implementation, rather than demonstrating a causal link with specific actions, such as designation and management of Ramsar sites, and species protection and management. Without the existence of a “control” situation, the assessment of such indicators could be interpreted in two ways if, for example, continuing population declines are reported: either that the conservation actions are not effective, or that without such actions the situation would have been far worse.

### Progress in the designation of Ramsar sites

The *Strategic Framework and guidelines for the further development of the List of Wetlands of International Importance*, adopted by the seventh Meeting of the Conference of the Parties to the Ramsar Convention (Ramsar Convention 1999), calls for “coherent and comprehensive national and international networks” of Ramsar sites, and for these sites to form the basis of a status and trends monitoring network (Objective 4.1 of the *Strategic Framework*). Such networks are recognized as an essential basis for delivering flyway-scale migratory species conservation.

Two (Criteria 5 and 6) of the nine criteria established for the identification and designation of Ramsar sites are quantitative criteria for waterbirds. The long-term goal and guidance for the application of these criteria indicate that all such wetlands that qualify should be designated as Ramsar sites. In addition, wetlands can be designated for waterbirds under several of the other, qualitative criteria. As the initial emphasis of the Convention focused on a priority for Ramsar site designation for waterbirds (Article 2.2), we can assess how comprehensive an international site network has been created 35 years on.

The application of Criterion 6 for Ramsar site designation depends on two types of information being available: a) knowledge of the population size regularly dependent on the site concerned; and b) sufficient knowledge of the overall size of the biogeographical population to establish a 1% threshold for that population. *Waterbird Population Estimates* has been recognized by the Ramsar Convention as the key authoritative source for these 1% thresholds. For African-Western Eurasian populations, WPE3 has established 1% thresholds for 668 (89%) extant waterbird populations in the region.

As at April 2004, 1 132 Ramsar sites in the African-Western

Eurasian region recognize the value of the wetland for waterbirds in one way or another. More specifically, of these, 465 sites had been designated using waterbird Criterion 5 (>20 000 waterbirds) and/or Criterion 6 (>1% biogeographical population). This suite of designations represents almost three-quarters (73%) of sites globally designated under these quantitative Criteria, and overall covered 30.4 million hectares of wetlands in the region. By June 2006, this had increased to 512 such sites covering 38.0 million hectares.

Although this may appear as significant progress towards the “coherent and comprehensive national and international networks” of Ramsar sites called for by the Convention’s *Strategic Framework* (Resolution VII.11) (Ramsar Convention 1999), there are major imbalances and gaps in the site network. Of the sites designated by April 2004 specifically for waterbirds, 83% are in Europe, and only 17% in western Asia and Africa. Over half (55%) of all such waterbird sites in the region have been designated by just six countries: United Kingdom (115 sites), The Netherlands (35 sites), Denmark (32 sites), Russia (31 sites), Islamic Republic of Iran (22 sites) and Ukraine (20 sites). At that time no wetlands had been designated under Criterion 5 and/or Criterion 6 in 35 (39%) of the African-Western Eurasian countries which are Party to the Ramsar Convention, and this included almost half (18 countries) of the Ramsar countries in Africa. Many other sites have been recognized as being important for waterbirds, but quantitative data are as yet lacking for the application of Ramsar’s numerical criteria.

Despite these major gaps, the Ramsar site network for migratory waterbirds is nevertheless greatly more developed in this region than are the site networks elsewhere. By June 2006, Criteria 5 and/or 6 had been applied to only 55 wetlands in North America, 49 in the Neotropics, 44 in Oceania (almost all in Australia), and 70 in Asia outside the African-Western Eurasian region.

Recent analyses by BirdLife International of Important Bird Areas (IBAs) in relation to Ramsar sites in Europe, the Middle East and Africa found that only 24% of European IBAs, 25% of Middle Eastern IBAs and 14% of African IBAs which appear to qualify for Ramsar designation are wholly or partly Ramsar sites (BirdLife International 2001, 2002, 2004). At least a further 2 176 wetlands appear to qualify for Ramsar designation for waterbirds in these regions. This suggests that fewer than one quarter (22%) of wetlands needed to complete the comprehensive international site network for waterbirds (Ramsar Convention 1999) have as yet been designated by Ramsar Parties in Africa-Western Eurasia. However, this is better progress than elsewhere: only 11% of qualifying IBAs in Asia have part or all of their area designated as Ramsar sites (BirdLife International 2005). At least some of these internationally important sites, although not yet designated as Ramsar sites, are protected through classifications other than Ramsar status; for example, as Natura 2000 sites within the EU or as Emerald network sites elsewhere in Europe. However, it is not possible to readily determine the actual extent of functional protection for internationally important wetlands.

Furthermore, the Ramsar Convention recognizes that such site designations are just the starting point for securing wetland conservation and wise use, and that establishing and implementing management plans for all designated sites is essential. Yet in 2002, it was believed that management plans were being implemented for only 35% of Ramsar sites in Europe and 21%

of Ramsar sites in Africa (Ramsar Convention 2002). There is clearly a long way to go to secure the sustainable management of a comprehensive network of sites for waterbirds at flyway scale in Africa and Western Eurasia.

In addition, very few flyway-scale analyses of the conservation status of site networks for specific biogeographical populations have as yet been made. Exceptions are for the Red Knot *Calidris canutus* (Davidson & Piersma 1992), Greenland White-fronted Geese *Anser albifrons flavirostris* (Stroud 1992), and Lesser White-fronted Goose *Anser erythropus* and Red-breasted Goose *Branta ruficollis* (Dereliev 2006). Such analyses should, however, be a key to identifying action priorities to safeguard sites, since it is from the level of biogeographical populations that coherent flyway networks for migratory species need to be built. Such analyses are also necessary to highlight strategically important locations on flyways, the protection of which is critical in terms of individual migratory and eco-physiological strategies.

### Status and trends of African-Western Eurasian waterbird populations

With over 50 years of geographically extensive monitoring of waterbirds in parts of the region, the waterbird research community has a data set which is of unparalleled importance for biodiversity monitoring. This monitoring information has become of even more relevance in relation to the global biodiversity target established by the WSSD in 2002 of “significantly reducing the rate of loss of biological diversity” by 2010, and the even more challenging EU target of halting the decline of biodiversity by 2010.

From information presented in WPE3, indicators of waterbird population status can be derived to assess current status and trends. It is important to note that a suite of such “sub-indicators” is necessary in order to elucidate taxonomic and geographic patterns of status. It is also important to keep in mind that these analyses include only populations with known trends, and that, as described above, there are significant taxonomic and geographic gaps in this knowledge. Given that quantitative knowledge of waterbirds is best in northern, developed countries, there is the real risk of bias in interpretation of data.

Aggregated indices of status are increasingly attractive in that they can be seen to provide a simple answer understandable to policy-makers and decision-takers. However, accurate understanding and interpretation of such aggregated indices is essential if their results are not to be very misleading. As an example of a simple aggregated trend index at high taxonomic level, the median trend for populations in each of the 33 waterbird families covered by WPE3 suggests that more families are in a “healthy” state (13 families stable or increasing) than are not (eight families decreasing or stable/decreasing). But such analyses need to be treated with caution, since in many of those families that appear to be stable overall, there are many populations in decline as well as an equivalent number which are increasing.

A more detailed status assessment shows that the results are not encouraging. WPE3 reports that, of populations with known trends, 45% are decreasing and only 16% increasing in Africa. The picture is slightly better in Europe, where 39% are decreasing and 32% increasing. Thus, 2.8 times as many populations are decreasing in Africa as are increasing, compared with 1.2 times as many in Europe. More populations are decreasing than increasing in all regions of the world, but overall, waterbirds in Europe appear to be in a relatively more healthy state

than in all other regions except North America, where their status is similar. The ratio of decreasing to increasing populations elsewhere is: Asia 3.7 x; Oceania 3.8 x; Neotropics 2.2 x; and North America 1.1 x (Wetlands International 2002).

Recent flyway-scale analyses for African-Western Eurasian waders (International Wader Study Group 2003; Stroud *et al.* 2004, 2006) reveal a similar story. The East Atlantic Flyway is in the healthiest state, with only 37% of populations decreasing. In the Black Sea/Mediterranean Flyway, 65% are decreasing, while in the West Asian/East African Flyway, 53% are decreasing (Fig. 3). Comparison with 1990s population trends indicates that more (eight populations) are in long-term decline than are in long-term increase (three populations). Overall, almost three times as many migratory wader populations are declining as are increasing in the African-Western Eurasian region (Stroud *et al.* 2004, 2006). African resident and island populations have a particularly poor conservation status, yet these populations tend to be ignored with the international focus of attention on migratory populations under, for example, AEWA.

A preliminary analysis for Anatidae suggests that similar declines are widespread across the region. Overall, 43% of the 121 African-Western Eurasian Anatidae populations are decreasing, while only 33% are increasing. Swans (25% decreasing, 75% increasing) and migratory geese (23% decreasing, 50% increasing) have a healthier conservation status than migratory ducks (44% decreasing, 31% increasing) and especially non-migratory populations (45% decreasing and only 14% increasing). Similar analyses for migratory species in other taxa suggest that rails (70% decreasing), cranes (61%), terns (45%), ibises and spoonbills (40%) and herons (40%) have as bad a status as Anatidae and waders, or are in an even worse state. Only grebes and gulls (each 9% decreasing) appear to have a relatively “healthy” status in the region.

Analyses of common characteristics of populations in decline can help point at likely sources of the problem, and can help to focus establishment of priorities for conservation policy and management interventions. For migratory waders, Stroud *et al.* (2004) have identified three groups of populations which are in particular trouble:

- i) populations breeding in the arid and semi-arid zones of western and central Asia and the Mediterranean;
- ii) populations breeding in temperate wet grassland in Europe; and
- iii) certain long-distance, non-stop migrants in the East Atlantic Flyway.

The likely causes of the declines in coastal wintering populations in the East Atlantic Flyway are not yet wholly clear. These populations breed and overwinter in different geographical areas, and share their wintering and/or breeding areas with other populations that are increasing. It may be that the problems are in the migratory staging areas, since it has been established that, for a number of long-distance migrants, high quality feeding opportunities on spring staging areas are of critical importance for the ability both to reach Arctic breeding areas in adequate nutritional condition and for adult survival (Baker *et al.* 2004, Fox 2003, Piersma 1994, Morrison *et al.* submitted). For waders in the East Atlantic Flyway, Davidson (2003) demonstrated a strong relationship between a high dependency on the

**Fig. 3.** The status (percentage of biogeographic populations of known trend which are in decline) of wader populations on the different flyways in the African-Western Eurasian region. The status of African resident populations is also shown. The number above each bar is the percentage of decreasing populations on that flyway. Data source: Wetlands International (2002).

Wadden Sea for spring staging and population declines, and suggested that this may be a consequence of deteriorating site quality resulting from the well-documented changes to the intertidal ecosystem of the Wadden Sea caused by intensive industrial-scale shell-fisheries (Piersma & Koolhaas 1997). Such findings stress the critical importance of maintaining the ecological character of key staging areas for migratory populations – yet many world-wide continue to be destroyed or degraded.

Few such analyses have as yet been undertaken for other waterbird taxa, although the data to underpin them are readily available in WPE3 and elsewhere. For example, the Anatidae in the African-Western Eurasian region which seem to be in particular trouble are those dependent on the Black Sea/Mediterranean region (25% of the decreasing populations of Anatidae), and Madagascan resident populations (13% of the decreasing populations). Further such regional and synoptic analyses are urgently needed for all waterbird taxa.

Industrial-scale dredging for cockles has severely degraded the intertidal sediments of the Dutch Wadden Sea, with wide ecological impacts. Note the two standing people, indicating scale. Photo: Jaap de Vlas.

Conversely, further insights can be gained from a better understanding of why some populations are increasing, whilst others using similar breeding and/or wintering areas are in decline. More attention to increasing populations is needed to establish whether, for example, these are generally the already widespread and common species. Indications that this may be the case come from an aggregated trend indicator under development for a suite of common, widespread Anatidae and wader species in Europe (Wetlands International *in litt.*), which indicates a long-term stability or increase of such populations, contrary to the findings of more holistic analyses reported above.

## CONCLUSIONS

### Waterbird science is not adequately made available to policy-makers and decision-takers

There is a very extensive science base for waterbird populations in the African-Western Eurasian region. There are unparalleled long-term data sets for waterbirds, and developing a clear status assessment (series of indicators) from these will be invaluable for assessing progress towards the 2010 targets established by the world's governments. However, this science base is still not being fully utilized to produce the key messages for those responsible for making decisions and deciding trade-offs between development and the maintenance of the ecological character of the wetlands on which waterbirds depend.

Most of the analyses reported here had to be undertaken for this paper, rather than being, as they should be, readily available "off-the-shelf". The waterbird science community needs to mine these data more imaginatively to identify likely causes of declines. Essential for this is to provide full access to key data sets, especially Wetlands International's *Waterbird Population Estimates*. The current development by the Ramsar Convention of ecological indicators of the effectiveness of Convention implementation, which will include an indicator of waterbird status and trends, may help to focus, encourage and make available to a wide audience, such information.

In addition to the well-warranted attention being paid to populations and threatened species in decline, and especially those which are globally threatened, more attention also needs to be paid to those populations which are increasing, to establish how and why they have increased whilst others using the same flyway, breeding, staging and wintering areas are in rapid decline.

There also appears to be a tendency to focus research and conservation attention only on migratory species and populations in the region, yet it is clear that many resident waterbird populations, especially those which are endemic to islands, are in serious decline (although many are also very poorly known). Indeed a number are already extinct.

Furthermore, very few broad-scale syntheses of status at the flyway and/or higher taxon scale, such as the International Wader Study Group's 2003 Cadiz Conclusions (International Wader Study Group 2003), seem to have been made, yet these form an essential basis to guide effective use of limited conservation resources: we cannot hope to address all the individual conservation issues on a population by population basis, so this

broader analytical approach is needed to determine at which habitats, regions and key sites our resources and conservation actions should be aimed for maximum effect.

Waterbirds have considerable potential as indicators, acting as surrogates of the overall ecological status of wetlands, since they can be, and often are, more readily and easily surveyed than other features of wetlands. However, care does need to be taken in interpretation of waterbird indicators since, for example, common and ubiquitous species can benefit from wetlands in which the water quality is deteriorating through nutrient enrichment. Simplistic indices which aggregate data for all species may give seriously misleading results.

Whilst continuing research and continued monitoring and status assessment of waterbirds are valuable and necessary in gaining further understanding of whether the 2010 biodiversity targets are being met, and in determining what further conservation action is needed, it is not sufficient only to provide listings of such information. More innovative and focused analyses and better presentation of the messages these convey, in forms suitable for raising public and governmental awareness, are essential to point clearly at what is driving the problems – and what policy and management responses are needed.

### Flyway-scale conservation provision for African-Western Eurasian waterbirds is not yet adequate

Despite there being several well-established and long-standing conservation and wise use frameworks for waterbirds in Africa and Western Eurasia, these have yet to realize their full potential as networks of protected areas for waterbirds. Indeed, international designation of wetlands does not in itself deliver their sustainable management. There remain major gaps in the Ramsar site network for waterbirds in the region, notably in Africa and west Asia, and the ambitious AEWA Action Plan and its associated implementation plan have yet to be substantively funded or implemented. Furthermore, there remain significant gaps in AEWA country membership.

Conservation provision for most of the highly threatened waterbirds is also inconsistent. Of the 17 migratory waterbird species globally threatened with extinction, nine<sup>1</sup> are the subject of international action plans (generally those species occurring in Europe) with most existing plans having been driven by the European Union and/or Council of Europe), whilst eight<sup>2</sup> are not (generally those occurring in Africa and the Middle East). All those species without action plans are still declining, whilst at least some with action plans are either stable or increasing in numbers. Lack of international action planning in Africa and the Middle East is a significant issue to address in the immediate future.

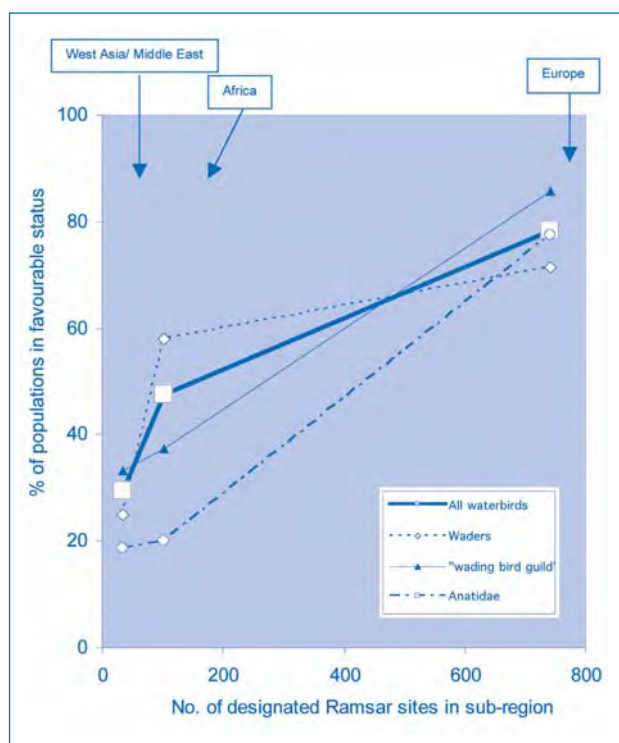

However, there are some indirect indications from the global patterns of waterbird population status that the widespread wetland conservation activity in Europe may have contributed to maintaining waterbirds in a healthier state than would have otherwise been the case, since there are relatively more populations which are increasing in Europe (and similarly in North America) than in other regions of the world. Furthermore, since many

<sup>2</sup> Socotra Cormorant *Phalacrocorax nigrogularis*, Bank Cormorant *Phalacrocorax neglectus*, Madagascar Pond-Heron *Ardeola idae*, Slaty Egret *Egretta vinaceigula*, Blue Crane *Grus paradisea*, Wattled Crane *Grus carunculatus*, White-winged Flufftail *Sarothrura ayresi*, and Black-tailed Godwit *Limosa limosa*.

**Fig. 4a.** The percentages of different waterbird 'guilds' in favourable status (stable or increasing populations) dependent on different African-Western Eurasian sub-regions during the non-breeding season. The category "widespread" is for populations occurring in more than one sub-region. "Fishing guild" is divers, grebes, pelicans and cormorants; "wading bird guild" is herons, storks, ibises and spoonbills, and cranes. No status data is available for "fishing guild" populations in Africa. Data source: Wetlands International (2002).

**Fig. 4b.** The relationship between the number of designated Ramsar sites which are important for waterbirds in each sub-region and the percentage of migratory waterbird populations in favourable status (population trend stable or increasing) which are wholly dependent on that sub-region during the non-breeding season.

waterbirds are more aggregated during their non-breeding seasons than when breeding, it could be predicted that if site safeguard is contributing to securing a favourable conservation status for migratory waterbirds, then those spending their non-breeding

seasons wholly in Europe, with its extensive network of Ramsar sites and other protected areas, would have a more favourable status than those depending on other parts of the region. Analysis of the proportion of migratory populations with favourable status (stable and increasing populations) during the non-breeding season in different parts of the African-Western Eurasian region provides some support for this view (Fig. 4). Of populations which spend their non-breeding season wholly within Europe, 78% are in favourable status, compared with only 47% depending on Africa and just 29% depending on West Asia and the Middle East. As might also be expected, populations which are widespread (occurring in more than one of these sub-regions) have a relatively favourable status (56%). This pattern holds for several different groups of waterbirds: fish-eating birds, wading

birds, duck, geese, swans, waders, gulls, terns and skimmers.

Nevertheless, this is no cause for complacency. Stroud *et al.* (2004) showed that for waders in Africa and Western Eurasia the largest proportion of populations with known status which are declining breed in north-west and western Europe (effectively the European Union - EU15), and consider that, since most of these waders breed in wet grasslands or other low-intensity agricultural land, this is most likely a reflection of Europe-wide agricultural policies which have led to intensification of farming practices (Donald *et al.* 2000). It may therefore be that, whilst broad-scale land-use change is affecting the viability of breeding populations, site-focused conservation action has benefited waterbirds during the period in the non-breeding season when many are more aggregated in their distribution and occur in different habitats. Even if this proves to be the case, it still remains a cause for concern, since to maintain the populations of migratory species, it is pointless to secure their well-being at one stage in their annual cycle whilst other policies lead to their decline at other times of the year. This matter would merit further analysis.

### Many African-Western Eurasian waterbird populations remain in serious decline

Despite the relatively healthy status of waterbirds in Europe in comparison to most other parts of the world, it is clear that many continue to decline; indeed, there are more populations in long-term decline than are increasing, and some populations are in serious long-term decline. For waders, Stroud *et al.* (2004) considered that 45 populations (34% of migratory populations in the Africa-Western Eurasia region) are of significant conservation concern by virtue of their decreasing and/or small populations. Populations in decline exhibit a variety of characteristics, but it is clear that populations dependent on some flyways (notably the Black Sea/Mediterranean and West Asian/East African) and regions (e.g. Africa and especially its islands) are particularly threatened, as are some waterbird taxa (e.g. rails, cranes, ducks and terns) and some populations dependent on West Asia/Middle East or Africa during their non-breeding season.

There are undoubtedly a variety of direct drivers of change to wetlands in Africa and Western Eurasia which are causing these declines, but it seems that broadly it is change in land use leading to loss and deterioration of wetland habitats which remains of major significance. However, in some situations, it is likely that this is being exacerbated by the effects of changing climate; for example, the effects of increasing and prolonged droughts in the Middle East and Central Asia (e.g. Shevchenko 1998). Other aspects of the changing climate may, at least in the short term, benefit some waterbirds. For example, there appears to be a northwards and eastwards shift in the wintering distribution of coastal waders in Britain, which is leading to shorter migration routes to northern breeding grounds (Austin *et al.* 2000, Rehfisch & Austin 2006). However, any benefit gained from reducing migration distances will be counterbalanced if the ecological character of critically important staging areas such as the Wadden Sea continues to deteriorate and/or predicted losses to Arctic breeding habitats occur (Zöckler & Lysenko 2000).

Overall, this assessment of the status of waterbirds in Africa and Western Eurasia indicates that their status is getting worse rather than better, and that much more needs to be done if the 2010 biodiversity targets are to be approached, let alone attained.

### Is waterbird research, monitoring and conservation relevant to human well-being and poverty reduction?

It is clear that securing the health of waterbird populations can make an important contribution to biodiversity conservation, but it is important also to recognize that this can seem largely distant and irrelevant to the governments of developing countries and others charged with addressing the pressing issues of delivering the Millennium Development Goals concerning food and water security, sanitation and poverty reduction. This urgent issue for Africa is reflected in the development and implementation of the New Partnership for African Development, which recognizes that the sustainable management of wetland ecosystems is a key contribution to sustainable development in the continent.

But maintaining the health of ecosystems is fundamentally a matter for societal choice, so it is essential that the science and conservation community gets its message across better to civil society and global governance. However, species-focused arguments are unlikely to have any influence on decision-making on trade-offs between the maintenance of wetland ecosystems and sustainable development, and more potent arguments are likely to involve the importance of maintaining and enhancing ecosystem services so that they continue to support human livelihood. To achieve this requires the maintenance of wetland biodiversity and processes, which in turn will help maintain the ecosystems upon which waterbirds depend. Using waterbirds as flagship indicators of the health of wetland ecosystems can help to secure adequate trade-offs to ensure that these ecosystems can continue to deliver their services. However, more clearly articulating these arguments for continued research and monitoring of waterbirds for the benefit of decision-makers is much needed.

### ACKNOWLEDGEMENTS

We thank Simon Delany and his colleagues at Wetlands International for making available in spreadsheet format data on African-Western Eurasian waterbird populations from *Waterbird Population Estimates - Third edition* (Wetlands International 2002). We also thank Gerard Boere, Peter Bridgewater, Simon Delany, Tony Fox, Lieuwe Haanstra, Bert Lenten, Mike Pienkowski and Theunis Piersma for valuable discussions and information which have helped to develop the ideas addressed in this paper, and Rodney West for preparing Fig. 1. In particular, we thank the many thousands of dedicated waterbird researchers and counters throughout the region who have collected and made available the data and analyses upon which this review paper is based.

Piersma, T. 2006. Migration in the balance: tight ecological margins and the changing fortunes of shorebird populations. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 74-80.

### ABSTRACT

Dependent as they are on rare and remote open habitats for breeding and survival, shorebirds connect continents and hemispheres with their individual movements. Although many of the wetland systems on which shorebirds rely, especially in the rich West, have now some form of protection, two case studies on man-induced declines of Red Knots *Calidris canutus* in The Netherlands and the USA demonstrate that despite the legislation in these countries, the responsible authorities have tragically failed to provide the necessary safeguards. At the same time, these examples indicate how instructive shorebirds can be in elucidating ecosystem changes at local, and at global, scales. I advocate continued close scientific scrutiny of complementary sets of shorebird species so that we can be informed about their fate, and about the fate of ecosystems world-wide that are so effectively connected by their movements.

### INTRODUCTION

Seasonal migration, the phenomenon of birds commuting between parts of the world where they do not reproduce to areas where they do, is a massive phenomenon that has attracted enormous ornithological attention. Shorebirds, or waders, are an important group of truly long-distance migrant waterbirds. These shorebirds connect continents and hemispheres with their individual movements, dependent as they are on rare and remote open habitats for their breeding (mainly in the far north), and on the coastal fringes of the continents or the ephemeral freshwater habitats of continental basins for their survival during the non-breeding season (van de Kam *et al.* 2004, Gill *et al.* 2005). By their very nature, they are particularly susceptible to the effects of human encroachment on coastal habitats, over-exploitation of marine resources, loss of scarce freshwater resources and global climate change (Piersma & Baker 2000,

**Fig. 1.** The world-wide network of flyways of the six subspecies of the Red Knot *Calidris canutus*. The dots scale to the approximate size (in 2004) of the respective wintering populations

Piersma & Lindström 2004). A recent survey by the International Wader Study Group has shown that of 207 shorebird populations with known population trends (out of a total of 511), almost half (48%) are now known to be in decline whereas only 16% are increasing (International Wader Study Group 2003, Stroud *et al.* 2006). With three times as many populations in decline as are increasing, shorebirds must be considered as one of the most globally threatened group of the world's long-distance migrants.

In this contribution, I will focus on two case studies that show how human interference at key staging sites can threaten the survival of supposedly large and healthy migrant shorebird populations. The stories emphasize that the human hand is often involved in population declines. My focal species will be the Red Knot *Calidris canutus*. The first case study concerns the recent population history of Red Knots of the *islandica* subspecies trying to establish themselves in the Dutch Wadden Sea after their return from the breeding grounds in Greenland and north-eastern Canada; the second reveals a similar story for the *rufa* subspecies which, at quite some risk, is now dependent on a single stopover site during its northward migration, Delaware Bay in the USA.

Red Knots are a suitable model species because of their highly specialized feeding behaviour and habitat requirements, which restrict their occurrence outside the breeding season to open coastal intertidal wetland habitats, and their diet to hard-shelled molluscs and crustaceans. Red Knots are sandpipers that breed only on high Arctic tundra but move south from their disjunct, circumpolar breeding areas to non-breeding sites on the coasts of all continents (apart from Antarctica), between latitudes 58°N and 53°S (Fig. 1). Due to their specialized sensory capabilities (Piersma *et al.* 1998), Red Knots generally eat hard-shelled prey found on intertidal, mostly soft, substrates (Piersma *et al.* 1995, 2005a). As a consequence, ecologically suitable coastal sites are few and far between, so they must routinely undertake flights of many thousands of kilometres. The six separate tundra breeding areas each host a population with a sufficiently distinct external appearance during the breeding season (body size and plumage) as to have been assigned subspecific status (Piersma & Davidson 1992, Tomkovich 1992, 2001). There appears to be little overlap in occurrence between any combination of subspecies except for the temporary overlap of some *canutus* and *islandica* Knots in the Wadden Sea, an extensive area of intertidal flats shared by The Netherlands, Germany and Denmark (Davidson & Wilson 1992, Piersma *et al.* 1995, Nebel *et al.* 2000), and of *roselaari* and *rufa* in Delaware Bay in the eastern USA (Piersma *et al.* 2005a, Atkinson *et al.* 2005). The extant Red Knots shared a common ancestor as recently as within the last 20 000 years or so (Baker *et al.* 1994, Buehler & Baker 2005). As a result of a recent expansion from this severely bottlenecked stock, the subspecies show little genetic divergence across their world-wide range (Buehler & Baker 2005, Buehler *et al.* 2006).

Red Knots are amenable to studies in captivity, and this has enabled us to quantify in great detail the relationships between environmental conditions, time budgets, levels of energy expenditure, prey quality and quantity, and relevant features of the digestive tract (e.g. van Gils *et al.* 2003, 2005a, 2005b, Battley *et al.* 2005). Of particular relevance here is the fact that prey is ingested whole and crushed in a strong muscular stomach, or gizzard (e.g. Piersma *et al.* 1999, Zwartz & Blomert 1992,

Battley & Piersma 2005). This information has turned out to be very important in enabling us to interpret information collected in the field.

## THE DECLINE OF *ISLANDICA* KNOTS IN THE DUTCH WADDEN SEA

The intertidal flats of the Dutch Wadden Sea are a State Nature Monument, and are protected under the Ramsar Convention on Wetlands and the EU Habitats and Birds Directives (Reneerkens *et al.* 2005). Despite this high-level conservation status and the widespread scientific and political concerns about the damaging effects of shellfish-dredging to marine benthic ecosystems (e.g. Hall & Harding 1997, Jackson *et al.* 2001, Coleman & Williams 2002, Dayton 2003), until 2004, three-quarters of the intertidal flats of the Dutch Wadden Sea were open to mechanical dredging for edible cockles *Cerastoderma edule*. A direct, immediate effect of dredging is the complete removal of all organisms larger than 19 mm in the top 5-cm layer. As the dredged sites are usually the most biodiverse (Kraan *et al.* 2006), dredging may also affect smaller cockles, other bivalves such as blue mussels *Mytilus edulis*, Baltic tellins *Macoma balthica* and sandgapers *Mya arenaria*, polychaetes, and crustaceans such as shore crabs *Carcinus maenas*. More indirectly, and over longer time scales, sediments lose fine silts during dredging events, it is this that may lead to long-term reductions in settlement success in both cockles and Baltic tellins (Piersma *et al.* 2001, Hiddink 2003). Between the winters of 1997/1998 and 2002/2003, the numbers of wintering Red Knots in north-west Europe declined by about 25% (from c. 330 000 to c. 250 000; unpubl. data of BTO, SOVON and others), and the numbers in the Dutch Wadden Sea by some 80%, from a level of c. 100 000 to 20 000 or fewer (van Roomen *et al.* 2005). Here we ask whether the decline in the Dutch Wadden Sea can be explained by the short- and long-term effects of suction-dredging, and whether this local decline can then explain what has happened in north-west Europe as a whole. The original analysis is provided by van Gils *et al.* (2006a).

We studied dredging-induced changes in food quantity and quality and their effects on digestive physiology and survival in Red Knots. In an area of roughly 250 km<sup>2</sup> in the western Dutch Wadden Sea, we annually sampled the density and quality of knot food in great detail. Each year from early September into December, immediately after completion of our sampling programme, mechanical dredging took place at some of the intertidal flats previously mapped for benthos. Using the black-box GPS data on dredging activity that fishery organizations are obliged to present annually to the Dutch Government (Kamermans & Smaal 2002), we could categorize 1 km<sup>2</sup> sample blocks as dredged or undredged. During the years of the study, Red Knots mostly consumed first-year cockles (58%, based on 174 dropping samples of 50–100 droppings), and for this reason we focused our analysis on the effects of dredging on freshly settled, first-year cockles (the so-called “spat”; 16 mm).

It emerged that in dredged areas densities of cockle spat remained stable, whereas densities increased by 2.6% per year in undredged areas (van Gils *et al.* 2006a). This result is consistent with a previous assessment that showed that dredged areas become unattractive for cockles to settle in, perhaps because such sediments lose silt and good structure (Piersma *et al.* 2001). In addition, the quality of cockle spat declined by 11.3% per year in dredged areas and remained stable in undredged areas,

**Fig. 2.** The percentage of intertidal area in the western Dutch Wadden Sea that yielded insufficient intake rates for Red Knots *Calidris canutus* ( $< 4.8$  W) increased between 1998 and 2002 due to an increase in blocks made unsuitable by dredging in previous years (filled bars, as opposed to open bars indicating unsuitable blocks that were never dredged). Based on an analysis of 272 sample blocks of one km<sup>2</sup> (van Gils *et al.* 2006b).

something we explain by supposing that coarser sediments lead to worse feeding conditions (Drent *et al.* 2004) and therefore to reduced body condition in deposit-feeding bivalves such as freshly settled cockles (Rossi *et al.* 2004). Thus, both the abundance and the quality of the food of Red Knots decreased in areas where dredging took place. The consequences of these declines were quantified by calculating, for each year, the percentage of the intertidal area that would yield insufficient intake rates for Red Knots to maintain a positive energy balance (Fig. 2). In the Wadden Sea, only a limited part of the available intertidal flats is rich enough in suitable prey to be of any use to foraging Red Knots (Piersma *et al.* 1995, van Gils *et al.* 2006b). From 1988 to 2002, the percentage of 1 km<sup>2</sup> blocks that were too poor for Red Knots to obtain a threshold intake rate of 4.8 W increased from 66% to 87% (van Gils *et al.* 2006a). This loss was entirely due to an increase in previously suitable blocks that were dredged; the number of previously unsuitable (and undredged) blocks did not increase.

As a consequence of the widespread dredging in the most biodiverse areas of intertidal flat (Kraan *et al.* 2006), diet quality declined by 11.7% per year and, to compensate for such reductions in prey quality, Red Knots should (Dekinga *et al.* 2001, van Gils *et al.* 2003) and did (van Gils *et al.* 2006a) increase gizzard mass. Nevertheless, re-sightings of individually colour-banded birds of which the gizzards were measured before release demonstrated that birds not seen in our study area within a year after release had undersized gizzards, whereas individuals that we did see again had gizzards that enabled them to achieve a balanced daily energy budget (van Gils *et al.* 2006a). The local annual survival rate (calculated from re-sighting rates of colour-banded birds) increased with year-specific food quality. In summary, this means that birds arriving from the tundra breeding areas with too small a gizzard needed more time to adjust their gizzard than their fat stores allowed them: they faced starvation unless they left the area.

Colour-banded Red Knots that disappeared from our study area may have died or, perhaps more likely for a wide-ranging migrant, emigrated to other areas such as estuaries in the UK. Here they probably paid a mortality cost due to the extra travel

and/or due to uncertainties in the food supply at their new destination. Whatever happened to them, the dramatic decline in numbers of Red Knots wintering in the Dutch Wadden Sea can be satisfactorily explained by these documented population effects of deteriorating feeding conditions (van Gils *et al.* 2006a). The local disappearance can also account for much of the 25% decline of the entire north-west European wintering population over the same period. We must thus conclude that the industrial forms of commercial exploitation allowed by the Dutch Government in one of its best legally protected nature reserves have been directly responsible for the population decline of a long-distance migrant shorebird species which itself is fully protected. Precisely the same conclusion has been reached in studies of the decline of another fully protected shellfish-eating shorebird, the Eurasian Oystercatcher *Haematopus ostralegus*, in the Dutch Wadden Sea (Verhulst *et al.* 2004) and a nearby estuary (the Wash) in the UK (Atkinson *et al.* 2003).

### THE DECLINE OF *Rufa* KNOTS USING DELAWARE BAY AS A STAGING SITE

Most of the *rufa* subspecies of Red Knots make an enormous annual return migration of 30 000 km between over-wintering sites in Tierra del Fuego and breeding sites in the Canadian Arctic. To achieve this feat, they must make stopovers at a few productive refuelling sites at strategic locations in the flyway. As these Red Knots are moving northwards to their breeding grounds in the central Canadian Arctic, the timing of departure from the stopover sites becomes increasingly synchronized, and at the last stopover site in Delaware Bay, departure for the breeding grounds occurs within a period of a few days (Myers 1986, Clark *et al.* 1993). Here, in Delaware Bay, Red Knots feed almost exclusively on a superabundant supply of eggs of spawning horseshoe crabs *Limulus polyphemus* (Castro & Myers 1993, Tsipoura & Burger 1999). This has traditionally enabled them to approximately double their body mass from 90–120 g on arrival to 180–240 g on departure (Baker *et al.* 2001). At an average rate of mass increase of 4.6 g/day (Piersma *et al.* 2005a), the highest recorded, the birds need to refuel over a period of approximately 17 days. Birds depart from Delaware Bay *en masse* on about 28–30 May each year (Baker *et al.* 2001). Based on an average fat-free mass of 130 g (Piersma 2002), Red Knots need to achieve a departure mass of at least 180–200 g just to cover the costs of the flight to the breeding grounds and to survive an initial few days of snow cover.

Over the past 15 years, there has been a dramatic increase in the commercial fishery of horseshoe crabs by so-called “watermen”. This fishery, which provides bait for eel and conch fisheries, began in 1990 and peaked in 1995/96 (Walls *et al.* 2002). There was a six-fold decline in the numbers of horseshoe crabs caught in survey trawls in Delaware Bay by the Delaware Division of Fish and Wildlife (Andres 2003). The analyses by Baker *et al.* (2004) have provided strong evidence that the decline in food resources at this last stopover site during northward migration is negatively impacting the staging *rufa* population. Baker *et al.* (2004) showed that the proportion of well-conditioned Red Knots (200 g or greater) in Delaware Bay near the departure time in late May decreased significantly by 70% between 1997/98 and 2000/02. Within 2–3 days of the mass departure for the Arctic, mean body masses declined from 183 g in 1997 to 162 g in 2002. The annual survival of birds marked and re-sighted in Tierra del

**Fig. 3.** Locations of recoveries and re-sightings (up to December 2005) yielded by 2 400 Ruffs *Philomachus pugnax* that were captured in the spring of 2004 and 2005 in south-west Frysland, The Netherlands, and marked with individual colour-ring combinations.

Fuego and Patagonia declined significantly from an average of 87% in the three migration years from 1994/95 to 1997/98 to 55% in the ensuing three year period to 2000/01 (Baker *et al.* 2004). On the basis of a larger mark-recapture data set for the whole flyway (Tierra del Fuego, Patagonia, southern Brazil and Delaware Bay) for the period 1993/94 to 2001/02, Baker *et al.* (2004) detected a similar large decline in annual survival, and pinpointed it to after the birds left Delaware Bay in 2000.

The increases in annual mortality were reflected in the aerial censuses of the non-breeding flocks in Tierra del Fuego: there were 51 000 Red Knots in February 2000, 37 000 in February 2001 and 27 000 in January 2002 (Morrison *et al.* 2004), confirming the large mortality in 2000. The peak count of Red Knots during the stopover in Delaware Bay in May 2000 was only 5 000 lower than the peak count in 1999, again suggesting that the largest loss of birds occurred after departure from this key site. A demographic model suggested that if the 1997/98 to 2000/2001 levels of annual survival were to prevail, *rufa* knots would reach extremely low numbers by 2010 (Baker *et al.* 2004). The aerial census data collected on the non-breeding

grounds in Tierra del Fuego (Morrison *et al.* 2004, pers. comm.) have so far confirmed this doomsday scenario.

The over-harvesting of horseshoe crabs in Delaware Bay has led Red Knots to concentrate their feeding activity on fewer and fewer sites where crab eggs are still abundant. The increasing dependence of birds on so few vulnerable areas and the increasing proportion of birds in poor condition at the time of departure now seem to threaten the viability of the *rufa* subspecies.

#### SHOREBIRDS AS INTEGRATIVE SENTINELS OF GLOBAL ENVIRONMENTAL CHANGE

As the two foregoing case studies have shown, even shorebirds that embrace the entire globe within their migration routes provide us with information about local environmental changes. At the same time, they integrate phenomena at larger spatial scales. As proposed by Piersma & Lindström (2004), variations in the number, phenotype and behaviour of particular shorebirds could help provide us with biological “integrators” of global environmental information in ways that no network of observers

could realistically ever give us. Weather stations and GIS analyses of land use can tell us about ongoing changes, but bird populations integrate this information in potentially insightful and surprising ways. To illustrate the use of shorebirds as integrative sentinels of our changing world, I will now briefly introduce a third case, involving long-term studies of a species that is doing rather well, the Eurasian Golden Plover *Pluvialis apricaria*. Annual catches of 2 000–3 000 Golden Plovers that make autumn and spring stopovers in The Netherlands have enabled us to monitor their breeding success (a likely function of body condition in spring, summer weather and predator densities) (Jukema *et al.* 2001). We have also been able to follow changes in the degree of stopover site philopatry (a function of the quality of the staging area in terms of food and predation risk), condition and moult in autumn (a function of the food quality at the staging area, that is itself partly weather dependent), timing of southward migration (possibly a function of the quality of the staging area and weather), wintering area (a function of weather, food and predators further south), alternative staging sites in spring (a function of weather and food), condition and moult in spring (a function of weather, food and predation risk), and population size (a demographic function of “everything” listed above) (Jukema *et al.* 2001, Piersma *et al.* 2005b).

Thus, even with relatively simple programmes such as this, we can monitor life cycles that integrate environmental factors from the whole of western and northern Europe. It would be even more informative if sets of complementary species were monitored in similar ways. For example, inclusion of the Northern Lapwing *Vanellus vanellus* and Ruff *Philomachus pugnax* in the comparison would enable us to distinguish between environmental changes on the breeding grounds (the three species breed in different habitats) and on the wintering grounds (the Northern Lapwing and Eurasian Golden Plover winter in Europe, the Ruff in tropical Africa) or en route (they show considerable overlap in the staging areas). Inclusion of shorebird species frequenting intertidal staging areas, such as the Red Knot and Bar-tailed Godwit *Limosa lapponica*, would further increase the scope for relevant comparisons and enable the rejection of more competing explanatory hypotheses. If the Eurasian Golden Plover, Red Knot and Bar-tailed Godwit all showed population declines, but Ruff and Northern Lapwing did not, changes occurring in the northern dry tundra might provide a suitable explanation, especially if the percentage of juveniles in the catches was low. However, if only the Ruff decreased, we would seek changes in the environmental conditions in the Sahel region of Africa, especially if such a decline coincided with reduced survival rates, late arrival in spring, and arriving birds that were lean and showed little development of their nuptial plumage.

Thus, in a comparative framework, the failures and fortunes of migrating shorebirds could be highly informative about the state of their world as well as ours (Piersma & Spaans 2004). In the case of the Ruff, my research team at the University of Groningen recently individually colour-marked as many as 2 400 birds over two spring seasons. All these birds were captured by traditional methods by artisanal bird-catchers (the “wilsternetters”), a group of ringers that also keeps a tally of Eurasian Golden Plovers (Jukema *et al.* 2001). Observers over much of Europe and in West Africa ensured that within a short period of time quite a comprehensive picture of the flyway of Ruffs staging in the west of the province of Fryslân was built up (Fig. 3; Piersma 2006). The fact

that this has been achieved within two years of study also means that we should be able to document changes in flyways in real time; flyway changes that, as we have seen, may often be a consequence of human-induced habitat loss and modification.

## ACKNOWLEDGEMENTS

I am grateful to Gerard Boere and David Stroud for inviting me to contribute to the Edinburgh Conference and to Gerard for being an understanding but persistent compiler of the proceedings. I thank my dear colleagues in the wader world for providing such a congenial social and intellectual environment in which to worry about the future of the earth’s biota, and to jointly do as much as we can to turn the tide.

Mundkur, T. 2006. Successes and challenges of promoting conservation of migratory waterbirds and wetlands in the Asia-Pacific region: nine years of a regional strategy. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 81-87.

### ABSTRACT

The Asia-Pacific Migratory Waterbird Conservation Strategy is an international cooperative initiative for the conservation of migratory waterbirds and wetlands, involving governments, conventions, NGOs and local people. Launched in 1996, the Strategy is coordinated by a free-standing international committee, comprising representatives of governments, the Ramsar Convention, CMS, UNDP/GEF, UNEP, NGOs and technical experts. The Strategy provides a framework for the development and implementation of action plans for migratory waterbird species (Anatidae, cranes and shorebirds) in the East Asian-Australasian region, and through it, networks of internationally important sites have been developed. These networks serve as a focus for site-based conservation efforts, including networking, training, awareness raising, research and sound management of wetlands, through international cooperation and resource mobilization. Based on the successes during the period 1996-2000, the Strategy was renewed for a second five-year period (2001-2005). An Action Plan for the Central Asian Flyway is being developed as a framework for this region. The Strategy is recognized by the Ramsar Convention on Wetlands and the Convention on Migratory Species of Wild Animals through a number of Resolutions. This paper presents a review of the approaches used in the initiative, its successes and challenges, in a region dominated by developing countries.

### INTRODUCTION

The Asia-Pacific region is home to over 243 migratory waterbird species, including 49 threatened species. The region also contains over half the world's human population and the highest economic growth rates in the world, creating enormous pressures on wetlands and other natural habitats. Efforts to promote international cooperation have been ongoing through a range of different programmes. However, the outcome of an international meeting organized in Kushiro, Japan, in December 1994 and attended by government representatives, convention representatives and technical experts from across the East Asian-Australasian region was a turning point in the development of an international cooperative framework as outlined in the "Kushiro Statement". The Asia-Pacific Migratory Waterbird Conservation Strategy (Anonymous 1996) was launched in conjunction with the Sixth Conference of the Parties to the Ramsar Convention in Brisbane, Australia, in 1996, as a five-year regional initiative to enhance the long-term conservation of migratory waterbirds and their wetland habitats involving governments, conventions, NGOs and local people. With a primary focus on the East Asian-

Australasian Flyway and on three groups of migratory species (Anatidae, cranes and shorebirds), a wide range of activities were undertaken to promote conservation. Flyway Action Plans served as the main tool in promoting conservation activities in the region, and networks of internationally important waterbird sites (established for shorebirds in 1996, cranes in 1997 and Anatidae in 1999) have provided a framework for site-based management, education and training activities.

Based on the success of the Strategy in its first five years, an international conference held in Okinawa, Japan, in October 2000 called for the continuation of the Strategy (as embodied in the "Okinawa Statement"), and recommended that countries in the region should enhance mechanisms for collaborative action to conserve waterbird species and their habitats, specifically through: (1) action plans for species groups and globally threatened species; and (2) effectively managed networks of sites that are internationally important for migratory waterbirds.

As a consequence, a second five-year Strategy was launched in 2001 and concluded in 2005 (Asia-Pacific Migratory Waterbird Conservation Committee 2001). Discussions are now focused on developing frameworks for post 2005, through the development of a stronger partnership framework linked to a WSSD Type II initiative to conserve migratory waterbirds in the East Asian-Australasian Flyway, and development of an Action Plan for migratory waterbirds and their habitats in the Central Asian Flyway.

The philosophy of the Strategy and the process of its development were first described by Mundkur & Matsui (1997) and Weaver (1997). Reviews of the Strategy and its achievements were presented at the first and second International Conference on Wetlands and Development held in Malaysia in November 1996 and Senegal in November 1998, and reported in Mundkur & Matsui (1998) and Mundkur *et al.* (1999), respectively. This paper is the fifth in the series; it outlines the scope of the current Strategy, and provides a review of the approaches used in the initiative, its successes and challenges, in a region dominated by developing countries.

### SCOPE OF THE STRATEGY

#### Geographic area and flyways

The Asia-Pacific region, as defined by the main migratory routes of waterbirds, extends from the Urals across Siberia to Alaska (USA) and southwards across East, Central, South and South-east Asia, Australasia and the Pacific islands, and covers about 57 countries and territories.

Within this region, there are three main migratory waterbird flyways, the Central Asian, East Asian-Australasian and Central Pacific. Some species and species groups have smaller flyway ranges within these broader flyways. In addition, some of the major flyways that extend into Europe, Africa and the Americas also have their origins in the northern latitudes of continental Asia. Here they converge with the flyways of the Asia-Pacific region and overlap in many important breeding, moulting and staging sites.

Conservation of migratory waterbirds in the adjoining flyways is covered by the African-Eurasian Waterbird Agreement (AEWA) under the Convention on Migratory Species of Wild Animals, and the North American Waterfowl Management Plan (NAWMP) and Western Hemisphere Shorebird Reserve Network (WHSRN) in the Americas. The Strategy thus complements these major frameworks to conserve the migratory waterbirds of the world.

### Waterbird species

The Strategy adopts the Ramsar Convention definition of waterbirds, i.e. “birds ecologically dependent on wetlands” (Ramsar Convention Secretariat 2002), with the exception of the wetland-related raptors (Accipitriformes and Falconiformes), coucals (Cuculiformes) and wetland-related owls (Strigiformes), and covers twenty groups of waterbirds (see Table 1 for a list of families). It covers 243 waterbird species, including 49 globally threatened species (BirdLife International 2001, 2003, Wetlands International 2002). Some of these threatened species, such as Oriental White Stork *Ciconia boyciana*, Swan Goose *Anser cygnoides*, Scaly-sided Merganser *Mergus squamatus*, Nordmann’s Greenshank *Tringa nordmanni* and Spoon-billed Sandpiper *Eurynorhynchus pygmeus*, are restricted to the Asia-Pacific region.

**Table 1. Waterbird families included in the Asia-Pacific Migratory Waterbird Strategy.**

Taxonomic group	English name
Gaviidae	Divers (loons)
Podicipedidae	Grebes
Phalacrocoracidae	Cormorants
Pelecanidae	Pelicans
Ardeidae	Herons, egrets and bitterns
Ciconiidae	Storks
Threskiornithidae	Ibises and spoonbills
Phoenicopteridae	Flamingos
Anatidae	Swans, geese and ducks
Gruidae	Cranes
Rallidae	Rails, gallinules and coots
Heliornithidae	Finfoots
Jacaniidae	Jacanas
Dromadidae	Crab Plover
Haematopodidae	Oystercatchers
Recurvirostridae	Stilts and avocet
Glareolidae	Pratincoles
Charadriidae	Plovers
Scolopacidae	Sandpipers
Laridae	Gulls, terns and skimmers

Note: Shorebirds (waders) include jacanas, Crab Plover *Dromas ardeola*, oystercatchers, stilts and Avocet, pratincoles, plovers and sandpipers.

**Table 2. Priority areas of the Asia-Pacific Migratory Waterbird Conservation Strategy: 1996-2000.**

#### Conservation of habitats

- Enhancement of site conservation
- Establishment of flyway reserve networks

#### Conservation of species

- Development and implementation of migratory waterbird conservation action plans
- Promotion of the sustainable management of migratory waterbirds

#### Research and monitoring

- Promotion of conservation-oriented monitoring and research activities
- Establishment of advanced migratory waterbird and wetland information storage and retrieval systems

#### Education, information and awareness

- Increased education and public awareness
- Promotion of information flow among waterbird and wetland conservation researchers
- Training of personnel associated with the survey, study and management of waterbirds and their habitats

#### Policy and legislation

- Review and strengthening of waterbird and habitat conservation policies and legislation
- Development of an Asia-Pacific Multilateral Migratory Waterbird Conservation Agreement

The Strategy has taken the approach of promoting the conservation of groups of waterbirds, focussing its efforts primarily on three groups, Anatidae (ducks, geese and swans), shorebirds (or waders) and cranes in the East Asian-Australasian region under three species-group Action Plans. In addition, it has served as a framework to promote conservation of globally threatened species.

### Coordination

The Strategy is coordinated by an international committee, the Asia-Pacific Migratory Waterbird Conservation Committee (MWCC), comprising representatives of governments, the Ramsar Convention on Wetlands, the Convention on Migratory Species of Wild Animals (CMS), UNDP/GEF, UNEP and three international NGOs, as well as the Chairs of the Anatidae, Crane and Shorebird Working Groups and a representative of Wetlands International’s Specialist Groups (19 members as at April 2004). The MWCC is currently chaired and co-chaired by Australia and Japan, respectively. The MWCC maintains overall responsibility for coordinating, monitoring and reporting on implementation of the Strategy, fund raising, development of projects, and over-seeing activities of the Strategy Coordinator.

A Strategy Coordinator provides secretariat support to the Committee and liaison with the Working Groups. Three Flyway Officers coordinate implementation of the three action plans in the East Asian-Australasian Flyway. A Central Asian Flyway Officer coordinates development of activities in the Central Asian Flyway. Four staff operate from offices of Wetlands International (in Australia, India, Japan and Russia), while the coordinator for cranes is employed by the Wild Bird Society of Japan. Core support has been provided by the Australian Department of the Environment and Heritage, Ministry of the Environment, Japan,

**Table 3. Overview of actions implemented that contribute to achieving outcomes of the Asia-Pacific Migratory Waterbird Conservation Strategy: 2001-2005.**

Elements	Selected actions undertaken and outcomes achieved
1. Action plans for species groups and globally threatened species.	<ul style="list-style-type: none"> <li>Action Plans for Anatidae, cranes and shorebirds in the East Asian-Australasian Flyway updated for 2001-2005.</li> <li>North East Asian Crane Action Plan and Site Network extended to cover conservation action for the globally threatened Oriental White Stork <i>Ciconia boyciana</i>.</li> <li>International task forces established to develop conservation plans for selected globally threatened species: <ul style="list-style-type: none"> <li>Swan Goose <i>Anser cygnoides</i></li> <li>Baikal Teal <i>Anas formosa</i></li> <li>Spoon-billed Sandpiper <i>Eurynorhynchus pygmeus</i></li> </ul> </li> <li>Synergies developed with the UNEP/GEF/ICF Siberian Crane <i>Grus leucogeranus</i> project in two flyways across Asia.</li> <li>Coordination improved with monitoring and conservation groups for the threatened Black-faced Spoonbill <i>Platalea minor</i> in East Asia.</li> <li>Current status of the threatened White-headed Duck <i>Oxyura leucocephala</i> in Central Asia assessed.</li> <li>Increased marking and study of movements of the threatened Saunders's Gull <i>Larus saundersi</i> in East Asia.</li> </ul>
2. Effectively managed networks of sites that are internationally important for migratory waterbirds.	<ul style="list-style-type: none"> <li>Site Networks for Anatidae, cranes and shorebirds in the East Asian-Australasian Flyway, established during 1996-1999, have been strengthened by the addition of internationally important sites (as at April 2004, the networks covered 80 sites in 13 countries – see table 4).</li> <li>Increased visibility and recognition of sites at national and international level.</li> <li>Range of activities undertaken at network sites (and other important sites) including: <ul style="list-style-type: none"> <li>Public awareness and information dissemination</li> <li>Management planning of sites</li> <li>Training courses for site managers</li> <li>Field surveys at network sites and other important sites</li> <li>Monitoring and migration studies of waterbirds</li> <li>Art exhibitions on nature</li> <li>Crane Research Handbook of Field Study and Shorebird Study Manual produced and widely used.</li> </ul> </li> </ul>
3. Raised awareness of waterbirds and their link to wetland values and functions throughout the region and at all levels.	<ul style="list-style-type: none"> <li>A range of educational and awareness resources produced in many languages.</li> <li>Annual awareness-related activities promoted and implemented across the region, at network sites and other important areas, involving a wide range of stakeholders including politicians, government officials, school and college students, and local people at network sites.</li> <li>Awareness-related activities linked and integrated with national and international events such as World Wetlands Day (2 February).</li> <li>Wetland centres promoted and facilitated to implement awareness raising activities.</li> </ul>
4. Increased capacity of government agencies and non-governmental organizations to implement conservation actions for migratory waterbirds.	<ul style="list-style-type: none"> <li>Securing of government and other funding support for conservation, public awareness, education and research activities at the site, national and international level.</li> <li>Identification of new sites of national and international importance through survey activities.</li> <li>Strengthening of local capacity to manage wetland and waterbird conservation through organization of training courses.</li> <li>Study tours and visits organized for network site stakeholders nationally and internationally to build linkages and improve understanding of management and conservation practices.</li> <li>Increased involvement of community and children in the study and conservation of waterbirds and wetlands.</li> </ul>
5. Developed knowledge base and facilitated information exchange for the sound management of migratory waterbirds and their habitats.	<ul style="list-style-type: none"> <li>Regional waterbird and habitat monitoring programmes such as the Asian Waterbird Census strengthened through building of national networks (coordinated by Wetlands International).</li> <li>Improved cooperation on the study of migratory routes of waterbirds through adoption of flyway-wide colour marking schemes, such as through development of the Asia-Pacific Shorebird Colour Flagging Protocol.</li> <li>Development of a Science Action Plan for the Dunlin <i>Calidris alpina</i>.</li> <li>Up-to-date information on waterbirds, threats and conservation priorities collected and disseminated as technical and non-technical information through a range of media in English and several Asian languages.</li> <li>Publication of important regional information sources on waterbirds and wetlands including: Threatened Birds of Asia: the BirdLife International Red Data Book (2001) and Saving Asia's threatened Birds: a guide for government and civil society (2003) by BirdLife International, and Waterbird Population Estimates – Third edition (2002) and Numbers and distribution of waterbirds and wetlands in the Asia-Pacific region. Results of the Asian Waterbird Census: 1997-2001 (2004) by Wetlands International<sup>1</sup>.</li> </ul>

<sup>1</sup> This publication was formally launched at the Waterbirds around the world Conference.

**Table 3 (cont).** Overview of actions implemented that contribute to achieving outcomes of the Asia-Pacific Migratory Waterbird Conservation Strategy: 2001-2005.

Elements	Selected actions undertaken and outcomes achieved
5. Developed knowledge base and facilitated information exchange for the sound management of migratory waterbirds and their habitats. (Continued)	<ul style="list-style-type: none"> <li>• Development of four web-sites dedicated to informing the public about activities and issues relating to water-bird conservation.</li> <li>• Establishment of list servers and e-groups to promote information exchange on waterbird and wetland issues amongst people within the Asia-Pacific region (and globally).</li> <li>• Organization of international and national training courses and meetings to share expertise and information on waterbird and habitat management issues.</li> </ul>
6. Harmonized national and state policies and legislation as a foundation for the conservation of migratory waterbirds and their habitats.	<ul style="list-style-type: none"> <li>• Promotion of increased implementation of policies and legislation in response to resolutions and programmes of global conventions dealing with migratory waterbirds and their habitats:               <ul style="list-style-type: none"> <li>A. 7. Enhanced organizational relationships at all levels to increase cooperation and deliver greater conservation benefits.	<ul style="list-style-type: none"> <li>• Promoting awareness and support for the Strategy at a national and local level.</li> <li>• Seeking greater cooperation of all stakeholders (governments, research institutes, development agencies, business sector, local communities and others).</li> <li>• Implementation of actions outlined in the Strategy and species-group Action Plans through involvement of all stakeholders.</li> <li>• Strengthening the roles of NGOs in implementation of the Strategy.</li> <li>• Reporting on progress on implementation to meetings of the Ramsar Convention, CMS, BirdLife International and Wetlands International.</li> </ul>
8. Adequate planning and resources to implement the Strategy.	<ul style="list-style-type: none"> <li>• Strengthening of international coordination and communication through regular meetings of the MWCC involving a range of stakeholders.</li> <li>• Team of strategy and flyway coordination officers engaged to coordinate implementation of activities.</li> <li>• Resources implemented for activities from an increasing range of government, corporate, non-governmental and private partners and supporters.</li> </ul>

U.S. Fish and Wildlife Service and Government of The Netherlands.

Originally established under the aegis of the Wetlands International – Asia Pacific Council, in 2003 the MWCC became a free-standing committee that reports directly to the Ramsar Convention, CMS, BirdLife International and Wetlands International.

### Focus of the Strategy

The two Strategies have aimed to respond broadly to the issues of habitat destruction and loss, species declines, low public

awareness and support, and limited institutional capacity to manage and monitor waterbirds and their habitats. The Strategy 1996-2000 was structured along six broad and overlapping themes with a total of 11 objectives and a number of priority actions defined for each objective (Table 2). Based on the experience of assessing the progress that had been made during these first five years, the MWCC restructured the Strategy 2001-2005 such that it was presented as eight key elements with a number of expected outcomes for each element (Table 3). In recognition of the challenges and time needed for the development of a formal international agreement without strong interest and

commitment from the many governments concerned, no specific action to develop such an agreement was proposed within the timeframe of the second Strategy.

### Achievements to date

The Strategy has called for activities to be undertaken at the international, regional and national level. These activities have primarily been developed separately along the different flyways, although some activities have been more region-wide (such as the monitoring of waterbirds; see Li & Mundkur 2004). A range of activities, including promoting awareness, improving understanding of the migration strategies and conservation needs of waterbirds, and building local capacity to monitor and manage waterbirds and wetlands, have been implemented (Table 3). This work has been achieved largely through encouraging participation of an increasing number and range of stakeholders: governments, NGOs, academe, technical institutions, development agencies, etc. The East Asian-Australasian Flyway has remained the primary region of flyway-wide activities over the last nine years, although during the last few years coordinated work across the Central Asian Flyway has increased.

The three species-group Action Plans prepared during the first Strategy in the East Asian-Australasian Flyway have been reviewed and updated, and have continued to serve as the main tool for implementation of activities (Table 3). The three existing site networks have continued to serve as a focus for site-based conservation efforts for Anatidae, cranes and shorebirds. As at April 2004, thirteen countries, Australia, People's Republic of China, Indonesia, Japan, Democratic People's Republic of Korea, Republic of Korea, Malaysia, Mongolia, New Zealand, Papua New Guinea, Philippines, Russian Federation and Singapore, had nominated eighty sites of international importance for migratory waterbirds to the site networks (Table 4, Fig. 1). Of these, eight sites have been nominated to more than one network in recognition of their importance for multiple waterbird groups. Although the network sites cover both coastal and inland wetland habitats, a slightly larger number are currently coastal wetlands. Fifty-eight percent of the sites are also listed as wetlands of international importance under the Ramsar Convention, enabling a close linkage of many conservation activities under these two frameworks.

To date, many activities in the Central Asian Flyway have focussed on collation of information on waterbird distribution and abundance under the umbrellas of the International Waterbird Census (Gilissen *et al.* 2002) and Asian Waterbird Census (Li & Mundkur 2004), and revitalization of interest and linkages amongst agencies and institutions through rebuilding the capacity of expert networks, especially within the Central Asian countries (see Solokha *et al.*, this volume). The development of a Flyway Action Plan to promote action for all migratory waterbirds was recognized as a priority, and the first major meeting of flyway range states, organized in Tashkent, Uzbekistan, in 2001, has provided an impetus for its development (CMS Secretariat 2001). A follow-up meeting to finalize the Action Plan took place under the aegis of the CMS in New Delhi, India, in 2005.

Over the last few years, new information collected through activities implemented under the Strategy has benefited the production of a number of important global, regional and national reference publications on the status of species and their

**Table 4.** Status of the site networks for Anatidae, cranes and shorebirds in the East Asian-Australasian Flyway (as at April 2004).

Total number of sites designated on three networks	80
• East Asian-Australasian Shorebird Site Network	35
• North East Asian Crane Site Network	26
• East Asian Anatidae Site Network	27
Total number of sites also listed as Ramsar sites	46 (58%)
Number of countries involved in the site networks	13

habitats, such as those by BirdLife International and Wetlands International (Table 3). These references have in turn provided valuable guidance and support for activities and local publications and information resources.

Based on the wide range of activities undertaken during the last nine years, as summarized in Table 3, it is evident that the Strategy has proven to be an important regional initiative with involvement and support from a large number of national and local stakeholders and international partners, including multilateral environmental agreements and non-governmental organizations.

At the international level, the implementation of the Strategy has been widely recognized and supported by two important multilateral environmental agreements, the Ramsar Convention and the CMS. The Conferences of the Parties to these Conventions have passed six resolutions and recommendations at their triennial meetings that support or highlight the main

activities of the Strategy (Table 3). In addition, the activities of the Strategy have provided a mechanism for implementing a number of other resolutions of these two Conventions concerning promotion of wetland and species conservation, building local capacity, dissemination of information, monitoring of wetlands and their waterbirds, increasing awareness and public education, etc. The Strategy has also directly contributed to the priorities of the Convention on Biological Diversity, particularly with respect to protected areas, inland wetlands, public awareness and capacity building.

Implementation of the Strategy for migratory waterbirds has benefited resident birds and other wetland species through raised awareness of conservation issues and improved management of important waterbird sites. Thus migratory waterbirds have proved to be an important flagship group that can serve to unite people across the region to promote the conservation of a common heritage and resource.

### CHALLENGES AND PRIORITIES

The Asia-Pacific region is the most populated part of the globe, with a majority of developing countries or countries in transition where the primary focus remains national development, industrialization and improvement of the living standards of the people. Here, the development of conservation initiatives for migratory waterbirds and their habitats is normally given a much lower priority than human development and progress. While implementation of the Strategy has been quite successful in developing local awareness, capacity and interest in waterbird and habitat conservation, a lot more effort, activities and resources are needed to continue and strengthen the work. The main priorities include:

- **Enhancing awareness raising:** Actions to raise awareness need to be enhanced for decision makers, policy makers and the corporate sector.
- **Broadening government involvement:** Government agencies involved to date have been largely limited to the ministries responsible for the environment and forests. Engagement of government agencies responsible for the use and management of wetlands is also needed to enable sustainable development of the wetlands; such agencies include those responsible for water resources, irrigation, agriculture, fisheries, power supply, military, ports, industry, transport, rural development, etc. at the national and sub-national levels.
- **Enhancing species coverage:** The Strategy has focussed on three species groups; additional actions are needed to promote conservation of the ten other species groups covered by the Strategy and the large number of sites of importance for these species. Although good information has been collected on the status and distribution of some species, information across all countries is still lacking and serves as an impediment to quantifying their status and trends.
- **Enhancing site coverage of the networks:** The focus of the Strategy has been to obtain recognition for internationally important sites for migratory waterbirds, especially through the establishment of networks of international important sites in the East Asian-Australasian Flyway. Work undertaken during the Strategy indicates that there are at least 600 sites for migratory shorebirds, cranes and Anatidae (with additional sites for other species). The network of sites

currently includes only 80 sites (13%). Even though new sites are being added to the Site Networks each year, it is unlikely that the targets identified in the Strategy will be achieved unless strategies for site designation are enhanced.

- **Enhancing country coverage:** While the number of national and local partners is increasing, the initiative has not been able to involve all the countries in the region. Particularly in South-east Asia, where the Shorebird Network covers the entire region and the Anatidae Network covers some countries, very few sites have been designated compared to the large number of sites known to be of international importance. Mechanisms need to be developed to involve all countries in the region.
- **Strengthening national networks:** More people capable of collecting information on waterbirds and interested in developing and supporting conservation initiatives are needed.
- **Reporting and publicising the achievements of the initiative:** More effort is needed to publicise the achievements of the initiative to a wide range of audiences both within countries and across the region.
- **Securing a sound financial basis for the initiative:** To date the initiative has been successful in securing resources to develop and support activities on an annual basis. A variety of government, corporate and development agency funds have supported activities at the local and national level. Support for core coordination has been received from only a few government agencies. The lack of funding on a long-term basis has prevented the development of a more extensive regional conservation programme. Broadening of the funding base for coordination and project activities is a priority.

### WHAT OF THE FUTURE?

Despite all these successes over the past nine years of the initiative, the challenges for conservation of migratory waterbirds and wetlands in the Asia-Pacific region are increasing as the destruction and loss of important wetlands continue across the region through human-induced and natural causes. The capacity of local and national agencies and groups to monitor and manage species and their habitats needs to be strengthened in a majority of the countries.

In recognition of the need to ensure sustainable development and the conservation of species and habitats, and to gain support for future activities at flyway and national level in the East Asian-Australasian Flyway, the Governments of Australia and Japan and Wetlands International put forward a proposal to the World Summit on Sustainable Development (WSSD), held in Johannesburg in September 2002, under the Type II Partnership Initiative. The main values of the new initiative are: (a) to provide governments and non-governmental organizations with a formal mechanism for signing up and becoming partners to the broader framework of the initiative; (b) to broaden the work of the Strategy and to place the recognition and effective management of important sites in the international context of sustainable development; and (c) as security for Strategy activities and networks. This framework will be developed to support conservation in the flyway post-2005.

Likewise in the Central Asian Flyway, the Action Plan being developed under the framework of the CMS is being broadened to ensure that the needs of people living at sites used by waterbirds are addressed.

In summary, the prognosis for the conservation of migratory waterbirds and their habitats is brighter through the achievements of the Strategy, but efforts need to be sustained and expanded through improving and broadening the support and participation of all stakeholders to tackle the challenges of the future.

## ACKNOWLEDGEMENTS

The plenary presentation on the Strategy at this Conference was eloquently delivered by Lew Young, and has given a voice to our work. The Strategy has thrived as a cooperative effort, and full acknowledgement is given to all the agencies, organizations, bodies and committed individuals who have participated during the last nine years, even though it is not possible to list them all by name. Members of the MWCC have played an important role in shaping and guiding the development of this initiative. The MWCC Chair Jason Ferris, Vice-Chair Yoshihiro Natori and Alison Russell-French, our previous Chair, have given me strong support, encouragement and guidance. Working closely with my colleagues David Li Zuo Wei, Alexander Solokha, Doug Watkins, Lew Young, Mark Barter, Masuyuki Kurechi, Noritaka Ichida, Simba Chan, Warren Lee Long, Yoshihiko Miyabayashi, Yus Rusila Noor and Yutaka Kanai, we have jointly been able to stimulate our many international, national and local partners to achieve the positive outcomes of this important initiative. Support from Wetlands International has been unflagging and instrumental since 1994; Asae Sayaka, Chen Kelin, C.L. Trisal, Dibjo Sartono, Gerard Boere, Kaori Matsui, Olga Anisimova, Roger Jaensch, Simon Delany, Sundari Ramakrishna and Ward Hagemeyer deserve special mention. Flora George and Khadijah Ahmad have provided strong administrative and financial accountability to our work. My wife Samhita and sons Arnav and Aseem have given me constant support and encouragement to play my part in this work. Financial support from the Australian Department of the Environment and Heritage, Japanese Ministry of the Environment, U.S. Fish and Wildlife Service and Government of The Netherlands has been instrumental in sustaining this initiative. Lastly, funding for my participation in this Conference has been kindly provided by the organizers and many supporters.

### ABSTRACT

The atmospheric concentrations of greenhouse gases have increased since the pre-industrial era due to human activities, primarily the combustion of fossil fuels and changes in land use and land cover. These, together with natural forces, have contributed to changes in the Earth's climate (both mean and variability) over the twentieth century; land and ocean surface temperatures have warmed, the spatial and temporal patterns of precipitation have changed, sea level has risen, and the frequency and intensity of El Niño events have increased. These changes have affected wetlands and their biota, especially in coastal and high latitudes, including the timing of reproduction of species, migration of animals, the length of the growing season and the frequency of pest and disease outbreaks. The Earth's mean surface temperature is projected to warm by 1.4 to 5.8°C by the end of the twenty-first century, with land areas warming more than the oceans, and high latitudes warming more than the tropics. Sea level is projected to rise by 0.09 to 0.88 m, and is expected to have further effects on wetlands and their biota either directly (e.g. through changes in sea level and/or increased temperatures) or indirectly (e.g. through changes in hydrology, fire regime and pest outbreaks). These changes will increase the risk of extinction of vulnerable species, and could drastically alter the migration patterns of many others. Populations of some species will decline, whilst some will increase in both size and distribution. The consequences of climate change and variability for waterbirds is likely to be large, but our understanding of the role of climate change versus all the other changes due to human activities (such as changes in land use and land cover, drainage, invasive species etc.) is undermined by the limited extent of our data and existing knowledge. In all but a few cases, the data are totally inadequate. As many wetland habitats and waterbird species are currently under great pressure, we propose that quantitative risk assessments of individual and multiple pressures at multiple sites along flyways and at major wetlands are undertaken as a basis for developing adaptation options for these species and ecosystems.

### INTRODUCTION

We present an overview of the findings of the Intergovernmental Panel on Climate Change (IPCC) Third Assessment Report on climate change and its impacts on wetlands, in particular the information and graphics provided by IPCC (2001 & 2002). We also draw on a paper on climate change and wetlands prepared for the 8th Meeting of the Conference of the Parties of the Ramsar Convention on Wetlands (van Dam *et al.* 2002) and

recent analyses of the observed and projected effects of climate change on waterbirds.

It is well recognized that at the global level, human activities have caused, and will continue to cause, a loss and/or a change in biodiversity in general. More specifically, biodiversity in wetlands has been affected by, *inter alia*, changes in land use and land cover, soil and water pollution and degradation, air pollution, diversion of water to intensively managed ecosystems and urban systems, habitat fragmentation, selective exploitation of species, introduction of non-native species, and stratospheric ozone depletion. It is also well recognized that climate change will constitute an added stress that may act synergistically or cumulatively and further adversely affect biodiversity. In turn, given that wetland biodiversity supports or provides many ecosystem services on which many humans depend (see review by Finlayson & D'Cruz 2005), changes in wetland biodiversity will undoubtedly also affect human well-being.

We therefore consider climate variability and change in the context of global change that encompasses all pressures from human activities. We specifically look at some of the impacts on waterbirds and then look at possible response options (or adaptation options) through a risk assessment framework. The paper covers:

- 1 climate variability and change, and its impact on wetlands;
- 2 observed changes in the distribution of specific waterbird species in response to climate variability and change, and changes in land and water use; and
- 3 a risk analysis framework to develop responses that address the impacts of multiple pressures, including climate change, on wetlands.

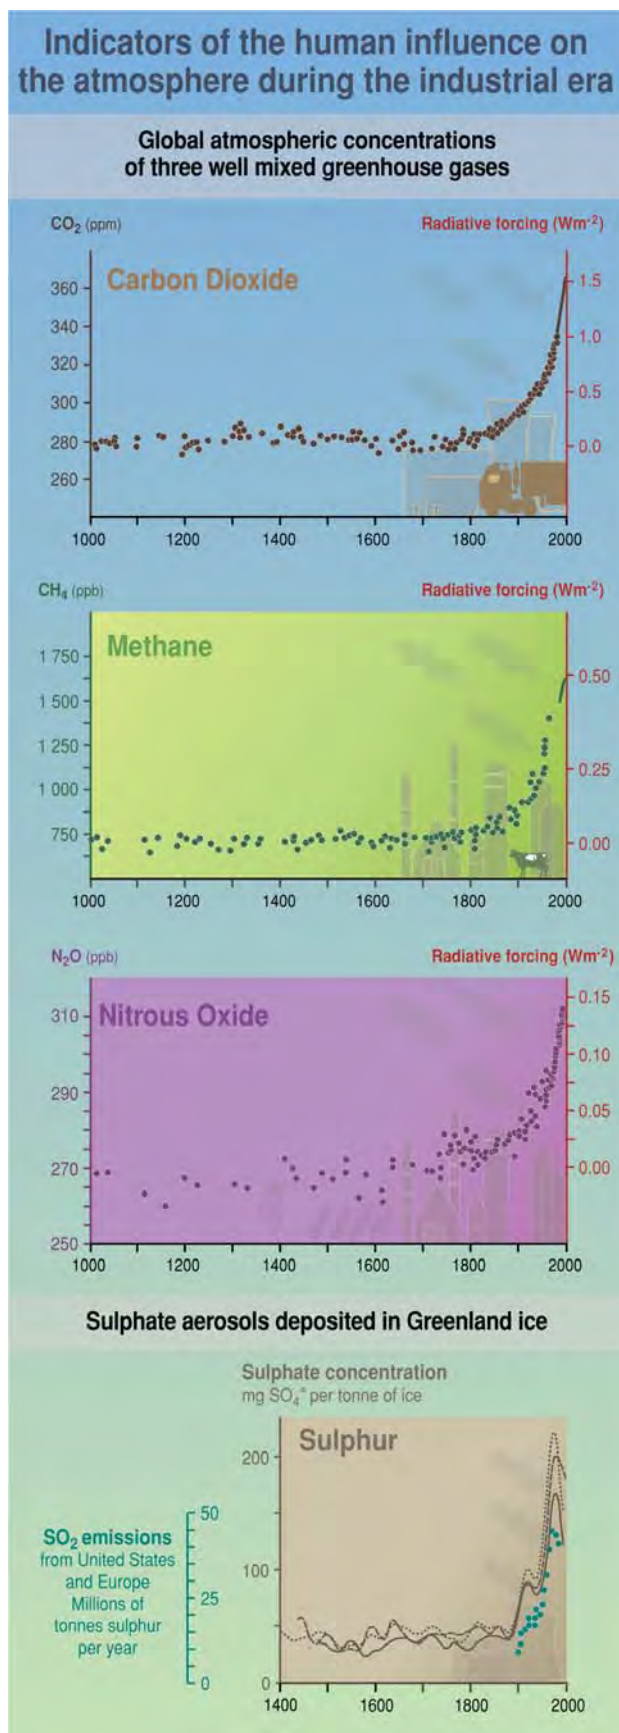

### CLIMATE CHANGE AND THE IMPACT ON WETLANDS

We summarize the following:

- 1 changes that have been observed in the biophysical systems (atmosphere, oceans) and the role of human activities in those changes;
- 2 the (observed) impacts of these changes on biological systems and especially wetlands; and
- 3 the role that adaptation can play in responding to these changes.

### Observed changes in biophysical systems

During the period 1750-2000, the concentrations of greenhouse gases in the atmosphere increased (Fig. 1): carbon dioxide by

**Fig. 1.** Observed changes in atmospheric concentrations of carbon dioxide (CO<sub>2</sub>), methane (CH<sub>4</sub>) and nitrous oxide (N<sub>2</sub>O) over the past 1 000 years and sulphur dioxide (SO<sub>2</sub>) aerosols over the last 600 years (from IPCC 2001).

about a third (2-35%); methane by about 150% (125-175%); and nitrous oxide by 17% (12-22%). The rates of increase over the past century are unprecedented when compared with the past 40 000 years for which a nearly continuous record exists. The increased concentrations of these gases are attributed to human activities, especially the burning of fossil fuel, leading to a release of 6.3 Gt C y<sup>-1</sup> on average during the 1990s, and changes in land use and land cover, including deforestation, releasing about 1.7 Gt C yr<sup>-1</sup>. Aerosols, such as sulphur dioxide, that are relatively short-lived and have a cooling effect on the atmosphere, have also increased (Fig. 1).

Due to the increase in the atmospheric concentration of greenhouse gases and natural factors during the twentieth century, the Earth's surface has warmed by 0.4-0.8°C; land areas have warmed more than the oceans, with northern, mid-high latitudes warming more than most other parts (Fig. 2). The mean annual continental precipitation has increased by 5-10% over the twentieth century in the Northern Hemisphere and parts of Australia, although it has decreased by 3% over much of the subtropical land areas (e.g. in north and west Africa and parts of the Mediterranean). These changes may be partly due to the increasing global mean surface temperature resulting in a change in atmospheric circulation, a more active hydrological cycle, and increases in the water-holding capacity throughout the atmosphere leading to a 2-4% increase in the frequency of heavy precipitation events in the mid- and high latitudes of the Northern Hemisphere over the latter half of the twentieth century (Fig. 3).

The severity of droughts has increased, with summer drying and an associated increased incidence of drought in a few areas. In some regions, such as parts of Asia and Africa, the frequency and intensity of droughts have been observed to increase in recent decades. El Niño events have become more frequent, persistent and intense during the last 20 to 30 years compared to the previous 100 years. This has increased the frequency and intensity of drought and floods in the land-masses around the Pacific, especially in the Southern Hemisphere sub-tropics.

Warming has driven sea-level rise through thermal expansion of seawater and widespread loss of land ice. Based on tide gauge records, and after correcting for land movements, Mean Sea Level increased by an average of 10-20 cm during the twentieth century. A limited number of sites in Europe have nearly continuous records of sea level spanning 300 years and show that the greatest rise in sea level occurred during the twentieth century. Records from Amsterdam (The Netherlands), Brest (France) and Swinoujscie (Poland), as well as other sites, confirm that there has been an accelerated rise in sea level over the twentieth century as compared to the nineteenth century.

Observed regional changes in temperature have been associated with observed changes in physical and biophysical systems. Examples include: the retreat of non-polar glaciers; a reduction in the extent and thickness of Arctic sea ice in summer; earlier flowering and longer growing and breeding seasons for plants and animals in the Northern Hemisphere (where most long-term studies have been carried out); pole-ward and upward (altitudinal) migration of plants, birds, fish and insects; and earlier spring migration and later departure of birds in the Northern Hemisphere.

Increasing sea surface temperatures were recorded in much of the tropical oceans during the last several decades of the

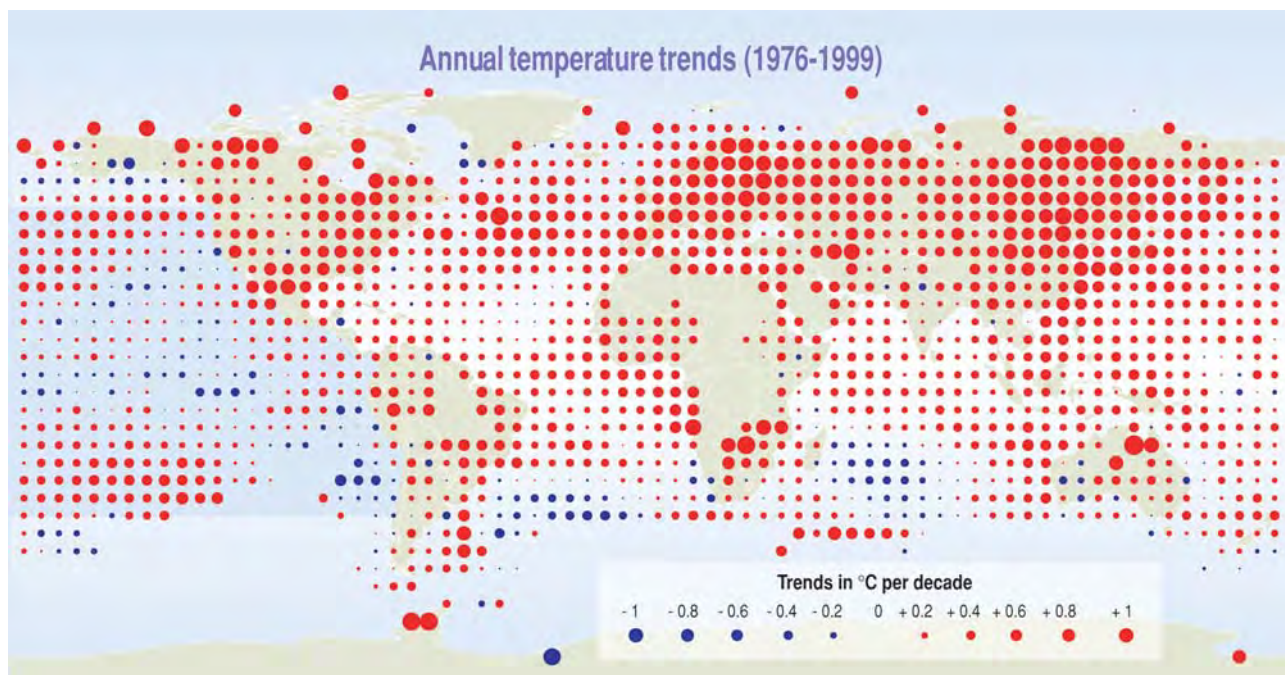

Fig. 2. Observed changes in global-average surface temperature (from IPCC 2001).

twentieth century. Many corals have undergone major, although often partially reversible, bleaching episodes when sea surface temperatures have risen by 1°C above the mean seasonal sea surface temperatures in any one season, and extensive mortality has occurred with a 3°C rise. Bleaching events are also associated with other stresses such as pollution and disease. Changes in the frequency and intensity of precipitation, pH, water temperature, wind, dissolved CO<sub>2</sub> and salinity, combined with

anthropogenic pollution by nutrients and toxins, can all affect water quality in estuarine and marine waters. Some marine disease organisms and algal species, including those associated with toxic blooms, are strongly influenced by one or more of these factors. In the last few decades of the twentieth century, there was an increase in reports of diseases affecting coral reefs and sea-grasses, particularly in the Caribbean and temperate oceans.

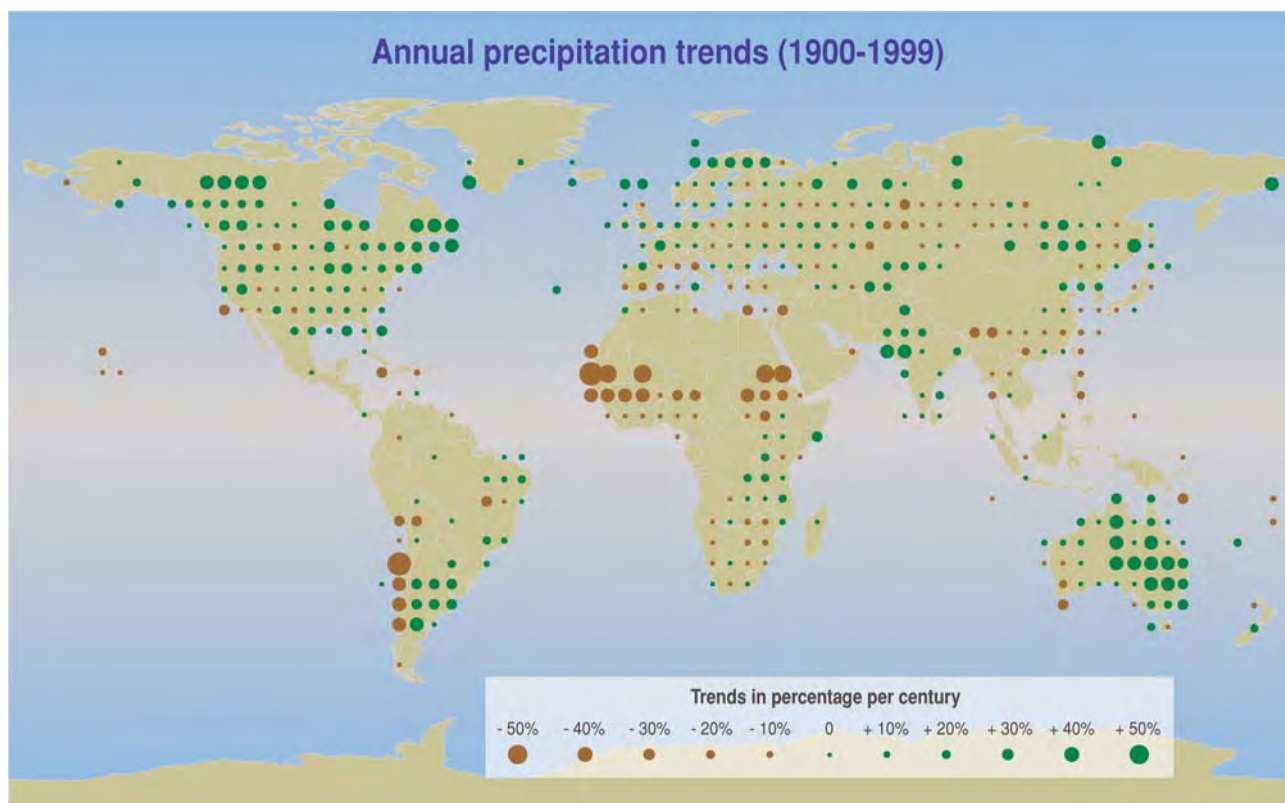

Fig. 3. Observed changes in precipitation patterns (from IPCC 2001).

As mentioned above, most of the warming has been attributed to human activities, particularly the emission of greenhouse gases originating from the burning of fossil fuel, and changes in land use and land cover; the evidence for this attribution has become stronger over time from the first assessment report of the IPCC in 1990 to the second in 1995 and the third in 2000. Specific conclusions from these assessments were:

- 1 First Assessment Report 1990: “...the observed increased [warming] could be largely due to ... natural variability; alternatively this variability and other human factors could have offset a still larger human-induced greenhouse warming”;
- 2 Second Assessment Report 1995: “The balance of evidence suggests a discernible human influence on global climate”; and
- 3 Third Assessment Report 2000: “Most of the observed warming in the past 50 years is attributable to human activities”.

### Projected changes in the climate system and sea level

Future emissions of greenhouse gases and aerosols are determined by driving forces such as changes in human population (total number and structure), socio-economic development and technological change. The IPCC Special Report on Emission Scenarios presents six groups of scenarios or plausible futures (so called “SRES scenarios”) which are based on narrative story-lines and span a wide range of driving forces. The scenarios are used to project the future emissions of the greenhouse gases carbon dioxide, methane and nitrous oxide and the aerosol sulphur dioxide. For gases that stay in the atmosphere for a long period, such as carbon dioxide, the atmospheric concentration responds to changes in emissions relatively slowly, whereas for short-lived gases and aerosols, such as sulphate aerosols, the atmospheric concentration responds much more quickly.

Using the SRES scenarios, the IPCC has projected that carbon dioxide concentrations, temperatures and sea levels will continue to rise long after emissions of greenhouse gases are reduced. This is due to the length of the half-life of carbon dioxide in the atmosphere as well as “inertia” in the system. Even if the emissions were to be stopped today, the Earth’s surface temperature could continue to rise for a few centuries, and sea level, due to thermal expansion and melting of ice, could continue to increase for several millennia.

Projected changes for surface temperatures, precipitation and sea level are:

- 1 The globally-averaged surface temperature is projected to increase by 1.4 to 5.8°C over the period 1990-2100. This is about two to ten times larger than the central value of observed warming over the twentieth century. The projected rate of warming is very likely to be without precedent during at least the last 10 000 years, based on long-term data on climate. For the periods 1990-2025 and 1990-2050, the projected increases are 0.4 to 1.1°C and 0.8 to 2.6°C, respectively. These results are for the full range of SRES scenarios, based on a number of climate models.
- 2 Some areas are projected to become wetter and others drier, with an overall increase in precipitation projected.
- 3 Global mean sea level is projected to rise by 0.09 to 0.88 m

between the years 1990 and 2100. For the periods 1990-2025 and 1990-2050, the projected rises are 0.03 to 0.14 m and 0.05 to 0.32 m, respectively. This is due primarily to thermal expansion and loss of mass from glaciers and ice-caps.

Projections for climate-related extreme events (e.g. floods, heat waves etc.) include:

- 1 Higher maximum temperatures; more hot days and heat waves over nearly all land areas;
- 2 Higher minimum temperatures; fewer cold days, frost days and cold spells over nearly all land areas;
- 3 More intense precipitation events over many areas;
- 4 Increased summer drying over most mid-latitude continental interiors and associated risk of drought; and
- 5 Increase in peak wind intensity and mean and peak precipitation intensities in tropical cyclones.

These projections could lead to increased heat stress in humans and livestock and decreased productivity in some regions, but could also provide some relief from extreme cold events, especially in mid-high latitudes of the Northern Hemisphere.

### Impacts on wetlands

Climate change is likely to affect wetlands and their biodiversity directly (e.g. through changes in temperature) and indirectly (e.g. through affecting the hydrology). Impacts will depend on the coastal morphology and the balance between sea-level rise, deposition and erosion within catchments and the coastal zone. Wetlands play important roles in the global cycling of water and chemicals, including greenhouse gases; cycles that will be affected by climate change. The risk of impacts of climate change increases with the rate and magnitude of climate change. Specific impacts are projected to include:

- 1 Initially increased productivity in some mid-latitude regions and a reduction in the tropics and sub-tropics, even with warming of a few degrees;
- 2 Adverse affects on coastal wetlands and coastal fisheries, e.g. coral bleaching events are expected to increase and mangroves are expected to decline in many coastal zones;
- 3 Decreased water availability in many arid- and semi-arid regions; and
- 4 Increased forest productivity, including that of forested wetlands, although forest management will become more difficult because of an increase in disturbances (pest outbreaks and forest fires).

Overall, it is projected that there will be more adverse than beneficial impacts on wetlands. Inland and coastal systems are likely to experience large and early impacts. These include:

- 1 Increased levels of inundation, storm flooding, accelerated coastal erosion, seawater intrusion into fresh groundwater, encroachment of tidal waters into estuaries and river systems, and elevated sea surface temperatures and ground temperatures; and
- 2 Adverse impacts on marine mammal and bird species, especially migratory and nomadic bird populations that depend on coastal habitats.

Developing countries are projected to be the most vulnerable to climate change; many are already more prone to floods and droughts. Large portions of the economies of these countries are in “climate sensitive sectors”, and they have a lower capacity to adapt because of a lack of financial, institutional and technological capacity and access to knowledge. Traditional indigenous societies that depend on inland and coastal wetlands are already vulnerable (see also McDonald *et al.* 1997), and would become more vulnerable as a result of these projected impacts.

Changes in climate will exert additional pressure on ecological systems. Furthermore, processes such as habitat loss, modification and fragmentation, and the introduction and spread of non-native species will affect the impacts of climate change. A realistic projection of the future state of the Earth’s ecosystems needs to take into account patterns of human land use and water use that will greatly affect the ability of organisms to respond to climate change via migration. The composition of most current ecosystems is likely to change, as the species that make up an ecosystem are unlikely to shift together. The most rapid changes are expected where they are accelerated by changes in natural and anthropogenic, non-climatic disturbance patterns.

The risk of extinction will increase for many species that are already vulnerable. Species with limited climatic ranges and/or restricted habitat requirements and/or small populations are typically the most vulnerable to extinction, such as endemic species and biota restricted to islands, peninsulas or coastal areas. In contrast, species with extensive, non-patchy ranges, long-range dispersal mechanisms and large populations are at less risk of extinction. While there is little evidence to suggest that climate change will slow species’ losses, there is evidence that it may increase species’ losses.

### Impacts on waterbirds

The general nature of the impacts of climate change on waterbirds can be identified, but the exact extent, intensity and time frames are difficult to project with certainty, as all models of global climate change are at too large a scale and the ecology of most waterbirds is insufficiently understood. Potentially, almost all aspects of their ecology could be affected, either directly or indirectly. However, the most severe effects and those most likely to occur earliest (some have already been detected) include the loss of inter-tidal habitats and increased salinity of coastal freshwater habitats caused by rising sea levels, a reduction in the extent of wetlands and duration of flooding in arid and semi-arid areas resulting from changes in climate variability, and the loss of wetland breeding habitats in Arctic and sub-Arctic areas caused by increasing temperatures, expanding boreal forests and forest fires.

The extent of loss of inter-tidal habitats and its effects on coastal waterbirds will depend on the ability of coastal environments to move inland as sea level rises. Where this is possible, either because of a lack of artificial coastal defences or by their removal, inter-tidal areas might expand and some changes in sediment characteristics, especially an increase in coarser sandy sediments, might be expected. This would benefit some species such as the Eurasian Oystercatcher *Haematopus ostralegus*. However, it is more likely that coastal defences around many areas will be strengthened, resulting in a compression of inter-tidal habitats and loss of total inter-tidal area. For the United States, Galbraith *et al.* (2002) have predicted losses of between

20% and 70% of current inter-tidal areas by 2100. This will have serious implications for the total numbers of shorebirds that can be supported (Norris & Atkinson 2000). Critically, the length of time that remaining inter-tidal areas are exposed during each tidal cycle will be reduced. The time shorebirds spend feeding during low tide depends on their body size and ambient temperatures, and is also increased when accumulating reserves prior to migration (Zwarts *et al.* 1990, Piersma & Jukema 1990). Smaller species spend almost all of the time feeding (Dann 1999) and potentially could be the most seriously affected. A reduction in the expenditure of metabolic energy through rising temperatures is unlikely to offset the loss of feeding time. Some inter-tidal areas will probably become unusable by the smaller species. In other areas, reductions in survival during winter and subsequently during migration might be expected, and lower body condition on arrival at Arctic breeding areas might reduce breeding success of migratory waders and other species such as wildfowl (Newton 1998, Pettifor *et al.* 2000).

Changes in immersion periods, sediment characteristics and also rising temperatures will cause changes in the distribution, abundance and growth of the inter-tidal invertebrate populations which constitute the prey of shorebirds (Decker & Beukema 1999, Beukema 2002), and in some cases, this might increase the availability of food. However, this relationship is not clear, as increased temperatures can also lead to a decrease in body condition of some invertebrates during winter, reducing the food value of individual prey items (Honkoop & Beukema 1997).

The effects of rising temperatures on plant communities will be particularly strong in the Arctic (Neilson & Drapek 1998), and this will lead, among other changes, to an expansion of boreal forest into current tundra areas where two thirds of all goose species and 95% of all Calidrid sandpipers breed. Losses in the breeding ranges of these tundra breeding waterbirds of between 5% and 93%, depending on the species and the degree of warming, have been predicted as a result of this forest expansion by 2070/2099 (Zöckler & Lysenko 2000). The annual breeding success of some species is correlated with spring temperatures (Zöckler & Lysenko 2000), so rising temperatures could increase productivity, which might compensate to some extent for habitat loss. Set against this, however, is a likely increase in loss of nests and chicks to predation as temperate climate predators such as the Red Fox *Vulpes vulpes* expand their range (Parmesan & Yohe 2003).

Changes in global circulation patterns will result in alterations to rainfall patterns, with some areas experiencing increases and others decreases. Included in the latter are some currently dry areas, such as Australia and parts of Asia and Africa. Wetlands and waterbird populations in these areas are already highly stressed from habitat loss to agriculture, reduced water flows caused by water abstraction for irrigation, pollution and increasing salinization (Kingsford & Johnson 1998, Kingsford 2000, Kingsford & Norman 2002). Waterbird populations in the drier continents are characterized by unpredictable and relatively infrequent breeding, high adult survival and high mobility. Successful breeding often requires exceptional flooding events that last long enough for completion of the breeding cycle (Leslie 2001, Kingsford & Norman 2002). Reduced rainfall will increase the intervals between flooding events and shorten their duration. Reduced breeding success and recruitment should be expected as a first response, followed by reduced survival of adults and then

widespread population declines. Some indication of the sensitivity of such systems is provided by an analysis of the survival rates of the Sedge Warbler *Acrocephalus schoenobaenus*, a wetland passerine, breeding in Britain and wintering in West Africa. Annual survival rates are strongly correlated with rainfall in West Africa, and have varied from 2.5% to 55% (Peach *et al.* 1991).

Changes to waterbird populations should also be expected in less severely affected areas. Increased temperatures will advance breeding seasons and possibly reduce winter mortality (Crick & Sparks 1999, Winkler *et al.* 2002). The vegetation structure of wetlands can be expected to change, altering the physical aspects of habitats and plant productivity. There will almost certainly be great regional variation, with some areas experiencing increases in waterbird populations and others, decreases (Smart & Gill 2003).

### THE ROLE OF ADAPTATION

Adaptation has the potential to reduce the adverse effects of climate change, but cannot prevent all impacts. Numerous adaptation options (projects and processes designed to reduce the impact of climate change) have been identified that can reduce adverse and enhance beneficial impacts of climate change, but will incur costs (see van Dam *et al.* 2002, Gitay *et al.* 2002). Adaptation is a necessary strategy to complement efforts to mitigate climate change (deliberate actions to reduce the sources or enhance the sinks of greenhouse gases). Adaptation and mitigation can contribute to sustainable development objectives for wetlands.

Adaptation activities can promote conservation and sustainable use of biodiversity and reduce the impact of changes in climate and climatic extremes on biodiversity. These activities include the establishment of a mosaic of interconnected multiple-use reserves designed to take into account projected changes in climate, and integrated land and water management activities that reduce non-climate pressures on biodiversity and hence make the systems less vulnerable to changes in climate. Some of these adaptation activities can also make people less vulnerable to climatic extremes. The effectiveness of adaptation and mitigation activities can be enhanced when they are integrated within broader strategies designed to make development paths more sustainable.

The way in which different species respond to changes caused by global warming will be determined by their individual inherent adaptive capacity and the time necessary for those adaptations to take effect. In particular, patterns of bird migration will change and be very different across species, for different latitudes and different regions of the biosphere. The most general definition of animal migration is given by Baker (1978): "Migration: the act of moving from one spatial unit to another". The classic form of bird migration is the regular seasonal movement from the breeding areas to the resting grounds (often called wintering quarters) and back (Schüz *et al.* 1971), but bird movements occur in an abundance of different forms: dispersal, irruption, partial migration, differential migration etc. (Berthold 1993).

Many studies have shown that all the main morphological, physiological and behavioural prerequisites for bird migration are under direct genetic control (Seelbohm 1901, Butler & Woakes 1990, Mönkkönen 1992). Therefore, endogenous migratory patterns may not change in a time frame sufficient to adapt to global warming, and as a consequence the species will

be forced to change the extent of their migratory patterns. There is evidence that some species of migratory birds in the Mediterranean region have reduced their migratory behaviour in relation to global warming (Berthold 1988, Berthold & Terrill 1988). The predicted increased incidence of drought in sub-tropical regions could lead to an increase in dry-season migration amongst resident species causing direct competition for food between resident and migratory species. At higher latitudes, mild winters could increase the survival of resident and partially migratory species, with the consequence that long-distant migrants would find themselves at a disadvantage on their arrival on breeding grounds occupied by larger numbers of residents. On the other hand, climatic changes may also have positive effects, such as the expansion of subtropical populations to higher latitudes (Berthold 1988), and result in an unprecedented gene flow and thus a multitude of micro-evolutionary processes.

From the above considerations, it is implicit that, in the next decades, global change (including climate change) in general will play a major role in favouring the survival of certain species and will pose a disadvantage to others, if not threaten their survival. It is likely that partially migratory or less markedly migratory species would succeed in developing resident populations, but it is not clear how quickly long-distance migrants would succeed in reducing their migratory behaviour to such an extent that they would be able to stay on the breeding grounds throughout the year in the event of severe climatic changes (Berthold 1993). Migratory species with restricted ranges, restricted foraging niches (in their breeding and non-breeding ranges), or under threats from other pressures such as loss and modification of habitat, pollution and weed invasion, are likely to be the most affected.

For migratory species, and in particular long-distance migrants, scientists need to devote more research effort to determine:

- 1 the effects of habitat alteration at stopover points and wintering areas;
- 2 the amounts and locations of major habitat types, through inventories, as well as the carrying capacities of these habitats; and
- 3 the behaviour, home range and resource needs of species most likely to be vulnerable to global warming.

On the management and conservation fronts, efforts should be devoted to:

- 1 maintaining population inventories of migratory birds. These inventories should form the basis for determining and designating critical habitat under various management responses, and hence encourage specific known adaptations;
- 2 identifying, obtaining and protecting critical stopover and wintering sites, particularly for those species whose populations tend to concentrate at few sites; and
- 3 addressing policies and legislation at a continental scale, or better flyway scale where possible.

### RISK ASSESSMENT

Ecological risk assessment is not a new tool, but in recent years the usefulness of its application to wetland management has been promoted and accepted formally through the Ramsar

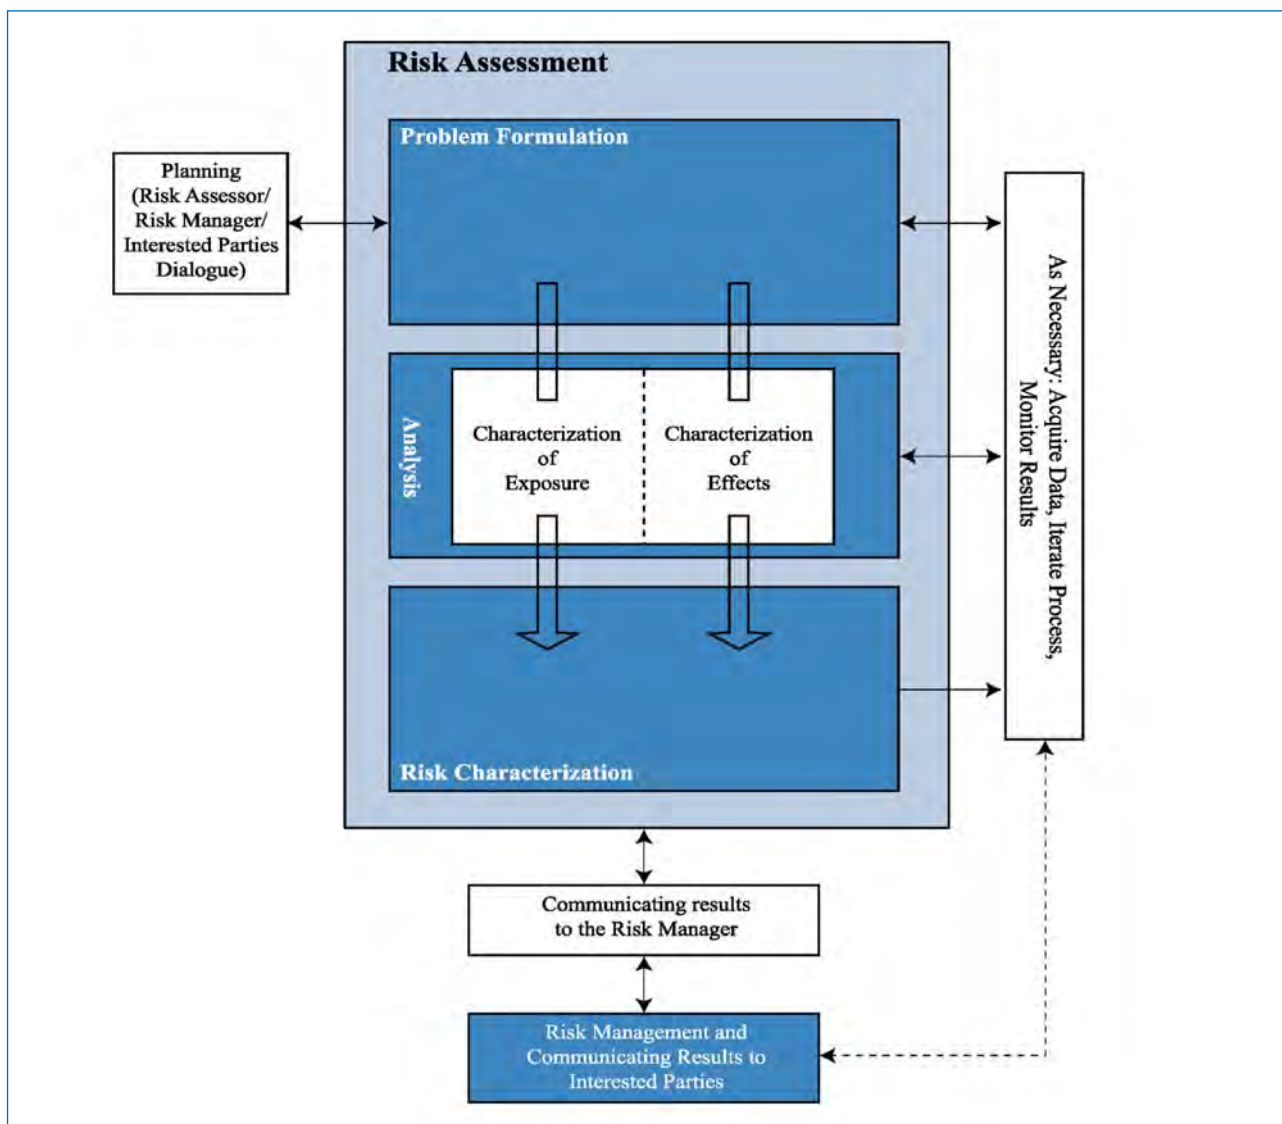

Fig. 4. Generalized framework for ecological risk assessment (modified from US EPA 1998).

Convention on Wetlands (van Dam *et al.* 2002). Ecological risk can be described as the likelihood of the occurrence of an adverse ecological effect of specific magnitude. Thus, ecological risk assessment attempts to quantify both the magnitude of an ecological effect and the likelihood of the effect occurring (US EPA 1998). It provides a structured, iterative approach for making rational and transparent decisions based on the best available knowledge and recognition of the associated uncertainties.

Risk assessment frameworks exist in a variety of forms (US EPA 1998, AS/NZS 1999, van Dam *et al.* 1999, US EPA 2003, Hart 2004), although they generally encompass similar steps, most commonly *problem formulation/hazard identification*, *effects assessment*, *exposure (likelihood) assessment* and *risk characterization* (Fig. 4). Additional steps, such as risk communication, risk reduction and monitoring, are also critical in the overall decision-making process, and are necessary to complete the risk management cycle (Burgman 2004). Moreover, identification (and quantification) of the key uncertainties and gaps in knowledge enables prioritization of research and data acquisition, which, through iteration of the risk assessment, decreases uncertainty in the risk predictions and outcomes.

Applications of ecological risk assessment are numerous and include assessments that range from: screening-level (qualitative) to detailed (quantitative) or a combination of both (i.e. tiered ecological risk assessment); predictive to retrospective in temporal scale; local to global in spatial scale; and single stressor to multiple stressors (US EPA 1998, Burgman 2004). Increasingly, risk assessment is being used in a catchment or basin context to assess, prioritize and manage multiple stressors, pathways, ecological resources/assets and competing social values (Serveiss 2001, Hart *et al.* 2003). For example, catchment (or watershed) scale risk assessments have been undertaken in North America (see summaries by Serveiss 2001) and Australia (eg. Begg *et al.* 2001, Pollino *et al.* 2005) estimating relative and/or cumulative risks to aquatic ecosystems of multiple stressors including toxicants, nutrients, sediments and altered flow regimes. Further, the development of a decision support tool to prioritize and protect or restore wetlands of importance to the water quality of Australia's Great Barrier Reef includes a process that assesses and compares ecological risks across multiple wetland sites and from multiple threats (Finlayson *et al.* 2004).

Although climate change poses one of the greatest threats to wetland ecosystems (see van Dam *et al.* 2002), to date there

appear to have been few, if any, applications of ecological risk assessment to this issue. Generally, vulnerability assessment has been used to help identify potential impacts of climate change and sea-level rise (IPCC & Coastal Zone Management Subgroup 1991, Waterman 1996). The vulnerability assessment process requires identification of both climatic and non-climatic (e.g. deforestation, water pollution, water extraction, over-fishing) pressures, but does not specifically involve a structured assessment of the relative risks of these pressures or the interactions between them. There are many similarities between ecological risk assessment and vulnerability assessment – a topic that is currently being addressed by the Scientific and Technical Review Panel of the Ramsar Convention on Wetlands (Gitay 2006).

It is anticipated that utilizing existing and emerging methodologies for ecological risk assessment (e.g. Bayesian and frequentist approaches; see Burgman 2004) should enhance vulnerability assessments of the impacts of climate change on wetlands by:

- 1 including ecological risks of existing pressures as well as projected climate change;
- 2 comparing ecological risks of existing and predicted/forecast pressures, including climate change;
- 3 assessing the impact of climate change on risks of existing/forecast pressures (e.g. invasive species, water extraction/availability); and
- 4 providing a structured process by which to identify explicitly the key uncertainties and associated gaps in information and research.

A catchment scale, multiple stressor ecological risk assessment underway for the Magela Creek catchment in the Alligator Rivers Region (ARR) of northern Australia (Finlayson & Bayliss 2005) provides an example of the application of risk assessment to multiple pressures on wetlands. The assessment is focusing on the relative and cumulative ecological risks of uranium mining, invasive weeds, feral animals and salt water intrusion, the latter threat being one of the major consequences for the region of projected sea-level rise due to climate change. Initial analyses have assessed the probability of adverse change occurring as a consequence of individual pressures and provide a basis for comparing the relative probability of adverse affects. The comparative analyses also provide a basis for reassessing the results and the veracity of the information that was used, particularly if the results were unexpected. Furthermore, it is possible to link ecological models to the risk assessment models.

For the Magela analyses, it is intended to incorporate habitat suitability models for key weeds such as Paragrass *Urochloa mutica* and Mimosa *Mimosa pigra* and conceptual models for the feeding ecology of waterbird populations to assess the relative risks from various pressures including climate change projections. This provides an example of the usefulness of risk assessment in addressing multiple pressures, but it should be emphasized that the success of such assessments will only be realized through the accumulation of essential information. In addition to providing information on the relative risks, the risk assessment model provides a structured way to identify information gaps. In terms of the ongoing assessment of the consequences of climate change for wetlands and waterbirds, the various projections given above could potentially be supported

through application of ecological risk assessment, particularly where multiple pressures may be involved and where probabilistic analyses could be used to identify individual responses and overcome information gaps. This is well known scientifically, but there is insufficient evidence that such approaches are being effectively incorporated into management and monitoring regimes for wetlands and waterbirds.

## IDENTIFIED INFORMATION NEEDS AND GAPS

As noted above, it is widely accepted that human activities are adversely affecting ecosystems and their ability to provide ecosystem services that support humans and life on earth more generally. As climate change and other environmental pressures are inter-linked, we need to assess the effects of these multiple pressures if we are to develop programmes and actions that support sustainable development and human well-being. This assessment includes:

- 1 obtaining knowledge of the extent of many wetland types, their condition and their hydrology (Finlayson *et al.* 1999);
- 2 improved understanding of the response of wetlands and wetland species to changes in climatic factors and other pressures (van Dam *et al.* 2002);
- 3 development of data and models for the geographical distribution of species and their response to climate change at regional level (van Dam *et al.* 2002, IPCC 2002);
- 4 development of models that include patterns of human land use and water use to provide a realistic projection of the future state of wetlands; and
- 5 indicators to measure the effect of adaptation and mitigation options for climate change.

Increased desertification resulting from changing climate on its Asian breeding areas is one of the possible causes of the severe decline of the Sociable Plover *Vanellus gregarius*. Photo: Sergey Dereliev.

Increasingly, decision support systems of various complexity are being developed to assist managers make decisions about complex management scenarios, such as that presented by the pressures generated by climate change. Various technical experts have recently promoted ecological risk assessment as a means to support decision making for wetland management (Finlayson *et al.* 2004, Hart 2004). As it is unclear what the interactions are between climate change and the many other pressures affecting wetlands, it is recommended that quantitative wetland risk assessments be undertaken as a means of addressing the uncertainty that currently characterizes many management or adaptation options for sustainable use of wetlands.

## Sustainable harvest of waterbirds: a global review

Niels Kanstrup

CIC Migratory Bird Commission, Director of Wildlife Management, Danish Hunters' Association, Molsvej 34, DK-8410 Rønne, Denmark. (email: nk@jaegerne.dk)

Kanstrup, N. 2006. Sustainable harvest of waterbirds: a global review. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 98-106.

### ABSTRACT

Waterbirds have a long tradition of being harvested in various ways. In many countries, the harvest takes place as a primary food source, but recreational hunting is also very popular. Various methods are used. Subsistence hunting of waterbirds has a history that dates back to the dawn of modern mankind. In many remote regions, waterbirds are still an important food resource. At the same time, sustainable utilization at all levels is regarded as a cornerstone in the conservation of nature. Sustainability is considered from the perspectives of two main fields: ecology and socio-economic (political) issues. Aspects of ecological sustainability include the harvest and other direct impacts on bird populations, here regarded as the hunting pressure. Socio-economic aspects include the active participation in nature conservation by local communities, motivated by the access to natural resources and the degree of stability in local communities obtained through nature conservation. In many countries there is a long tradition of detailed wildlife harvest management including programmes for bag surveys and monitoring of harvest levels. In most countries, however, the management of waterbird harvests is poor or completely lacking, and very little information is available on the annual harvest and its impact on populations. In addition, international and flyway based co-ordination is lacking in many regions, and systems need to be developed in order to obtain reliable data on harvest rates in relation to population levels and trends. Models for analysing and achieving sustainability and examples of local and integrated management of waterbird harvest are presented.

### INTRODUCTION

Most people equate sustainability with the definition first introduced in the Brundtland Report "Our Common Future": "The ability of humanity to ensure that it meets the needs of the present without compromising the ability of future generations to meet their own needs" (World Commission for Environment and Development 1987). This fundamental, but not very operational, definition will be the basis for this review. It can be rewritten as "ensuring a high quality of life for everyone, now and for generations to come". This goal will – in this review – be related to the value of the world's waterbirds *per se* and to the value of the human utilization of waterbird resources through sustainable harvest.

Some aspects of the harvest of waterbirds are poorly documented and understood compared to similar aspects for mammals and other wildlife taxa. Due to the high commercial value of meat and trophies, detailed management programmes, including research and monitoring programmes, have been set up for a large number of ungulates and other mammals in all continents. Likewise, it has been shown to be commercially beneficial to establish management programmes for fish

resources, resulting very often in highly sophisticated models for sustainable fishery regimes based on scientific analysis. In contrast, the national and, even more so, international management of wild birds are in a much poorer state, as research and flyway-based harvest programmes still have to be developed in most regions. However, in North America and a number of European countries, there is an elaborate system of monitoring and regulation of waterbird hunting. After many years, a general overview of the impact of bird hunting on populations and sustainability of the harvest is now available for these regions.

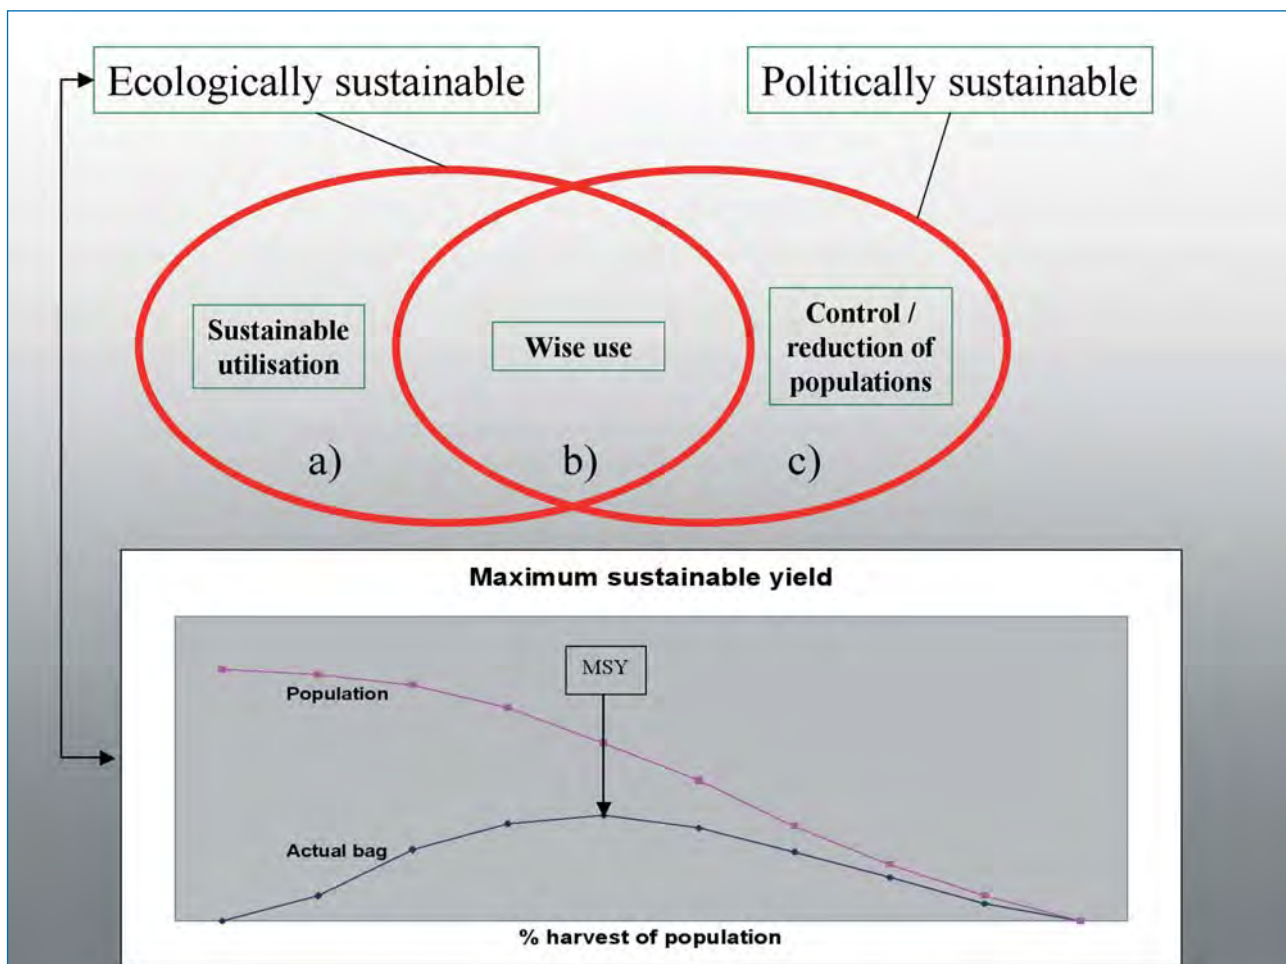

Of the 868 species of waterbirds recognized world-wide (Wetlands International 2002), a large proportion are known to be migratory and regularly cross national borders during the course of their migrations. The conservation and sustainable utilization of migratory birds constitute huge challenges in terms of international co-operation, which is very often made difficult by great differences in political regimes, language and culture over relatively short distances. The challenges differ widely from continent to continent. In the Palearctic region in particular, the migratory routes of waterbirds cross a very large number of political borders or limits between political regions where there were until recently (and in some instances, still are) historical and other politically created barriers that impede or prevent the integrated management of bird life. Even though the process of democratization has progressed quite far in many of the world's nations, and even though the last decade has witnessed radically improved means of communication, many countries and regions are lacking the resources and capacity for an elaborate programme of integrated waterbird management that also includes an assessment of harvest.

The terminology of international bird management and harvest assessment is imprecise and far from consistent. In this review, the term "harvest" is used to cover all kinds of active taking of wild bird resources, including any part or product of a bird, whatever the catching method used. Harvest in this sense does not cover the unintentional taking or killing of birds, and thus excludes the by-catch of waterbirds by fishing, and birds killed by oil disasters, traffic, pollution, etc. English terms for activities under this definition of harvest include collecting, gathering, hunting, shooting, wildfowling, trapping and netting.

### ELEMENTS AND TERMS OF SUSTAINABILITY

A widely accepted analysis divides sustainability into three equally important dimensions: ecological, economic and social. This review will focus on the dilemmas between ecological components on the one hand, and social and economic components on the other, and deal less with the significance of the economic resource itself (measured in monetary and meat values) and social dimensions. In the following discussion, social and economic components are treated together under the term "political components".

**Fig. 1.** Terms of sustainability. Fields of activities: a) ecologically, but not politically, sustainable harvest; b) politically acceptable activities that cause reduction or local extinction (regulation) of populations according to clearly set goals; c) ecologically and politically sustainable activities (“wise use”). See text for examples. The maximum sustainable yield (MSY) is defined as the percentage utilization that implies the largest yield and is obtained at intermediate harvest levels. Upper curve (pink): the size of the population; lower curve (blue): the size of the yield in absolute numbers; horizontal axis: the level of utilization of the population in percent.

The simplest component is the ecological one. This comprises the concept of the “harvest principle” which concerns population turnover and population dynamics. Basically, it is about production and mortality and the balance between these two. If production is greater than mortality, the population is growing; if production is smaller than mortality, the population is decreasing. In this context, it is important to consider the concepts of compensatory and additive mortality. The harvest principle is based on the fact that the causes of mortality may to some extent compensate for one another. If one mortality factor is reduced, another one increases, and the overall mortality remains constant. The same goes for mortality as a result of hunting. This effect appears to act within certain limits; it is most pronounced for r-strategists and least for K-strategists. If hunting mortality exceeds a certain limit, compensation mechanisms will no longer be sufficient to ensure that the other mortality factors are correspondingly reduced. Mortality has become additive, and hunting will, over time, cause a reduction in the population (see Fig. 1).

A fundamental concept in this context is maximum sustainable yield (MSY). This is defined on the basis of a given impact of utilization on the population in respect of density dependent productivity. Fig. 1 shows a classic relationship between utiliza-

tion, or harvest, of a population and the response of the population. The maximum sustainable yield is defined as the percentage utilization that implies the largest yield. It may be viewed as an element in the perception of ecological sustainability.

Ecological sustainability is a quantitative concept and requires only that a given harvest causes neither the extinction of the population nor a long-term decline. The term “long-term decline” is an open concept that until recently has not been formally defined in international bird management. At its third Meeting of Parties however, the African-Eurasian Migratory Waterbird Agreement (AEWA 2004) decided that: “A population in ‘significant long-term decline’ is one where the best available data, information or assessments indicate that it has declined by at least 25% in numbers or range over a period of 25 years or 7.5 generations.” When, where and how the harvest takes place is of secondary importance in relation to ecological sustainability. A quantitative optimization of the annual yield may require that the harvest occurs in the period after reproduction and, at least in the case of waterbirds, in a system where the hunting areas and hunting methods are planned in such a way that disturbance is minimized and birds are not prevented from utilizing a given area. To ensure wider ecological sustainability of a given harvest, it is essential that the system is selective in

relation to species or species groups, so that the harvest does not unintentionally influence the populations of other species in an unsustainable way through incidental catch or extensive disturbance.

Far more complex is the concept of political sustainability. This will be determined by what is “allowable” within a political region, typically a country, and will vary from region to region. Traditions, culture, ethics and a series of other societal elements will characteristically play a role in political sustainability.

It seems fundamental that a harvest must be ecologically sustainable in order to be politically sustainable, i.e. political sustainability is a subset of ecological sustainability. There is, however, an exception when management is aimed directly at reducing or eliminating a given species in a given area. The means to achieve such an objective maybe seen as ecologically unsustainable utilization – or what one may more appropriately call regulation or population control. Even though – or indeed because – the activity is ecologically unsustainable, it is politically sustainable. Hence, there is an extension of the politically sustainable field that falls outside the ecologically sustainable field (see Fig. 1).

In other words, in this model there are three fields within sustainability as a broad concept:

- a) A field that expresses sustainable harvest ecologically, but not politically. Hence, there exists a series of species and species groups which, from a strictly ecological viewpoint, could be hunted, yet in most countries this does not occur because culture, tradition and other socially created conditions do not allow it;
- b) A field that describes activities regarded as politically acceptable, in as much as they cause reduction or local extinction (regulation) of populations through management guided by clearly set goals. An example is the control measures taken against populations of waterbirds that damage agricultural crops. Even though there may not be a reduction in the overall population (meta-population), the objective of control is to reduce, or at best eradicate, a local population in a specific area; and
- c) A field that describes the overlap between what is ecologically and politically sustainable. This field may be categorized within “wise use”, a well-known concept that figures in a number of the international conventions on nature conservation.

On the whole, ecological sustainability may be viewed as a well-founded concept that refers to a mathematical assessment of MSY based on monitoring of populations as well as harvest, while political sustainability varies a great deal between countries and cultures, just as individual persons, on the basis of purely subjective judgement, may have widely differing perceptions of what may be accepted as sustainable utilization of natural resources.

## HARVEST – WHAT AND WHY?

As mentioned above, the term “harvest” is not unambiguous. In this review, the concept covers the “active taking of wild birds and products thereof”. This makes a distinction between the gathering of products (collecting), trapping (where the prey is utilized for consumption or in some instances kept or traded alive), and

hunting. Methods differ widely from country to country and from one continent to another. The harvesting of waterbirds has been a very important activity for mankind since the Stone Age, and has been practised particularly by trapping in nets and snares and the collection of products from birds, notably their eggs. Only in recent times has the use of firearms become widespread. Collection of products is still very widespread in many parts of the world. One example is the collection of down of the Common Eider *Somateria mollissima* in Iceland. Here, 400 collectors annually gather 17 gm of down from each of 180 000 nests, amounting to a total harvest of three tonnes (S.B. Hauksson pers. comm.). Another example is the collection of eggs of the Northern Lapwing *Vanellus vanellus* in The Netherlands. This remains a very popular activity. No detailed information is available on the extent of the harvest, but in 2003 the European Court of Justice recognized the activity as legal under the terms of the EC Birds Directive, Article 9, which states that such activities must only account for “small quantities” (European Community 1979).

The capture of waterbirds is still common the world over. Methods differ widely from poisoning to passive trapping with snares, nets or fish traps, and active trapping systems that involve the release of nets by the hunter or the bird itself. The driving of birds, e.g. moulting geese, into nets is also a common activity. Nets are employed on land, in areas of shallow water. e.g. where birds are moulting, and in deeper water where birds are caught during their dives. As one example of waterbird catching on a large scale, more than one million waterbirds may be caught in a single year at Lake Chilwa in Malawi (Malawi Government 2000).

Hunting with weapons began with the use of throwing and thrusting tools such as stones, lances and spears. Over 20 000 years ago, hunting was revolutionized by the development of the bow and arrow. Only much later – less than one thousand years ago – have real firearms come into play. Today, these weapons are crucial for hunting, particularly in Europe and North America, and in many countries, no other method of harvesting is permitted. The rifle is used in some types of hunting, but the shotgun is by far the most important weapon in the hunting of waterbirds.

One example is the hunting of ducks and geese in North America (Table 1). This hunting takes place in autumn during the migration of the birds from their breeding areas to their wintering areas, and also in the wintering areas. Another example is the spring hunting of geese in Siberia. It has been estimated that about 300 000 geese of several species, but particularly the Greylag Goose *Anser anser*, are killed during a single season (E.E. Syroechkovski, Jr. pers. comm.).

Why harvest? Throughout the millennia, the primary motivation for harvest has been to ensure a supply of food and other useful natural products. This is still a very important motivation,

**Table 1. Harvest of Anseriformes in the USA in 1998. After Rothe (1999).**

Flyway	Ducks	Geese
Atlantic	2 371 000	498 000
Mississippi	9 384 000	1 424 000
Central	3 743 000	1 187 000
Pacific	3 643 000	396 000
Total	19 141 000	3 505 000

not only in developing countries, but also in Arctic regions where access to food resources other than those produced by nature is limited. An element of this “consumptive” motivation is that the harvest may be converted into other values, including monetary value. In much of the developed world, however, the primary motivation for harvest is relaxation, leisure and a passion for the hunt. This may be referred to as “recreational” motivation.

A third motivation for harvest is “management”. Here, harvesting activities are carried out as part of the regulation or management of nature. Such activities include the control of wildlife to reduce damage to croplands, fisheries and the like. Usually, a harvest is driven by two of these motivations – or possibly by all three of them.

A typical example of hunting driven by both the need for food and the desire for recreation is the duck hunting in Western Europe, for example in Denmark. Here, the principal motivation is overtly the pleasure and excitement of hunting, but the reward in the shape of fresh, tasty meat is to many an equally strong factor. In Denmark, as in many other countries, one may encounter the whole three-fold motivation, for example in connection with goose hunting, where the hunt, in addition to providing recreation and the prospect of nice meat, may also be driven by a local need for management of the goose populations.

## HOW MUCH IS HARVESTED? – IMPACT AND MONITORING

An obvious question that most people might ask in relation to the harvest of waterbirds is “how much is actually harvested?” In order to assess the ecological sustainability of the harvest, it seems essential to be able to answer this question. Yet there are no surveys or censuses that give anything like a reliable estimate of the global extent of harvest of waterbirds. In North America and a number of Western European countries, quite detailed assessments of the harvest exist. In North America, it is even possible in the case of some species to compare measures of harvest with estimates of population size and thereby obtain an impression of the mortality imposed by hunting on the populations. The Mallard *Anas platyrhynchos* is considered to be the most heavily hunted species in North America. Judging from estimates of population size and harvest, the annual hunting mortality for Mallard is estimated to be below ten percent of the total population in autumn. Other species of waterfowl are pursued less intensively, and it is considered that the hunting mortality for these is in the order of a few percent.

Programmes for the monitoring of hunting harvests exist in a number of countries. In some cases, the reporting of harvests is voluntarily, while in others, it is mandatory. Denmark is one of the countries with the best reporting systems. The official Danish harvest statistics are derived from a mandatory reporting system for all Danish hunters, and have existed since 1942. They indicate that in Denmark about one million waterbirds are brought down annually. Of these, about one-third are thought to be Mallard that have been reared and released for hunting. However, the reporting is not carried out at the species level, but primarily refers to groups of species. For instance, six species of dabbling ducks, Northern Pintail *Anas acuta*, Eurasian Wigeon *A. penelope*, Common Teal *A. crecca*, Gadwall *A. strepera*, Garganey *A. querquedula* and Northern Shoveler *A. clypeata*, are grouped under the heading “other dabbling ducks”. Hence,

no direct comparison of harvest and population size can be made at the species level. Therefore the Danish harvest statistics do not constitute a tool that can be used on its own for detailed management of species, either nationally or at the flyway level. First and foremost, the statistics provide basic information that can be used in a broader research context, e.g. interview surveys among hunters. For the last 20 years, the Danish harvest (bag) statistics have been supplemented by the collection of wings of bagged waterbirds and other migratory species. This is a voluntary system and provides valuable insight into the composition of the harvest with respect to species, age and sex. Moreover, it gives a picture of the geographical distribution of the harvest throughout the hunting season, as hunters report on the hunting ground. The number of collected wings has varied over the years, averaging about 11 000 per year (Clausager 2004).

Similar programmes for the collection of bag statistics are found in other countries, while at international level, there are various strategies, with that of Wetlands International’s Waterbird Harvest Specialist Group (WHSG) being the most relevant with regard to the integrated monitoring of waterbird harvests.

Statistics on hunting bags are based on reports by the hunters. In this regard, the following analysis is important. Two concepts of yield are employed: the real yield (B) which is unknown, and the reported yield ( $B_r$ ). The real yield (B) may be viewed as a product of the population size (N) of a given species or species group multiplied by the hunting mortality ( $m_h$ ):

$$B = N \times m_h$$

If it is assumed that the hunting mortality is constant, trends in the yield will reflect trends in the population size. If the hunting mortality is known, which is only rarely the case in waterbirds, the yield may be recalculated into an actual population size.

The reported yield ( $B_r$ ) is a product of the real yield and a factor ( $f_h$ ) that expresses the willingness and ability of the hunters to report. Hence,

$$B_r = B \times f_h$$

This factor varies according to a series of circumstances, which include legislation for and promotion of the reporting system, the efficiency of the system, and the scepticism of the hunters towards the use of the data.

Given the above relationship, it must be recognized that the possibility for using reported bags as a reflection of the real bag and population size relies on a series of assumptions, and that sound management requires analysis of the various factors in play. Data, not least data at the flyway level, are considered to be vitiated by such uncertainty that for a broad range of species it is not possible to develop a reliable system that can serve as a stand-alone monitoring tool in international bird management. Assessments of yield are viewed first and foremost as a valuable supplement to internationally co-ordinated population counts, for instance, when special yield surveys are launched in relation to “hot species”, e.g. huntable species that according to international standards have an unfavourable conservation status. It is, however, important to note that in many countries game yield statistics constitute a very valuable scientific basis for bird management. The systems that have been developed and the efforts which, for example, Wetlands International’s Waterbird Harvest Specialist Group is carrying out at flyway level should therefore be promoted and supported.

**Fig. 2.** Harvest management tools are the parameters that define the legal potential for harvest, here illustrated as a cube defined by three categories of management tools – period, methods and space – that specify 1) time periods, 2) harvest methodology, and 3) geographical areas, respectively.

### HARVEST MANAGEMENT TOOLS

The world over, there is a large number of different management tools regarding the harvest of waterbirds. In a few regions and countries, there are complete bans on harvest, but in by far the most countries, there is management that allows for harvest within certain limitations. The framework within which harvest can occur may be internationally established. At a global level, for example, the Ramsar Convention on Wetlands (Ramsar, 1971) sets certain guidelines for harvesting by referring generally to the principle of wise use, although it makes no specific demands regarding harvest.

In order to make the management tools operative, it may be useful to divide them into the following categories: (1) tools that specify time periods; (2) tools that specify harvest methodology; and (3) tools that specify geographical areas (Fig. 2).

The classic tool for management of harvest is the establishment of hunting seasons and hunting timetables. In many European countries, the first regulations based on hunting periods were established long ago in the nineteenth century. As mentioned above, the framework for hunting periods is determined in some regions by an international forum, e.g. within the European Union (EU). Hunting seasons are determined at national or sub-national level, and the fundamental principle is that there is no hunting either during spring migration or during the birds' breeding season, but rather immediately after reproduction when populations are at their largest and the biological potential for harvest is at its maximum. In many areas, however, hunting is also carried out before and during the breeding season. Such practice is not necessarily sustainable. In many countries, regulations are made concerning the time of day at which hunting is allowed. Thus, hunting at night is frequently regulated. In some countries, the hunting of geese, for example, is allowed only in the morning hours.

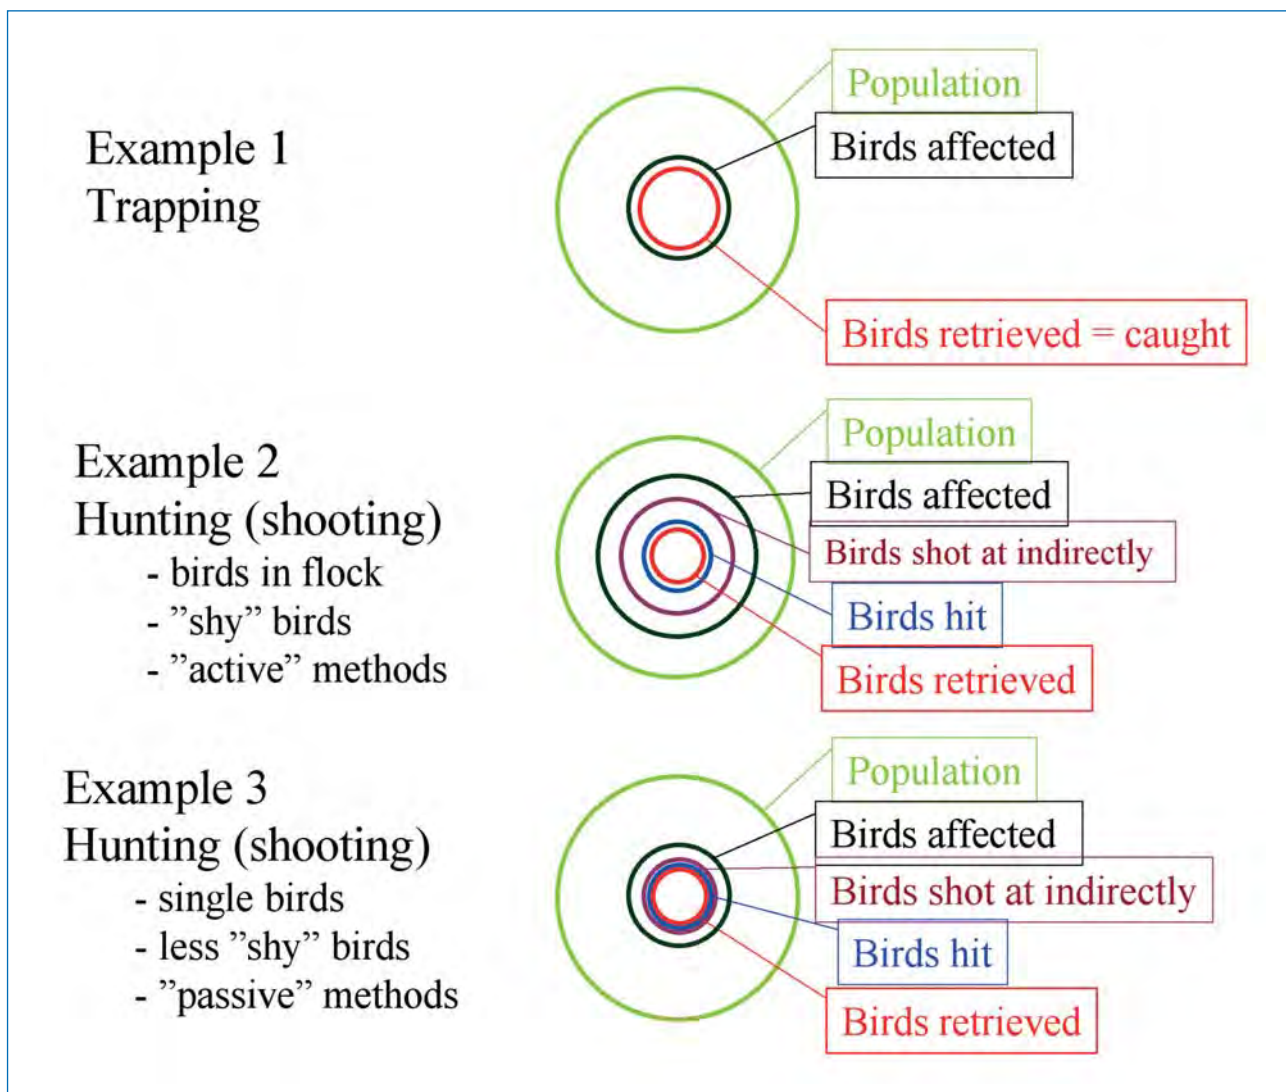

Another management tool which is frequently applied is based on regulation of the harvest in specific geographical management areas. There are a large number of definitions and concepts for such areas world-wide. The World Conservation Union – IUCN has established a series of categories, but the variation is great – from “strict nature reserves” to national parks, wildlife management areas and sanctuaries. Many of

these management areas relate to an international classification, while others relate to national legislation. A well-known global network of areas some of which are especially designated for waterbirds are Ramsar sites, designated under the Convention on Wetlands. The Natura 2000 network is a network of sites established under the Birds and Habitats Directives of the EU. Even though the Ramsar Convention and the EU Directives do not specify particular rules for harvest in their respective designated sites, but merely call for general sustainability and a limitation of extensive disturbance, specific limitations on harvest have been established in both Ramsar sites and Natura 2000 sites in a number of countries. These limitations may constitute a complete ban on harvest, but more commonplace is the establishment of core areas with a very restrictive management regime, e.g. with prohibition of harvest, surrounded by a zone in which harvest may be regulated both in time and in the harvest methods that may be employed.

The third category of management tools is based on the methods of hunting and capture. As mentioned earlier, the methods of harvest of waterbirds vary widely throughout the world. Harvest methods are products of culture, tradition and technological development through the millennia. No quantification of the distribution of use of the various methods has ever been made. However, in the vast majority of western countries, the harvesting of waterbirds is carried out almost exclusively with firearms. Several international texts establish particular rules for harvest methods. The AEWPA prescribes in its Action Plan (2.1.2 b) that the modes of taking are to be regulated. The EC Birds Directive (European Community 1979) prohibits the methods listed in its Annex IV, *inter alia*, snares, hooks, nets, traps, poisoned or anaesthetic bait, and semi-automatic or automatic weapons with a magazine capable of holding more than two rounds of ammunition. The Directive permits Member States to depart from these rules under certain conditions (Article 9). In many developing countries, firearms are used only to a limited extent in the harvesting of waterbirds. Here, nets, traps and snares are far more widespread.

A frequently used method of regulation is the establishment of bag limits. This is found in many regions of the Americas where the annual harvest is regulated by a special scoring system that sets limits on the number of waterbirds that a hunter may bag in a day. Bag limits are less widespread in Europe, where other means of regulation are more traditional. For certain species, the AEWPA Action Plan (2.1.2 c) requires that its Parties to “establish limits on taking, where appropriate, and provide adequate controls to ensure that these limits are observed”. Bag limits provide an option for regulating the total size of the harvest. However, the drawback to daily bag limits is that this system contributes to increasing the number of hunting days, and hence potentially increasing the temporal extent of hunting disturbance to waterbirds.

This model, in which management tools are divided into three dimensions (time periods, spatial tools and methods), provides a basis for analysing harvest management and comparing systems from different regions and countries. If the legal potential for harvest (the volume of the blue cube in Fig. 2) is perceived as a level for a sustainable harvest of a given population of waterbirds, it is up to the appropriate authorities in co-operation with stakeholders to organize each one of the dimensions of the cube in such a way that they comply best with

**Fig. 3.** Three examples of the impact of hunting / harvest. Example 1: passive capture, where the indirect effect of the harvest is limited relative to the yield. Example 2: active methods, where the effects are particularly strong, since the birds appear in flocks. Example 3: a situation is imagined where the hunting method is less aggressive and where the birds appear singly. The circles in Example 2 illustrate the gradient from all birds in the population (outer circle) to the birds that are bagged (innermost circle). In between lie the birds that are affected by the disturbance caused by the harvesting activity (circle 2), birds that are shot at indirectly or directly (circle 3), and birds that are hit (circle 4).

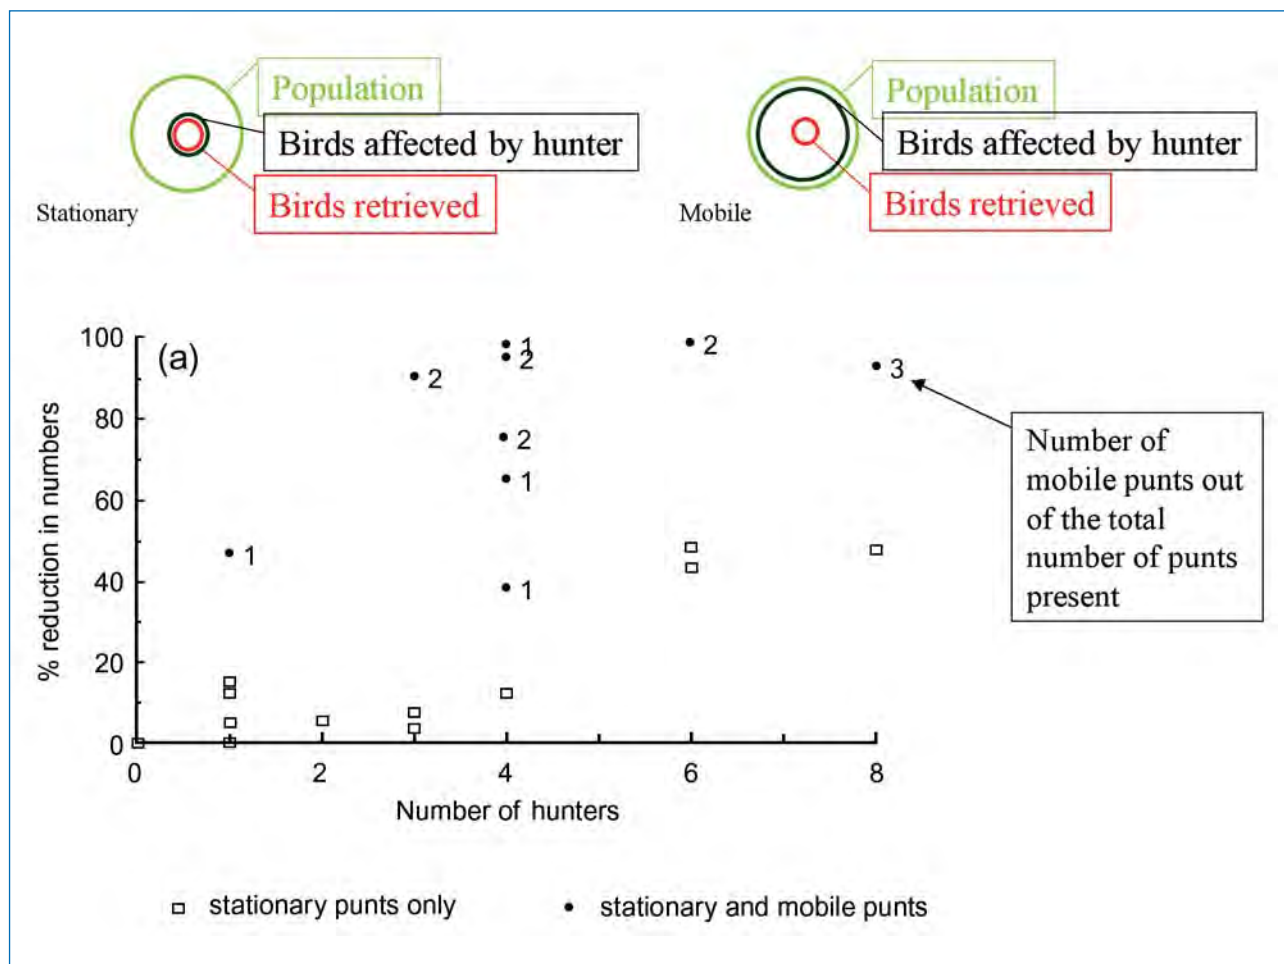

local traditions. This may produce an input to flyway-based management of migratory birds, with the Range States within the flyway first and foremost discussing and reaching agreement on levels of harvest, while the actual management takes place nationally or sub-nationally, and thereby in full compliance with the users and considering both ecological and social sustainability.

#### IMPACT ON POPULATIONS

An assessment of the ecological sustainability of a harvest should contain both an assessment of the actual yield and an assessment of the disturbance that a given harvest method inflicts on the population. Yield and disturbance both depend on the choice of harvesting methods. The use of firearms usually gives high selectivity in the yield itself, but has the potential to cause disturbance that has an impact on more species than just the target. The use of methods of passive capture, such as nets, traps and snares, gives low species selectivity, but also has a limited disturbance effect.

Fig. 3 shows a model that describes a gradient from the total number of individuals in a population to the number that are bagged. In between lie the number of birds that are affected by the disturbance caused by the harvesting activity, the birds that are shot at indirectly or directly, and the birds that are hit. It is customary for people involved in the administration of waterbird management to focus on the innermost and outermost quantities, i.e. the yield relative to the population, without giving serious consideration to the quantities lying in between. In effective management, however, it is important to assess sustainability with more refinement, so that it is emphasized in the choice of management that the populations are affected as little as possible relative to the purpose of the harvest. In this context, it is important to keep making a point of both the ecological and the political sustainability of the harvest.

One concrete example from Danish studies is shown in Fig. 4. This shows how the numbers of Eurasian Wigeon resting at Nibe Bredning are affected by the intensity of shooting from two types of shooting punts, i.e. small, flat-bottomed boats used

**Fig. 4.** The numbers of Eurasian Wigeon *Anas penelope* resting at Nibe Bredning, Denmark, in relation to 1) the numbers of punts, and 2) the type of hunting practice (stationary/mobile). After Madsen (1998).

for concealment during hunting (Madsen 1998). This analysis could open up a discussion of the selection of hunting methods. As trapping seems to cause less indirect impact on populations than other hunting methods, it might seem obvious to select this method instead of methods with a larger indirect impact. However, in most countries trapping is not seen as being selective (ecological aspects), and is therefore in direct conflict with national and international standards for the harvesting of waterbirds. Furthermore, in many countries, trapping of waterbirds does not meet ethical standards and does not comply with the general motivation for hunting. On the basis of the Danish studies, it could also be questioned why the use of mobile punts is allowed in Denmark. The answer is that mobile hunting can be managed in a sustainable way, even in areas with dense populations, as long as birds are provided with secure refuges (spatial tools). Furthermore, “stalking” birds with mobile punts is seen as a huge challenge, and complies very well with the “joy of hunting” motivation.

One more example to illustrate the model in Fig. 3 relates to circle 4, which describes the number of birds that are hit by shots. From a series of research programmes, it is known that only a subset of these are bagged. The difference between the two sets is calculated as the “non-retrieved harvest” which again may be subdivided into two groups: birds that die, and birds that survive. Birds that die without being retrieved should, from a management viewpoint, be added to the yield in as much as they

are lost to the population. In the USA, the “non-retrieved harvest” must be reported together with the rest of the yield. Birds that survive after being hit are defined as “wounded”. This group has been the focus of attention in a number of countries, and the debate has been particularly directed towards the political (ethical) sustainability of the harvest. Experience in Denmark, for example, has shown that it has been possible to reduce the numbers of wounded Pink-footed Goose *Anser brachyrhynchus* by 75% simply by means of a campaign directed at hunters, and without legal interference.

#### CO-MANAGEMENT

In order to ensure political sustainability – in particular, the socio-economic aspects – programmes have been developed in many parts of the world to involve the local population in the management of natural resources, including the harvesting of waterbirds. An overall term for these efforts is “co-management”. Co-management may be described in terms of co-operation between international, national and local stakeholders, and between stakeholders at the same level, e.g. various local user interests. Co-management is necessary, partly because many communities around the world are dependent on the utilization of natural resources including wild birds, and partly because no ecosystem is now “beyond the reach” of humans.

An example that illustrates the need for co-management is hunting in Greenland – a vast area with huge natural resources

**Fig. 5.** The regions of Greenland's vast coastal areas that can be reached by motorboat, shown by circles with a radius of 100 km from communities of more than 1 000 inhabitants (blue), and 50 km from settlements of less than 1 000 inhabitants (orange). Communities around the world are dependent on the utilisation of natural resources including wild birds, and no ecosystem is "out of reach" of humans. Source: Due & Ingerslev (2000).

and a very small human population. However, there are indications that waterbird management in Greenland is not sustainable in every respect (Hansen 2001). Greenland has developed from being a vast natural environment which, by virtue of its size, could not be overexploited, into an area that because of modern means of transportation and capture has become vulnerable to human exploitation. Fig. 5 indicates those coastal areas of Greenland within a 100 km radius of communities of more than 1 000 inhabitants and those within a 50 km radius of settlements of less than 1 000 inhabitants. The figure demonstrates that very substantial parts of the west coast of Greenland may be reached in a short time from both small and large villages by modern means of transportation such as fast motor boats.

Another example is found at Lake Chilwa in the southern region of Malawi. This wetland, which has been designated as a Ramsar site (Ramsar Convention 1996), comprises mainly open water, *Typha* swamps, marshes and floodplain grasslands. Every year, Lake Chilwa supports about 153 resident species of waterbirds and 30 species of Palearctic migrants. The Lake Chilwa

catchment has a population density of 162 persons/sq. km, one of the highest in Malawi. Most of these people are subsistence farmers and/or fishermen. The waterbird populations are heavily utilized. There are at least 461 bird trappers using traditional traps and snares. Catching of birds takes place every year with a peak period in the rainy season. Birds are harvested for local consumption and for trade.

Management plans were developed at Lake Chilwa in 2001. The objectives were to enable the local communities to manage the natural resources in a sustainable manner for their own benefit. Bird hunting committees and a bird hunters' association were formed. A project was initiated in 2004 to build capacity in the local community, to encourage the participation of local NGOs in advising communities on sustainable bird management, and to encourage international NGOs to participate in research and monitoring.

## CONCLUSION

Waterbird harvest is widespread and is an important activity in local communities around the world. It is diverse and includes a huge variety of management systems. Although there are some examples of harvest practices being non-sustainable, there seems to be no reason to believe that harvesting/hunting is a general contradiction to the conservation of bird life. On the contrary, the right to use natural resources can motivate local people – especially hunters – to get involved in conservation. Training is a vital element. To build capacity at all levels, more knowledge is needed in terms of (a) the direct impact of harvest (bag, products) and indirect impact (disturbance); (b) population status and trends at flyway, migration route and population level; (c) mankind and nature, *vis-a-vis* development and conservation systems. To secure the conservation of flyways across borders and across continents world-wide, co-operation is needed at all levels – including that of the hunters.

Lank, D.B. & Nebel, S. 2006. Cross-cutting research on a flyway scale – beyond monitoring. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 107-112.

### ABSTRACT

Research on the population ecology of migratory birds is facilitated by a holistic or “cross-cutting” approach that synthesizes information gathered across the entire flyway, throughout the annual cycle and utilizing different research disciplines. Radio-tracking Western Sandpipers *Calidris mauri* from non-breeding to breeding grounds documented migration timing and usage of stopover sites. Data collected throughout the non-breeding range showed that females migrated farther south than males, and that juveniles were over-represented towards the extremes. Collaboration documented a latitudinal “life-history divide”: northerly juveniles migrate and attempt to breed, while southerly juveniles overwinter at non-breeding sites. As predicted by life history theory, southerly birds appear to have higher annual survival rates than migrants. Comparing daily survival rates during breeding, non-breeding and annual periods permits the calculation of survival rates during migratory periods. Integrated studies of behavioral ecology, demography and physiology allowed interpretation of an apparent local population decline in migrating Western Sandpipers. Dramatically decreased usage of a small stopover site occurred despite abundant food resources, and appeared to be caused by a behavioral change in response to increasing falcon populations, rather than a decrease in numbers of migrants. The combination of approaches allowed testing alternative hypotheses as likely causes for the change in site usage.

### INTRODUCTION

Understanding population regulation is a key issue in the study of migratory birds, but it acquires special urgency in species that suffer from decreasing population numbers. In shorebirds (family Scolopacidae), population declines are widespread: more than half of all shorebird populations world-wide are thought to be declining (International Wader Study Group 2003, Stroud *et al.* 2004, 2006), and within North America, this estimate is as high as 80% (Morrison *et al.* 2001).

A long-term research program organized by the Centre for Wildlife Ecology (CWE) at Simon Fraser University, Canada, is using a cross-seasonal and cross-disciplinary approach to study population ecology and, ultimately, population regulation of a migratory shorebird (Nebel & Lank 2003). This holistic approach is based on the synergy gained from synthesizing information sampled across the entire flyway, throughout the annual cycle, and utilizing different research disciplines, creating opportunities for conservation work (Harrington *et al.* 2002).

The Western Sandpiper *Calidris mauri* was chosen as a model species, being the most abundant shorebird on the American Pacific coast. Western Sandpipers breed in western Alaska and eastern Siberia, and overwinter along the American

Pacific coast between southern Canada and Peru, and, in smaller numbers, along the Atlantic coast and in the Caribbean (Wilson 1994, Nebel *et al.* 2002). Over 90% of captured birds may be confidently assigned a sex based on bill lengths (Page & Fearis 1971).

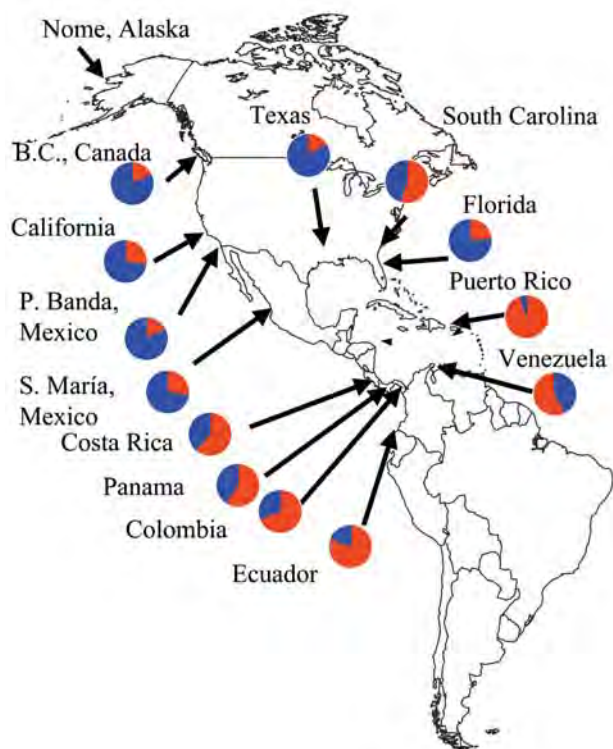

The CWE fostered research on diverse aspects of the species' biology by organizing a loose association of researchers working throughout the species' range to collaborate and exchange information (see Acknowledgements). Members consulted with government wildlife managers and non-governmental agency scientists, recruited academics in complimentary fields to work with the species, steered post-doctorate, graduate and undergraduate students towards particular projects, and provided seed funding for researchers elsewhere, particularly in Latin America. The group created a sense of common purpose during annual workshops, which attracted additional participants to the network, and through an electronic list-server.

### CUTTING ACROSS THE FLYWAY

A series of radio-tracking studies of migrant Western Sandpipers conducted over five seasons between 1995 and 2004 during northward migrations from Mexico and California to Alaska capitalized on this network. Collaborators produced detailed information on the movements and stopovers of individual shorebirds with respect to age, sex, time of year, weather conditions, staging site, and year (Iverson *et al.* 1996, Butler *et al.* 1997, Bishop & Warnock 1998, Warnock & Bishop 1998, Butler *et al.* 2002). These studies strengthened the evidence that 80-90% of the Western Sandpiper population use the Copper River Delta, Alaska, towards the end of their northward migration. The length of stay estimated for that site from radio-tracking data was integrated with census data to improve estimates of the species' total population size (Bishop *et al.* 2000). Further analysis of the wealth of data generated by this work will help test individually-based models of migratory strategy, which may be used to predict the population consequences of migratory habitat change.

As a second example, we improved the resolution of a pattern of sexual segregation of Western Sandpipers during the non-breeding season by combining information from 13 different sites, and discovered a novel pattern with respect to age (Nebel *et al.* 2002). Females migrate farther south than males, creating a latitudinal cline between sex ratio and Great Circle distance from the breeding grounds (Fig. 1). The local proportions of juveniles fit a significant U-shape with respect to migration distance (Fig. 2), which interacts with the sexual segregation such that juvenile males are substantially over-represented in samples from the northern end of the distribu-

**Fig. 1.** The proportion of female (red) and male (blue) Western Sandpipers *Calidris mauri* on the non-breeding grounds.

**Fig. 2.** Age ratios of Western Sandpipers *Calidris mauri* captured at 12 non-breeding locations. The local proportions of juveniles caught at each site vs. migration distance described a U-shaped pattern ( $F_{1,22}=5.08$ ,  $P<0.005$ ; after Nebel *et al.* 2002, reproduced with permission from The Auk).

tion, and juvenile females over-represented in samples from the southern end.

The distributions of sex and age classes also interact with a latitudinal difference in life history strategy (Fernández *et al.* 2004, O'Hara *et al.* 2005). Juveniles at non-breeding sites in Mexico predominantly migrate north and attempt to breed as

one-year-olds, while juveniles in Panama do not migrate, and instead "oversummer" on the non-breeding grounds. We infer that juveniles adopt one of two life history strategies, with shorter-distance migrants opting to attempt migration and breeding at a younger age, and longer-distance migrants maximizing first year survival at the expense of an earlier potential breeding opportunity.

This difference in strategies could map onto biological population differentiation, but none is currently recognized, and disproportionate representation of the sexes at different non-breeding areas makes this seem an unlikely situation. Alternatively, we may have documented two tactics of a conditional strategy (*sensu* Gross 1996), in which case the choice of tactics depends on an environmental cue, such as hatch date, and/or on developmental characteristics, such as body size. In this situation, migration distance itself might follow from a life-history decision based on condition made in Alaska prior to migration, or the opposite might occur, namely that the life history difference might follow from factors determining migration distance (O'Hara *et al.* 2002, O'Hara *et al.* 2005).

If lifetime reproductive success of individuals migrating south to different latitudes is similar, annual survival rates should be higher among oversummering juveniles than among juveniles migrating north in their first year, in order to offset the earlier age of first reproduction of migrants. Western Sandpiper researchers throughout the range and annual cycle have used mark-recapture studies to estimate  $\phi$ , the rate of local survival, which provides a minimum estimate of true annual survival rate (Table 1), and return rates, which will approach  $\phi$  if detection rates are high. Estimates of survival rates obtained at breeding and non-breeding grounds show some general agreement, assuming similar levels of permanent emigration. As predicted, local annual survival is lower in Mexico than Panama. As mark-recapture studies proliferate, comparisons among local survival rates derived from different situations and/or populations may refine our views of local habitat suitability and other aspects of population structure.

## CUTTING ACROSS THE ANNUAL CYCLE

Population managers recognize that partitioning the timing of annual mortality across seasons and locations improves their ability to target conservation action. Studies based on band recovery data can rarely address this question directly. The development and widespread availability of capture-recapture analysis tools (Lebreton *et al.* 1992, White & Burnham 1999) enabled researchers at different sites and seasons to collaborate to obtain the necessary information. The best examples are studies of individually marked geese, which carry conspicuous markers that facilitate re-sightings. For some populations, lower daily survival rates occurred during migration than in winter or summer (Owen & Black 1991, Clausen *et al.* 2001), perhaps due to hunting (Ward *et al.* 1997). Other studies found lower survival rates during breeding seasons (including migratory flights) (Madsen *et al.* 2002), concluded that breeding, wintering and even migration seasons had similar rates of natural mortality (Gauthier *et al.* 2001), or that seasonal patterns differed by sex (Schmutz & Ely 1999). Each study suggests specific management actions, and the ecological reasons for the diversity of situations contribute towards our general understanding of population regulation.

The use of mark-recapture information was taken a step further by combining information derived from different

populations of marked individuals. Sillett & Holmes (2002) obtained estimates of seasonal and annual survival rates from separate local populations of Black-throated Blue Warblers *Dendroica caerulescens* on the breeding grounds in New Hampshire, USA, and on the wintering grounds in Jamaica. Under the assumption that the individuals studied were representative of summer and winter populations, they combined their seasonal estimates with estimates of annual survival rates, and calculated survival rates during the migratory periods, which could not be studied directly. They concluded that the daily mortality rate during migration was 15 times higher than during the two residency seasons. Multiple mark-recapture data sets are becoming available for many non-game species, and comparisons among them may permit additional analyses along these lines. With Western Sandpipers, for example, we hope to develop techniques for combining information from the mark-recapture studies shown in Table 1 to address questions about seasonal survival rates and relative habitat quality.

### CUTTING ACROSS DISCIPLINES

Wildlife managers are often called upon to act in response to changes in local population size. Over the past decade, the cumulative number of Western Sandpipers counted during southward migration at the Sidney Island lagoon, a small stopover site in British Columbia, Canada, declined drastically from c. 16 000 to 4 000 (Ydenberg *et al.* 2004), creating a strong incentive to understand the factors causing this change. Members of the Western Sandpiper research group have collaborated, integrating behavioral, ecological, demographic and physiological studies to address this question.

The Sidney Island lagoon includes c. 100 ha of mudflat, surrounded on three sides by a forest and beach. Across the Strait of Georgia, 40 km east of Sidney Island, is the Fraser River estuary, the major stopover site in British Columbia, with over 5 000 ha of open mudflats that are used by up to a million shorebirds every autumn and spring. We do not know whether population changes have also occurred at the Fraser estuary because the size of the site makes it difficult to census. However, comparisons of attributes of both areas, and of birds captured at them, have

been useful in our analysis of this situation (Lissimore *et al.* 1999, Ydenberg *et al.* 2002, Ydenberg *et al.* 2004).

At Sidney Island, migrating Western Sandpipers were captured, measured, individually marked, and re-sighted daily during the years of population decline; birds were also captured and measured at the Fraser estuary. At Sidney Island, the body mass of captured birds decreased by c. 10% during this period, while no change was observed at the Fraser estuary. Mark-recapture analysis showed a decline in the length of stay of south-bound Western Sandpipers using Sidney Island, falling from about eight days in 1992 to about three days in 2001. These changes suggested that deteriorating food conditions at Sidney Island might cause changes in sandpiper numbers.

Western Sandpipers feed on soft-bodied macro-faunal and meio-faunal invertebrates (Sutherland *et al.* 2000, Wolf 2001), making it difficult and time-consuming to measure food abundance directly. However, recent advances in physiological methods offer novel ways to obtain indicator values for the quality of the resources at a site. Blood plasma triglyceride levels in Western Sandpipers correlate with fattening rates as well as with direct measures of food abundance (Williams *et al.* 1999, Guglielmo *et al.* 2005, Seaman 2003). Triglyceride levels of Western Sandpipers caught at Sidney Island in 1996 were twice as high as at the Fraser estuary (Ydenberg *et al.* 2002), casting doubt on lower food availability as an explanation for decreased usage of Sidney Island. Why, then, did Western Sandpipers leave Sidney Island before reaching a body mass comparable to birds at the nearby Fraser Estuary?

The past two decades have seen a steady increase in populations of the Peregrine Falcon *Falco peregrinus* in western North America (Hoffman & Smith 2003), following severe declines caused by the extensive use of DDT after the Second World War. Daily Peregrine sightings during southward migratory periods in the Strait of Georgia increased steeply since at least 1985 (Ydenberg *et al.* 2004). Western Sandpipers are preyed upon by Peregrines, and their escape performance decreases with increasing body mass (Burns & Ydenberg 2002). Individuals accumulating fat for onward migration are therefore especially vulnerable to predators. Peregrines are most successful when

**Fig. 3.** Comparison of annual cumulative daily counts (NC) of Western Sandpipers *Calidris mauri* stopping over at Sidney Island with estimates of the true number (NT), which take into account the estimate of length of stay. The values for NC indicate a significantly declining trend of c. 18% per year. In contrast, estimates of NT indicate no significant ( $P = 0.24$ ) decline (after Ydenberg *et al.* 2004; reproduced with permission from The Royal Society of London).

**Fig. 4.** A bird should switch from a more dangerous but more profitable site to a safer but less profitable site as a function of body mass, which determines its relative escape performance. With increasing predation danger over time, the threshold body mass for changing habitats decreases.

attacking by surprise, which is facilitated by cover, such as high vegetation. The Fraser estuary is large and open, and therefore a relatively safe place for a foraging sandpiper, while Sidney Island is small, enclosed, and inherently more dangerous (Ydenberg *et al.* 2002).

Within this context, Ydenberg *et al.* (2004) developed a hypothesis to explain the change in census numbers at Sidney Island: site choice is driven by a mass-dependent trade-off between local predation danger and foraging profitability. An individual is predicted to switch from a profitable, but dangerous site, to a less profitable, but safer site, contingent on relative marginal fitness values which may be represented as a threshold mass (Fig. 4). With increasing falcon abundance, this trade-off is thought to have led to the following dynamics at Sidney Island: increased danger  $\Rightarrow$  lower mass departure threshold  $\Rightarrow$  shorter length of stay  $\Rightarrow$  fewer birds counted.

Estimates of the true population size of migrants based on census data are particularly sensitive to length of stay. Ydenberg *et al.* (2004) used the mark-recapture data to estimate the actual annual number of birds moving through Sidney Island, incorpo-

rating information on length of stay. There was no evidence that fewer individuals passed through the site in later years (Fig. 3); instead, the steep census decline was accounted for almost entirely by the shortened length of stay. Thus, a change in behaviour, rather than a decrease in local population size, was responsible for the apparent decline.

Recoveries in raptor populations are taking place on continental scales in both the eastern and western hemispheres (Cade *et al.* 1988, Kjellén & Roos 2000, Hoffman & Smith 2003), and must have direct effects on mortality rates of their prey. More important, however, may be indirect effects, such as the changes in habitat usage as illustrated here, in response to changes in environmental danger (*sensu* Lank & Ydenberg 2003). The evidence for declining shorebird populations in North America comes primarily from counts made during migration (Morrison *et al.* 2001). Changes in length of stay alter the cumulative number of birds censused and peak counts, both of which are commonly used as indices in analyses of trends in population size. If changes in the use of smaller stopover sites, which are more easily monitored with precision, are taking place elsewhere, behavioral changes could account for part of the perceived population declines (Ydenberg *et al.* 2004). Other behavioral variables that could affect census data include changes in the timing or route of migration, which also may be influenced by predation danger (Lank *et al.* 2003). The potential effects of habitat or other behavioral changes should be taken into account when designing monitoring programs and interpreting data from them.

## CONCLUSION

The potential benefits of “cross-cutting” approaches to studies of the population ecology of migratory species may seem obvious, but what are the additional costs associated with this approach? These include generating and adopting common protocols for gathering data, steering students towards projects suitable for thesis topics, and spending far more time in the production of multi-authored reports than might be the case for more independent research. Enticing researchers who work in related fields to address questions of interest is potentially a highly cost-effective approach, as these researchers may subsequently bring more resources to the table as their interests grow, but it has the disadvantage that progress with a project will be limited by the schedules of multiple collaborators, each of whom can slow things down. We have invested considerable time in organizing meetings; this time paid off not only with exchange of information, but also in fostering a sense of common purpose and identity that kept participants engaged with the work. But fundamentally, we have found that collaborations are most likely to prosper if they take advantage of pre-existing interests in the populations or topics being addressed. Much of the success of our network came simply by identifying persons already enthusiastic about a question, supporting their individual efforts, and fostering communication and collaboration among them and with ourselves.

## ACKNOWLEDGEMENTS

We thank the Western Sandpiper Research Network, including the persons listed below, each of whom has made a substantial original contribution, knowingly or not. Fred Cooke and Rob Butler (Canadian Wildlife Service) initiated the CWE’s focus on this species. For work covered in this review: Nils Warnock, Mary

Anne Bishop and John Takekawa organized northward radio-tracking; Patrick O'Hara worked with Francisco Delgado and others in Panama; Guillermo Fernández worked with Horacio de la Cueva and others in Mexico; Tony Williams and his students Chris Guglielmo and Dana Seaman pursued physiological approaches; and Ron Ydenberg promoted interest in the potential effects of predators on everything. Additional researchers working on the breeding grounds include: Bart Kempenaers, Rick Lanctot, Brian McCaffery, Julie Neville, Dan Ruthrauff, Brett Sandercock, and Doug Schamel and family; on migration: Pat Baird, James Burns, Colin Clark, Oliver Egeler, Bob Elner, D.L. Jackson, Gary Kaiser, Barbara Kus, Moira Lemon, Darren Lissimore, James Lyons, Kim Mathot, Edmund Martinez, Amanda Niehaus, Katie O'Reilly, Lew Oring, Brent Ortego, Andrea Pomeroy, Pippa Sheppard, Mary Sewell, Will Stein, Barry Smith, Terri Sutherland, Nick Wolf, Peggy Yen, and Janet Yu; and on the wintering grounds: Felipe Becerril, Alejandra Buenorostro, Roberto Carmona, Jaimie Collazo, Daniel Estrada, Ben Haase, Brian Harrington, Francine Mercier, Susan Rice, Yolanda Sandoval, and Brian Watts.

Barbara Ganter pointed us towards studies of seasonal survival rates in geese, and Ron Ydenberg provided feedback on drafts of the manuscript.

Participants in the Western Sandpiper Research Network have received support from: the Centre for Wildlife Ecology and other programs at Simon Fraser University, The Canadian Wildlife Service and its Latin America Program, Environment Canada, the National Research and Engineering Council of Canada, the Department of Northern and Indian Affairs, Queen's University (Canada), and the Killiam Postdoctoral Program at the University of British Columbia; the US Geological Survey, US Fish and Wildlife Service, National Parks Service, Forest Service, National Science Foundation, Department of Defence, and Environmental Protection Agency; the Smithsonian Tropical Research Station; the Marine Ecosystem Health Program; the National Fish and Wildlife Foundation; Centro de Investigación Científica y de Educación Superior de Ensenada (CICISE); the Consejo Nacional de Ciencia y Tecnología (CONACYT, Mexico); the Patolandia Hunting Club; the European Science Agency; the Konrad Lorenz Institute for Comparative Ethology; the Belgium Fund for Scientific Research; the Point Reyes Bird Observatory; the American Wildlife Research Foundation, Inc.; Chase Wildlife Foundation; Ducks Unlimited; the Lincoln Park Zoo; Sigma Xi; and the John Cooper, Frank M. Chapman, and Jennifer Robinson Memorial Funds.

The authors thank the organizers of the Waterbirds around the world Conference for the invitation to present this work, and Wetlands International for financial support that facilitated Silke Nebel's participation at the meeting.

## Conservation of albatrosses and petrels of the Southern Ocean

John Cooper

Avian Demography Unit, Department of Statistical Sciences, University of Cape Town, Rondebosch 7701, South Africa.  
(email: jcooper@adu.uct.ac.za)

Cooper, J. 2006. Conservation of albatrosses and petrels of the Southern Ocean. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 113-119.

### ABSTRACT

Albatrosses and petrels are among the world's most threatened birds, and among the most migratory, undertaking vast movements at sea, including when breeding. Their single-most important threat is from commercial fisheries, especially longlining and demersal trawling. On land, introduced predators constitute the most serious threat, especially to the smaller burrowing species, but human disturbance, habitat degradation and pollution all play a role. A number of initiatives has been undertaken to address these threats. The International Plan of Action for Reducing Incidental Catch of Seabirds in Longline Fisheries, adopted by the Food and Agriculture Organization of the United Nations in 1999, sets out detailed guidelines for nations to follow in adopting their own National Plans of Action (NPOA-Seabirds). Covering a broader suite of threats, the international Agreement on the Conservation of Albatrosses and Petrels (ACAP), which came into force in February 2004, aims to improve the conservation status of albatrosses and the larger petrels, both on land and at sea. At the non-governmental level, the Global Seabird Programme of BirdLife International encourages action by governments and commercial fisheries alike, as do a number of other international

and national NGOs. The level of international co-operation achieved between international bodies, national governments and non-governmental organizations to further the conservation of southern albatrosses and petrels can be regarded as an exemplar for the conservation of pelagic seabirds in other oceans.

### INTRODUCTION

Albatrosses and petrels are among the world's most threatened birds (Robertson & Gales 1998, Brooke 2004). According to the latest international listing (BirdLife International 2004a), 60 (47%) of the 129 living species of the order Procellariiformes (tubenoses) have been accorded a global category-of-threat status, ranging from Critically Endangered (extremely high risk of extinction in the wild; 15 species), through Endangered (very high risk of extinction in the wild; 17 species) to Vulnerable (high risk of extinction in the wild; 28 species). A further 14 species are considered to be Near Threatened (Table 1). Within the family Diomedidae (albatrosses), all but two of the 21 species recognized are considered to be globally threatened. This is a relatively recent phenomenon: the 1979 version of the Red Data Book listed just 12 procellariiforms as globally threatened, of

A 27-year old Wandering Albatross *Diomedea exulans* guards its downy chick on South Africa's Marion Island. Photo: J. Cooper.

**Table 1.** Numbers of species and conservation status of procellariiform seabirds (after BirdLife International 2004a).

Family	Critical	Endangered	Vulnerable	Near Threatened	Total	% threatened
Albatrosses, Diomedidae	2	7	10	2	21	90.5
Petrels, Procellariidae	11	8	17	11	82	43.9
Storm petrels, Hydrobatidae	2	1	1	1	22	18.2
Diving petrels, Pelecanoididae	0	1	0	0	4	25.0
<b>Totals</b>	<b>15</b>	<b>17</b>	<b>28</b>	<b>14</b>	<b>129</b>	<b>46.5</b>

which only one was an albatross, the Short-tailed Albatross *Phoebastria albatrus*; this was listed as Endangered (King 1979). What has caused this calamitous change in fortunes?

It might be considered that the occurrence of albatrosses and petrels far away from the world's centres of human habitation and activity has lent them a good measure of safety. This might have been so once, but it is assuredly no longer the case. There is some cause for optimism, however, since the threats now facing these charismatic species are being addressed on many fronts. In this paper, I first review the current threats facing albatrosses and petrels, concentrating on those species that frequent the Southern Ocean and its oceanic islands. I then consider the actions underway to enhance their conservation status, and what actions are still required. I end by attempting to show by way of examples of specific initiatives that the level of international co-operation that has been achieved in the Southern Ocean to date may yet allow southern pelagic seabirds to survive this century. At the same time, I suggest that this co-operation stands as an exemplar for the conservation of pelagic seabirds of the other oceans of the world.

#### ALBATROSSES AND PETRELS AS MIGRATORY SPECIES

Albatrosses and petrels are arguably the world's most pelagic seabirds, breeding on remote oceanic islands, and ranging over seas far away from continental shores (e.g. BirdLife International 2004b). In so doing, most species migrate over vast distances, especially when not breeding. Several species, notably the albatrosses, can undertake movements that encircle the Southern Ocean, either as non-breeding adults or as juveniles, whereas others may range from Antarctic to subtropical waters (e.g. Weimerskirch *et al.* 1999, BirdLife International 2004b, Croxall *et al.* 2005, P.G. Ryan *in litt.*). Even when breeding and so partially tied to land, albatrosses and petrels may travel hundreds and sometimes a thousand or more kilometres during a single foraging trip (e.g. Nel *et al.* 2000, 2002a). These movements take them out of territorial waters and Exclusive Economic Zones (EEZ) and onto the High Seas. During such movements, they may enter the territorial and EEZ waters of nations other than those of their breeding grounds (Nichols *et al.* 2000, BirdLife International 2004b), making them truly international animals, and thus their conservation a matter of international concern and shared responsibility.

#### CURRENT THREATS FACING SOUTHERN ALBATROSSES AND PETRELS

All seabirds, including albatrosses and petrels, are creatures of land, air and sea. The threats they face may be conveniently divided into those that occur on land, and those at sea. These are discussed separately below.

#### Land-based threats to southern albatrosses and petrels

The subantarctic and cool-temperate islands of the Southern Ocean were, in the main, discovered around the end of the eighteenth century. Very rapidly, they were visited by sailing vessels that exploited their populations of fur seals *Arctocephalus* spp. and Southern Elephant Seal *Mirounga leonina* to near extinction (e.g. Headland 1990, Richards 1992). At this time, sealers stayed ashore for extended periods, living partially, and at times wholly, off the land. Their diet included seabirds and their eggs, and albatrosses and petrels were not spared. This level of exploitation was very high at times, especially when sealers were marooned or shipwrecked (e.g. Busch 1980). However, a more serious and longer-lasting threat has come from the various alien species that the sealers brought with them. These inadvertent or deliberate introductions have included biota of every description, but the most serious in respect to seabirds have been mammalian predators that have preyed directly on especially the smaller petrels, and herbivores that have altered their habitats. A prime example of the former is the feral domestic cat *Felis catus* which has devastated burrowing petrels on a number of southern islands, most probably causing several local extinctions (Cooper *et al.* 1995, Dingwall 1995, Bester *et al.* 2002). An example of the latter is the European Rabbit *Oryctolagus cuniculus* that has severely affected the megaherb fields of Australia's Macquarie Island (Copson & Whinam 1998). Accounts of other alien species on southern islands that have affected, and in some cases continue to affect, seabirds may be found in papers within Dingwall (1995). In the main, the larger albatrosses (Diomedidae) have been less seriously affected by introduced species, when compared to the smaller, burrowing petrels (families Procellariidae, Hydrobatidae [Oceanitidae] and Pelecanoididae). Two notable exceptions to this observation are the continuing deleterious effects of the omnivorous domestic pig *Sus scrofa* on New Zealand's Auckland Island (which both disturbs the ground by rooting and can kill and eat albatross chicks; Dingwall 1995) and the House Mouse *Mus musculus*, which, surprisingly, is able to kill large chicks of the Endangered and near-endemic Tristan Albatross *Diomedea dabbenena*, as well as chicks of burrowing petrels, on Gough Island by literally eating them alive (Cuthbert & Hilton 2004, Angel & Cooper 2006, R.M. Wanless pers. comm.).

Another current land-based threat comes from human disturbance, including by commercial tourists (e.g. de Villiers *et al.* 2005). Scientific research and tourism take place at a number of southern islands, and if not properly managed, have the capacity to reduce breeding success, introduce new disease-bearing agents (Weimerskirch 2004), and ultimately reduce population sizes of albatrosses and petrels. Habitat degradation also plays a role at some breeding localities. This may be caused, for

A group of Endangered Atlantic Yellow-nosed Albatrosses *Thalassarche chlororhynchos* incubating on their pedestal nests among *Phylica* trees on Gough Island, a United Kingdom World Heritage site in the South Atlantic. Photo: J. Cooper.

example, by fires or grazing by introduced herbivores, such as several species of domestic animals on New Zealand's southern islands and on the inhabited main island of Tristan da Cunha (Dingwall 1995).

### Sea-based threats to southern albatrosses and petrels

Southern albatrosses and petrels face their greatest risks at sea. Paramount among these is the mortality caused by fisheries. Attention was first drawn to the large numbers of albatrosses killed by the southern longline fishery for tuna *Thunnus* spp. in the early 1990s (Brothers 1991). Species ranging from the great albatrosses *Diomedea* spp., to the smaller mollymawk albatrosses *Thalassarche* spp., the two species of giant petrels *Macronectes* spp. and burrowing petrels of the genera *Procellaria* and *Puffinus* (shearwaters) are all at serious risk from longlining (see the species accounts in BirdLife International 2004a and references therein). As well as the pelagic tuna fisheries, many southern seabirds are killed by demersal longlining for Patagonian Toothfish *Dissostichus eleginoides* in the Southern Ocean, including by "Illegal, Unreported and Unregulated" (IUU) fishing vessels (Brothers *et al.* 1999). The highest levels of mortality are now thought to take place around the French subantarctic Kerguelen Islands, most especially of White-chinned Petrels *Procellaria aequinoctialis* (Delord *et al.* 2004), although until recently, many birds were killed by both illegal and legal toothfish fisheries elsewhere in the Southern Ocean (e.g. around the South African Prince Edward Islands; Nel *et al.* 2002b).

More recently, it has been shown that demersal trawling in the Southern Hemisphere has the capacity to kill large numbers of albatrosses and petrels, which collide with trawl cables while attempting to feed on offal and discards from factory ships (B. Sullivan *in litt.*, S.L. Petersen pers. comm.). Collisions can result in broken wings and entangled birds being dragged below the surface and drowning.

Albatrosses and petrels face other threats at sea. Ingestion of plastic particles and fish hooks both take their toll (Ryan 1987, Nel & Nel 1999). Entanglement with fishing gear is also a problem (Nel & Nel 1999). Direct persecution of southern albatrosses and petrels at sea now seems to be rare (in the past some species were deliberately caught for human consumption, or shot from sailing vessels for sport or scientific specimens; Robertson & Gales 1998), but isolated cases of birds with their legs apparently tied together deliberately have been reported in recent years (R.M. Wanless pers. comm.). Lastly, changes due to over-fishing and global warming are likely to be affecting the food supplies of albatrosses and petrels adversely in some regions, although offal dumped from fishing vessels can be to the birds' advantage (e.g. Ryan & Moloney 1988).

### ENHANCING THE CONSERVATION STATUS OF SOUTHERN ALBATROSSES AND PETRELS

A number of initiatives has been undertaken to address the threats of pelagic seabirds, including albatrosses and petrels, at the international, national and non-governmental levels. Three of the most significant (although there are many other examples that could have been chosen) are described below.

### The International Plan of Action for Reducing Incidental Catch of Seabirds in Longline Fisheries

The International Plan of Action for Reducing Incidental Catch of Seabirds in Longline Fisheries, adopted by the Food and Agriculture Organization of the United Nations (FAO) in 1999, sets out detailed guidelines for nations to follow in adopting their own National Plans of Action (NPOA-Seabirds; FAO 1999, Cooper *et al.* 2001). Perhaps because it is a voluntary measure, forming part of the FAO Code of Conduct for Responsible Fisheries, few countries have as yet adopted their plans. Formally adopted NPOA-Seabirds exist for Brazil, the Falkland Islands, New Zealand and the USA. Other fishing countries have plans in varying stages of preparation or formalization: these include Australia, Canada, Chile, Japan, Namibia, South Africa and Taiwan.

Existing National Plans of Action vary in their scope and detail, but all list a suite of mitigation measures aimed to reduce seabird mortality to levels defined in terms of the number of individual birds killed or by setting a number of birds killed per thousand hooks. Mitigation measures that are commonly adopted into national regulations include night-setting, use of a bird-scaring “Tori” line, avoiding the dumping of offal and discards during line setting, and adding weights to the line to increase sink rates.

### Agreement on the Conservation of Albatrosses and Petrels

In 1997 and 1999, primarily occasioned by knowledge of the effects of longline mortality, all species of albatrosses and of *Macronectes* and *Procellaria* petrels were listed in the Appendices of the Bonn Convention on the Conservation of Migratory Species of Wild Animals (CMS). Following these listings, Australia took the lead in proposing an Agreement under the CMS to increase the protection of albatrosses and the larger petrels. Successful negotiation meetings were held in Australia and South Africa during 1999 to 2001, and the Agreement on the Conservation of Albatrosses and Petrels (ACAP) came into force with its required five Parties (Australia, Ecuador, New Zealand, South Africa and Spain) in February 2004. By July 2006, four more countries, Chile, France, Peru and the United Kingdom, had become Parties (Cooper & Ryan 2001, [www.acap.aq](http://www.acap.aq)). It is expected that Argentina and Brazil, both signatories to the Agreement, will ratify and become Parties soon. When these two ratifications are achieved, practically all of the breeding range states for ACAP-listed species will be Parties (Fig. 1, Table 2),

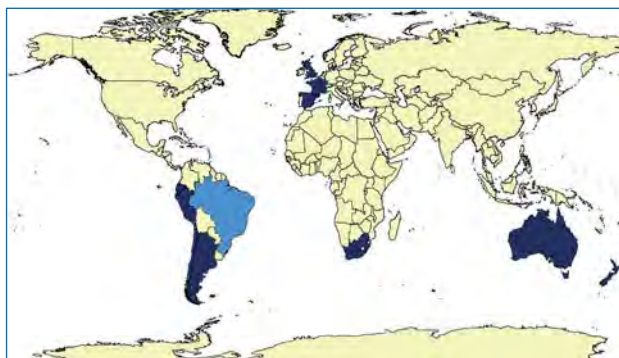

Fig. 1. Parties (dark blue) and Signatories (light blue) to the Agreement on the Conservation of Albatrosses and Petrels (as at November 2006).

Table 2. Albatrosses and petrels listed within the Agreement on the Conservation of Albatrosses and Petrels and their global conservation status.

Species	Conservation status (BirdLife International (2004a))
Wandering Albatross <i>Diomedea exulans</i>	Vulnerable
Tristan Albatross <i>D. dabbenena</i>	Endangered
Antipodean Albatross <i>D. antipodensis</i>	Vulnerable
Amsterdam Albatross <i>D. amsterdamensis</i>	Critical
Southern Royal Albatross <i>D. epomophora</i>	Vulnerable
Northern Royal Albatross <i>D. sanfordi</i>	Endangered
Waved Albatross <i>Phoebastria irrorata</i>	Vulnerable
Shy Albatross <i>Thalassarche cauta</i>	Near Threatened
Salvin's Albatross <i>T. salvini</i>	Vulnerable
Chatham Albatross <i>T. eremita</i>	Critical
Buller's Albatross <i>T. bulleri</i>	Vulnerable
Black-browed Albatross <i>T. melanophrys</i>	Endangered
Campbell Albatross <i>T. impavida</i>	Vulnerable
Grey-headed Albatross <i>T. chrysostoma</i>	Vulnerable
Indian Yellow-nosed Albatross <i>T. carteri</i>	Endangered
Atlantic Yellow-nosed Albatross <i>T. chlororhynchos</i>	Endangered
Sooty Albatross <i>Phoebastria fusca</i>	Endangered
Light-mantled Sooty Albatross <i>P. palpebrata</i>	Near Threatened
Southern Giant Petrel <i>Macronectes giganteus</i>	Vulnerable
Northern Giant Petrel <i>M. halli</i>	Near Threatened
White-chinned Petrel <i>Procellaria aequinoctialis</i>	Vulnerable
Spectacled Petrel <i>P. conspicillata</i>	Critical
Black Petrel <i>P. parkinsoni</i>	Vulnerable
Westland Petrel <i>P. westlandica</i>	Vulnerable
Grey Petrel <i>P. cinerea</i>	Near Threatened

Note: The taxonomy followed here is that of BirdLife International (2004a); ACAP has yet to decide on the exact specific taxonomy it will follow.

leading, it is hoped, to a strong Agreement. It is notable that all but four of the species currently listed within ACAP's Annex have a global category of threat ranging from Critically Endangered to Vulnerable (Table 2). The remaining four species are currently considered to be Near Threatened, but this is not grounds for complacency since such species are regarded as being close to qualifying for or likely to qualify for a global threatened category in the near future (IUCN 2001).

The Agreement describes a number of conservation measures to be implemented by Parties, summarized in its Action Plan. These call for a reduction in fishery-induced mortality, eradication of introduced predators at breeding sites, reduction of human disturbance and habitat loss, and measures to reduce marine pollution. The First Session of the Meeting of Parties was held in Hobart, Australia, in November 2004, immediately after an informal Scientific Meeting, when an Advisory Committee was established and rules of procedure discussed and adopted. The first formal meeting of the Advisory Committee was held in July 2005, again in Australia. At this meeting, several initiatives were progressed or commenced. These included formally constituting three working groups to consider taxonomic status, to gather data on population status and trends, and to review the protection and management of breeding sites ([www.acap.aq](http://www.acap.aq)).

The Advisory Committee confirmed a work programme for the inter-sessional period, with the three working groups requested to report back on their findings and recommendations at the next meeting of the Advisory Committee, held in June 2006. An important decision made at the First Advisory Committee was to commence engagements with a number of Regional Fishery Management Organizations (RFMOs) which manage high-seas fisheries that interact with southern seabirds. These include the Convention for the Conservation of Southern Bluefin Tuna (CCSBT), the Indian Ocean Tuna Commission (IOTC) and the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR). The last has already begun to attend ACAP meetings, and has extended an invitation to ACAP to attend its own meetings. As a first step to collaborative efforts, it was agreed that observer status should be sought by ACAP at meetings of these selected RFMOs, as well as at the biennial meetings of FAO's Committee on Fisheries, where nations' progress with their NPOA-Seabirds is reviewed. An important early decision taken by ACAP is that working documents and information papers submitted to its meetings will be made available publicly on its web-site at [www.acap.aq](http://www.acap.aq).

### BirdLife International Seabird Conservation Programme

BirdLife International is the world's largest international NGO that advocates the enhanced conservation of birds. In 1997, it initiated a Global Seabird Programme, initially based in South Africa but now managed from the United Kingdom (Cooper 1999, [www.birdlife.org](http://www.birdlife.org)). The programme took as its major emphasis longline fishery mortality, but this has now been expanded to consider seabird mortality from trawl fisheries as well. The programme raises awareness through BirdLife's national partners, and is currently active in sponsoring training schemes for fishery observers, undertaking research into mitigation measures and attending and contributing to international meetings, including those of ACAP, the CMS, FAO's Committee on Fisheries and the World Conservation Union (IUCN). It has also recently sponsored reviews and workshops that address aspects of seabird conservation relevant to the protection of albatrosses and petrels of the Southern Ocean (e.g. BirdLife International 2004b, Small 2004).

### Other international initiatives

Other international initiatives include actions taken by RFMOs to reduce longline mortality of seabirds. The leading RFMO in this regard is CCAMLR which has had regulations in place for toothfish vessels in the Southern Ocean to reduce seabird mortality for some time (Small 2004, [www.ccamlr.org](http://www.ccamlr.org)). However, most RFMOs, significantly including the several that manage tuna fisheries in the Southern Hemisphere, are yet to take such action (Small 2004).

The FAO's Committee on Fisheries has produced guidelines to deter IUU fishing (FAO 2001), but to date few countries appear to have adopted national plans: Chile is a notable exception. Such plans would be an effective way of reducing seabird mortality by longline fisheries, since it is believed that IUU "pirate" fishers are most unlikely to adopt mitigation measures.

Another initiative is the certification of fisheries by the Marine Stewardship Council, *inter alia*, as being "seabird friendly". To date, only one longline fishery has been so certi-

Light-mantled Sooty Albatross *Phoebastria palpebrata*. Photo: Chris Wilson.

fied, that for Patagonian Toothfish around the island of South Georgia ([www.msc.org](http://www.msc.org)). This fishery now kills very few seabirds, and stands as an example to others in the Southern Ocean.

### A WAY FORWARD

To date, ACAP is essentially a southern agreement, with only species breeding in the Southern Hemisphere being listed in its Annex (Table 2). However, the Agreement text does not make any geographical restrictions, allowing for expansion to the Northern Hemisphere if thought desirable by the relatively simple expedient of adding new species of procellariiform seabirds to those already listed within it. If, for example, the two threatened species of albatross of the North Pacific, the Short-tailed Albatross (Vulnerable) and the Black-footed Albatross *Phoebastria nigripes* (Endangered) (BirdLife International 2004a), are one day included within the Agreement, then many of the fishing nations encircling that region will become range states and might thus be more willing to become Parties to ACAP. Since many of these nations (e.g. China, Japan, South Korea, Taiwan and the USA) are distant-water fishing nations that interact with pelagic seabirds on the High Seas in the Southern Hemisphere, their membership of ACAP should enhance the conservation of southern albatrosses and petrels as well as of their northern counterparts. It is considered that this is a worthy goal for international bodies, national governments and non-governmental organizations alike to work towards over the next decade. At its First Meeting of Parties, ACAP decided to consider which new species might be added to its Annex in the future, and requested that South Africa and Spain take the lead in the matter, by first considering criteria for inclusion and preparing a discussion paper for presentation to and discussion at the third meeting of the Advisory Committee, likely to be held in 2007.

A high level of co-operation has developed between international bodies, national governments and non-governmental organizations to further the conservation of southern albatrosses and petrels. For example, both BirdLife International and the Scientific Committee on Antarctic Research (SCAR), represented by its Group of Experts on Birds, serve on ACAP's Advisory Committee, where they are able to contribute expertise and advise Parties to the Agreement, by way of submitting information papers and contributing to discussions (see examples of submitted papers by both bodies at [www.acap.aq](http://www.acap.aq)). I suggest that

this level of co-operation could be extended with effect to improve the conservation of pelagic seabirds in other oceans of the world, in ways that ACAP hopes to achieve in the Southern Ocean. Examples of where such international co-operation might well be advantageous include in both Arctic and Mediterranean waters (Cooper *et al.* 2000, Cooper *et al.* 2003).

## ACKNOWLEDGEMENTS

I thank the organizers of the Waterbirds around the world Conference for funding my attendance and for inviting me to deliver the closing plenary lecture in front of a distinguished audience. I particularly thank Gerard Boere for his editorial patience and Colin Galbraith for enabling me to realize a long-standing ambition to visit Bass Rock.

## The Arctic – origin of flyways

Kenton D. Wohl

U.S. Fish and Wildlife Service, Anchorage, Alaska 99503, USA. (email: Kent\_Wohl@fws.gov)

Wohl, K.D. 2006. The Arctic – origin of flyways. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 120-123.

### ABSTRACT

The Arctic and its waterbird resources are unique in at least two respects. In a circumpolar perspective, the eight Arctic nations have common species, shared populations and many similar conservation issues. Such waterbird attributes clearly link the Arctic in a circumpolar manner. The Arctic region is also unique in that it contributes many species of waterbirds to all the major international flyways, linking the Arctic to offshore international waters and to many other countries in both the Northern and Southern Hemispheres. Although Alaska (the U.S. “Arctic”) is used to illustrate the international importance of the Arctic, the other seven Arctic countries share a very similar story. In Alaska, about 88% of the regular breeding waterbird species migrate beyond the jurisdiction of the USA, and use as many as eight of the 10 or 11 international flyways. Over 80% of these waterbirds either move to offshore international waters in the North Pacific Ocean or use the four “Americas” flyways en route to Mexico, the Caribbean and South America. The others use the four international flyways to the south and west of Alaska en route to Oceania (Central Pacific), East Asia/Australasia, Central Asia/South Asia, and West Asia/East Africa. These circumpolar

and hemispheric linkages imply that countries share a joint responsibility for the conservation of migratory waterbirds. It also suggests that there is a need to improve international collaboration to manage shared populations most effectively.

### INTRODUCTION

I present a brief overview of international waterbird conservation in the Arctic and the Arctic’s linkages with flyways and non-breeding areas. The flyway concept and range-wide approach to migratory waterbird management is promoted. The “Birds of Arctic Conservation Concern” project of the Arctic Council’s Conservation of Arctic Flora and Fauna program, which highlights waterbird connections within the Arctic and flyways, is summarized.

### ARCTIC WATERBIRD CONSERVATION ISSUES

The key waterbird conservation issues in the circumpolar Arctic are listed below. They are common to all eight Arctic countries (Canada, Finland, Greenland, Iceland, Norway, Russia, Sweden, and the U.S. [Alaska]) and, as such, clearly demonstrate the need to share management, political, legal, and outreach experiences,

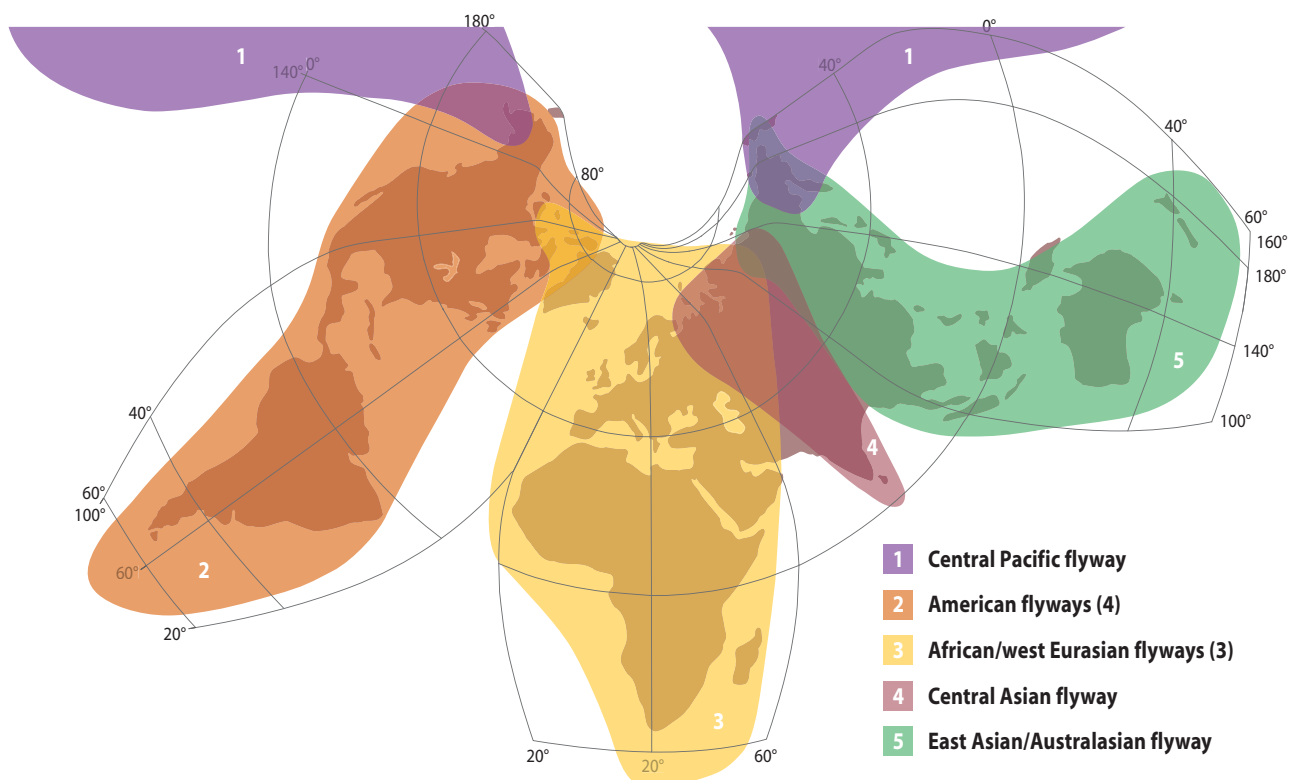

Fig. 1. International migratory bird flyways originating in the arctic.

approaches, and information with each other, and jointly develop resolutions.

- Harvest (sport, subsistence and unregulated)
- Invasive species
- Habitat alteration
- Oil pollution
- Plastics pollution
- Bycatch in commercial fisheries
- Contaminants
- Diseases
- Human disturbance
- Declining populations
- Climate change

Climate change is an issue receiving increased attention recently and is predicted to produce changes that will not only exacerbate some of the conservation issues above, but will create many new and very visible management conflicts for waterbirds in the near future. These are listed below and have been well-documented by several authors in the Arctic Council's Arctic Climate Impact Assessment Project (Hassol 2004, AMAP 2004):

- Changes in species composition and populations
- Extinction of species
- Changes in phenology/migration/foraging patterns
- Introduction of invasive species and diseases
- Inundation of coastal wetlands
- Drying of interior wetlands
- Changes in terrestrial habitats
- Changes in the values and functions of protected areas

Many of these issues are also shared in a flyway context, with some issues being a higher priority than others, depending on the flyway and the country.

### NEED TO COLLABORATE

It is well known that waterbirds are an important national heritage in the eight Arctic nations, and that the Arctic is the exclusive breeding grounds for many species of waterbirds that are important to Arctic populations of humans. It is not unusual that most work on waterbirds has focused on breeding ecology and population status and trends on the Arctic's breeding grounds. As such, Arctic birders are quite "Arctic-centric".

It is also recognized that most of the Arctic's breeding waterbirds move to offshore regions or migrate to more southerly non-breeding areas via flyways (Fig. 1). For example, in Alaska 89% of the regular breeding seabirds, all of the shorebirds, 73% of the waterfowl, and 92% of the remaining waterbird species migrate beyond the USA when they leave Alaska. When waterbirds leave their Arctic breeding grounds, Arctic birders not only expect them to return the following spring, but also assume or expect that the countries in the non-breeding regions will care for the conservation and protection of these migrants with a similar passion and enthusiasm. However, there are often different legal responsibilities and conservation and protection priorities within a flyway and for particular species or species groups. This necessitates approaching waterbird issues in a range-wide manner and having the international instruments available to promote and execute the communication,

Murre *Uria lomvia*. Photo: U.S. Fish and Wildlife Service.

coordination, and collaboration between countries within a flyway or total range of a given species.

### OPPORTUNITIES FOR INTERNATIONAL COLLABORATION

In the context of common species, shared populations, and similar conservation issues, it is obvious that circumpolar Arctic and flyway approaches are essential to resolve management and conservation issues most effectively. To initiate these approaches requires international frameworks. Such coordination mechanisms are, for example, formal and informal species, habitat, and flyway agreements, and bilateral and multilateral treaties. There are many good examples of flyway and range-wide instruments that provide the necessary mechanisms to create or enhance coordination between countries. In the circumpolar Arctic, the Arctic Council's Conservation of Arctic Flora and Fauna (CAFF) program and its Circumpolar Seabird Expert Group is a recent example of a very successful mechanism aimed at improving coordination of waterbird management issues and monitoring programs throughout the Arctic. The Convention on Migratory Species of Wild Animals (CMS) and its several flyway and species agreements, the Ramsar Convention on Wetlands, the Convention on International Trade in Endangered Species (CITES), and many other regional agreements represent successes in improving the flyway and range-wide approaches to waterbird conservation.

Two interesting movements have occurred in the recent past concerning institutional mechanisms for international cooperation in the conservation of migratory birds. Informal agreements are much more popular today than formal ones because they are much less expensive to implement, operate on a simpler institutional structure and decision-making process, and have the ability

to take action on issues in a timelier manner. In addition, flyway or range-wide instruments have been favored over more geographically-limited or regional instruments. Examples are: the bilateral treaties between the USA, Canada, and Mexico, reinvented into a “trilateral” approach; bilateral treaties among the USA, Japan, Russia, China, Australia, and India, some of which are being regrouped into a CMS Central Asian Flyway Agreement; and the many bilateral agreements in the East Asian-Australasian Flyway which are being coordinated by the Asia-Pacific Migratory Waterbird Conservation Committee. Of course, the CMS’s African-Eurasian Migratory Waterbirds Agreement (AEWA) is another good example of the flyway approach. Hopefully, there will soon be flyway agreements for the “Americas” flyways and for the Central Pacific Flyway that will unite the two hemispheres into range-wide approaches for waterbirds.

In 1993, the CAFF program gave recognition to the Arctic’s important migratory waterbird resources, the commonality of conservation issues, and the need to improve communication in the Arctic when it created the Circumpolar Seabird Expert Group (CSEG), formerly known as the Circumpolar Seabird Working Group. Since the CSEG’s first meeting in 1994, it has collaboratively addressed common issues such as seabird bycatch (Chardine *et al.* 2000, Bakken & Falk 1998), seabird harvest (Denlinger & Wohl 2001), and seabird disturbance guidelines (Chardine & Mendenhall 1998). The CSEG has also addressed circumpolar murre and seabird monitoring plans and common species initiatives such as the International Murre and Eider Conservation Strategies (CSWG 1996, CSWG 1997). The CSEG has addressed regional issues such as the North Atlantic murre banding (Petersen & Bakken 2004) and band/ring recovery projects. Another recent project demonstrating circumpolar collaboration is the murre climate change project (Irons *et al.* unpublished). It is an example of birders having a forum; i.e. CSEG, to discuss a common issue, share data and build a common database to develop a circumpolar story about the response of murre populations to climate change. The success of this project will certainly be the prelude for many more circumpolar data-sharing initiatives.

## BIRDS OF ARCTIC CONSERVATION CONCERN

It has often been recognized that Arctic birds are dependent on non-breeding habitats outside the Arctic. In 1996, CAFF commissioned a report that discussed Arctic linkages with other countries for bird species migrating beyond the Arctic (Scott 1998). As a result of that report, CAFF and Wetlands International conducted a workshop to review and prioritize recommendations of the Scott report (Scott 2001). Recognizing the need for improving the cooperation and collaboration for migratory waterbirds beyond the Arctic and value in prioritizing species and conservation issues in both a circumpolar and flyway context, CAFF instructed the CSEG to develop the report “Birds of Arctic Conservation Concern.” It is a project that is anticipated to be completed in 2005, and will discuss for each of the eight Arctic countries their migratory bird resources, national and international conservation status, migration routes, non-breeding areas, applicable domestic and international coordination instruments, population status and trends, and list of active international projects and programs. The report will also develop a list of high priority birds called “Birds of Arctic

Conservation Concern”. This project will be presented with country, Arctic and flyway perspectives. The report will be the template for documenting each country’s priority migratory bird species, international migratory bird programs, and means for international collaboration within the Arctic and the flyways. The document will serve as the template for the Arctic countries to enhance their international migratory bird programs.

## RECOMMENDATIONS

In summary, the eight Arctic nations and their birders have greatly improved their coordination and collaboration as a result of new international coordination mechanisms such as CAFF and its Circumpolar Seabird Expert Group. Arctic waterbird conservation is also greatly benefiting from recent flyway agreements and initiatives and the increasing recognition by Arctic countries of the need to focus on the range-wide and flyway concepts for the most effective approach to waterbird conservation. Effective resolutions to complex Arctic issues such as climate change will necessitate countries uniting for collaborative endeavors to protect shared populations whether on a circumpolar or flyway scale.

The highest priority needs to effect or improve waterbird conservation in the Arctic and the flyways are: 1) to initiate coordinated flyway or range-wide monitoring programs; 2) to create common flyway and circumpolar Arctic databases; and 3) to fill the species and geographic gaps in international coordination frameworks and instruments.

### 3.1 The Arctic: source of flyways. Workshop Introduction

**Gudmundur A. Gudmundsson**

*Icelandic Institute of Natural History, PO Box 5320, IS-125 Reykjavik, Iceland.*

Gudmundsson, G.A. 2006. The Arctic: source of flyways. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 126.

The immense tundra wetlands in the delta of the Lena river, northern Yakutia are the breeding grounds for millions of waterbirds. Whilst human densities are low, these areas are predicted to be widely impacted by changing global climates. Photo: Gerard Boere.

The arctic is the breeding ground for millions of waterbird connected to all global flyways. Environmental and climatic conditions in the arctic are critical for long term flyway conservation and management. The workshop reviewed recent developments in the arctic in relation to local and global changes, legislation and conservation issues, highlighting their importance for the long-term maintenance of the favourable status of migratory waterbirds.

Recent years have seen the active development of much organisational and institutional activity in the arctic, together with the progressive development of a range of multinational agreements and other international treaties (for example the Conservation of Arctic Flora & Fauna – CAFF – a working group of the Arctic Council). These all indicate greatly increased interest in the region.

Ornithological research in various regions of the arctic have focussed on studies of the factors influencing waterbird breeding success, as productivity can strongly vary between years. Soloviev *et al.* report on the development of an international programme to collate information on such between-year changes of productivity. Such fluctuations can also be measured on migration if trapping methods are carried out in a consistent manner as reported by Harebottle using the example of wader

productivity as assessed in South Africa – the far migratory terminus of the species' concerned.

Engelmoer *et al.* summarise the long-term and differential population trends of arctic breeding waders as monitored in temperate wintering areas (the Dutch Wadden Sea). The need to standardise much of the monitoring of arctic breeding waders has lead to the establishment of a Committee for Holarctic Shorebird Monitoring (CHASM). Lanctot, on behalf of the Committee, summarises the issues that led to its development and plans for the implementation and development of this important initiative.

In recent years, much more attention, both on the breeding and wintering areas, has been given to endangered arctic waders such as the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*. The reasons for the decline of this species are still unknown. A range of new techniques such as stable isotope analysis have been invaluable in determining the breeding and wintering areas of such rare and threatened species, as reported by Zöckler *et al.*

With climate change predicted to impact more rapidly on the arctic more than on other regions (see the section on the implications of climate change for waterbirds elsewhere in this volume), the need for increased research and conservation effort is strongly stressed.

## Monitoring Arctic-nesting shorebirds: an international vision for the future

Richard B. Lanctot

### ABSTRACT

The Pan-Arctic Shorebird/Wader Monitoring and Research Workshop brought together 30 specialists to discuss monitoring and research of Arctic-nesting shorebirds. The meeting was held in Karrebäksminde, Denmark, from 3-6 December 2003. Participants from seven Arctic nations, as well as five nations visited by Arctic migrants during the non-breeding season, convened with two primary objectives: 1) to summarize existing shorebird monitoring protocols and to explore opportunities for integrating them more effectively at a global level; and 2) to discuss the effects of climate change on those populations which have been monitored and studied to date.

This document presents the collective vision of the participants in regard to objective one, and as such, the document outlines the goals, an initial objective, and preliminary recommendations for globally integrated monitoring of Arctic-nesting shorebirds. Participants acknowledged the need to establish an informal working group, which would take the lead on moving the workshop's vision forward. Specifically, this Committee for Holarctic Shorebird Monitoring (CHASM) was formed as the essential first step for guiding the implementation of an effective circumpolar program for monitoring Arctic-nesting shorebirds.

CHASM is a "project" within the International Wader Study Group and is one of seven networks within the Circumpolar Flora and Fauna's Circumpolar Biodiversity Monitoring Program. A circumpolar monitoring program will help ensure that existing monitoring programs continue to be well coordinated and supported, while simultaneously integrating them into a Holarctic program. Participants suggested a number of essential items needed to develop a comprehensive circumpolar Arctic shorebird monitoring plan, and provided more specific recommendations for monitoring shorebirds in breeding and non-breeding areas.

### BACKGROUND

Arctic-nesting shorebirds (or waders) are among the most evocative creatures on our planet. Their tenacity while breeding in harsh northern environments, their spectacular concentrations, prodigious long-distance migrations, and the athletic grace of their aerial acrobatics inspire awe and appreciation. These wonders, however, are in jeopardy. There is a growing agreement among shorebird biologists from around the world that many shorebird populations are declining, some precipitously. A handful of species may soon tumble into the chasm of extinction.

Such declines give cause for concern. The loss of shorebird populations or entire species would be directly counter to the stated desire of world leaders to significantly reduce the rate of loss of biological diversity. Arctic-breeding shorebirds are impor-

tant members of wetland communities. Such habitats are under intense threat from human development and yet support some of the most diverse animal communities on earth. The potential ecological impact on the health and integrity of wetlands caused by the disappearance of shorebirds is unknown. The reduction or loss of shorebird populations may be a symptom of habitat degradation, but it may also be a cause of further degradation as well. Because shorebirds are critically dependent upon distinct staging sites spread across many nations and vast latitudinal distances, they effectively integrate, and thus their status reflects, environmental conditions over much of the globe. The essential reproductive activities of Arctic-nesting shorebirds occur in those northern regions of the planet most likely to experience the earliest and most severe effects of global warming. Sea-level rise induced by climate change also poses a threat to the inter-tidal areas favoured by these birds outside the breeding season. As long-distance migrants from these threatened habitats, shorebirds may serve as important messengers of global climate change.

Our ability to learn lessons from Arctic-nesting shorebirds is currently limited by a lack of sufficiently detailed, scientifically rigorous, and spatially comprehensive population information. Improved and more coordinated monitoring would allow suspected population trends to be confirmed and provide better estimates of the rates of change. This information, in turn, would be used to form many important management decisions, including 1) detecting species at risk, 2) identifying causes of population changes, 3) evaluating conservation and restoration programs, 4) setting priorities for conservation of species and habitats, 5) acting as indicators of anthropogenic impacts in the Arctic and elsewhere, and 6) implementing multilateral environmental agreements. Given this wealth of potential benefits, there is clearly an urgent need for more effective and extensive monitoring of shorebird populations.

### The Pan-Arctic Shorebird/Wader monitoring and research workshop

In response to this need, 30 specialists gathered in Denmark from 3-6 December 2003 to discuss monitoring and research of Arctic-nesting shorebirds. Participants from seven Arctic nations, as well as five nations visited by Arctic migrants during the non-breeding season, convened with two primary objectives: 1) to summarize existing shorebird monitoring protocols and to explore opportunities for integrating them more effectively at a global level; and 2) to discuss the effects of climate change on those populations which have been monitored and studied to date.

For both objectives, there was a concerted effort to expand the discussion beyond a simple presentation of results to date. Instead, workshop participants worked together to explore new and creative avenues for collaboration and coordination. For example, several

new analyses were initiated at the workshop, including a synthesis of efforts to estimate shorebird productivity on an annual basis across multiple flyways, as well as a compilation and pan-arctic analysis of short-term climate-related effects on shorebird breeding performance. Perhaps the most important outcome of the workshop, however, was the participants' shared vision concerning the need for an improved approach to monitoring shorebird population sizes and demographics. This document presents the collective vision of the Pan-Arctic Shorebird/Wader Monitoring and Research Workshop, and outlines goals, an initial objective, and preliminary recommendations for globally integrated monitoring of Arctic-nesting shorebirds.

### Vision

To coordinate and integrate monitoring of Arctic-nesting shorebirds at a global scale by collecting and synthesizing information on the population status and trends of all populations of Arctic-nesting shorebirds at all stages of their life cycles, and to make that information available in a timely manner to policy-makers, managers, the scientific community, educators, and the general public.

### Rationale

Monitoring programs allow biologists to assess the status and trends of animals, and to detect and assess the effects of human activities on these same animals. The Arctic region, while generally poor in species diversity, is home to a disproportionately large number of shorebirds. Indeed, roughly 20% of the world's shorebird species and some 30 million of the roughly 100 million individual shorebirds in the world breed in the Arctic. Population estimates have been derived recently for the 100 biogeographical populations of the 37 most typical Arctic-nesting shorebird species. Numerical trends were identified in 52 of these, 12% of which are thought to be increasing, 42% stable, 44% decreasing and 2% probably extinct. All of these Arctic-nesting species migrate to temperate and tropical regions of the globe, and through these migrations, Arctic-nesting shorebirds link every continent except Antarctica and visit nearly every country on earth.

### Goals

**1) Enhance the collection of scientifically rigorous monitoring data, and the coordination and support of existing and new monitoring programs for Arctic-nesting shorebirds.** This goal will be achieved by a) supporting new and continued funding of monitoring programs, b) providing a framework within which shorebird data are collected, analyzed, and integrated across large spatial and temporal scales, and c) preparing regional and global reports on a regular basis.

**2) Integrate these monitoring efforts with the Circumpolar Biodiversity Monitoring Program.** At the 2002 World Summit on Sustainable Development, world leaders expressed their desire to achieve "a significant reduction in the current rate of loss of biological diversity". To achieve this goal, the Conservation of Arctic Flora and Fauna (CAFF) group identified monitoring as a key objective for the conservation of Arctic biodiversity. Accordingly, CAFF initiated the Circumpolar Biodiversity Monitoring Program (CBMP) to "build on national and international work to implement a program to monitor

biodiversity at the circumpolar level that will allow for regional assessments, integration with other environmental monitoring programs, and comparison of the Arctic with other regions of the globe". Arctic-nesting shorebirds were among seven monitoring networks chosen by CAFF to provide adequate monitoring of circumpolar biodiversity as initial components of the CBMP. Workshop participants see their interests and concerns dovetailing markedly with those of the CBMP.

**3) Establish formal co-ordination with other international and regional programs.** A variety of existing conservation groups and programs share an interest in shorebirds, other wetlands species, and/or the habitats used by Arctic-nesting shorebirds throughout the year. Examples include the International Wader Study Group (IWSG), the Asia-Pacific Migratory Waterbird Conservation Strategy, the Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA), and the North American Migratory Bird Treaty Act. Concerted efforts should be made to integrate Arctic-nesting shorebird monitoring into the activities of these diverse programs.

### Initial Objective

To sustain the enthusiasm and impetus of the workshop, participants acknowledged the need to establish a formal working group, which would take the lead on moving the workshop's vision forward. Specifically, this Committee for Holarctic Shorebird Monitoring (CHASM) was formed as the essential first step for guiding the implementation of an effective circumpolar program for monitoring Arctic-nesting shorebirds. Such a program should ensure that existing monitoring programs continue to be well coordinated and supported, while simultaneously being integrated into a Holarctic program. As such, the group fulfils the need for a shorebird-monitoring network within the Circumpolar Biodiversity Monitoring Program. In addition, CHASM will also be a project within the IWSG. CHASM's members represent different regions of the circumpolar Arctic as well as temperate areas where Arctic-nesting shorebirds occur during the non-breeding season. Dr Richard Lanctot and Dr Mikhail Soloviev will serve as the first co-chairs of CHASM.

### GENERAL RECOMMENDATIONS

The principle recommendation of the workshop participants is to fully develop and implement a circumpolar Arctic-nesting shorebird monitoring program. Such a program requires the preparation of a plan that will include and build upon the existing Arctic Birds Breeding Conditions Survey and the Program for Regional and International Shorebird Monitoring (and the latter's predecessors such as the International and Maritimes National Shorebird Surveys). It will also be essential to recognize and take advantage of the contribution of existing waterbird population databases compiled by Wetlands International, the results of bird ringing compiled by the British Trust for Ornithology, and smaller monitoring schemes and programs currently underway within and outside the Arctic. The following features should be included in the final plan, although individual components should be completed as time permits with an overall goal of having the entire plan completed by 2006:—

- Description of the existing monitoring programs providing information on Arctic-nesting shorebirds, and the identifica-

tion of gaps in which species and subspecies are monitored and where additional monitoring is needed in and outside of the Arctic.

- Identification, definition, and encouragement of the collection of a core set of biological variables, including population (e.g. size and structure, seasonal distribution) and demographic (e.g. recruitment and survival) parameters of Arctic-nesting shorebirds.
- Expansion of existing monitoring programs to include the additional shorebird biological parameters identified above, as well as environmental factors important for interpreting the trajectories of population trends, including physical and biological parameters, such as climate, habitat, predator, and alternative prey variables.
- Identification of priority Arctic-nesting shorebirds based on a set of criteria, such as distribution across the circumpolar Arctic, international obligations, current monitoring activities, degree of endangerment, and available information. Such a prioritization will assist managers in determining how and where to allocate limited funds, and determine the potential to form international collaborations.
- Identification of the best locations at which to survey individual shorebird species and subspecies so as to maximize logistical and financial efficiency.
- Sharing and collaborative analyses of regional and global databases, by paying special attention to the design, creation, collection and entry of data. The creation of meta-databases will facilitate the exchange of data for joint analyses and assessments at the regional or global level, and allow comparisons between Arctic and non-Arctic regions. For instance, data exchange and analyses may be enhanced through the use of GIS and web-based tools.
- Improvement of existing status and trend assessments of Arctic-nesting shorebirds by conducting detailed species-by-species syntheses of existing data and knowledge at local and regional levels.
- Integration of short-term biological studies into the long-term monitoring program so as to address immediate management concerns.

### SPECIFIC RECOMMENDATIONS FOR MONITORING IN THE BREEDING AREAS

- 1 Acknowledging that Moscow University, with the support of Wetlands International and the IWSG, has successfully conducted the “Arctic Birds Breeding Conditions Survey” for more than 10 years, in which Arctic-nesting shorebirds constitute a major part, and that national and bilateral programs exist in several parts of the Arctic, the workshop participants recommend that these programs receive sufficient long-term funding, and that international cooperation and coordination be further developed.
- 2 Workshop participants further recommend that a number of quantitative elements (e.g. breeding performance, prey and predator abundances) be added to the existing Arctic Birds Breeding Conditions Survey, as deemed necessary and appropriate given the program’s overall goals.
- 3 Immediate funding should be sought to monitor and conduct research on Arctic-nesting shorebirds currently thought to be under severe decline and under threat of becoming endan-

gered or extinct. Potential candidates for study include the Slender billed Curlew *Numenius tenuirostris*, Bristle-thighed Curlew *N. tahitiensis*, Far Eastern Curlew *N. mada-gascariensis*, Spoon-billed Sandpiper *Eurynorhynchus pygmeus* and Buff-breasted Sandpiper *Tryngites subruficollis*, which are globally threatened according to current IUCN Red List Criteria.

### SPECIFIC RECOMMENDATIONS FOR MONITORING IN THE NON-BREEDING AREAS

- 1 Acknowledging that monitoring shorebirds on the Arctic breeding grounds will never be geographically extensive enough to provide fully representative data on population trends and demography for the entire Arctic-nesting shorebird community;  
And that Wetlands International (through the International Waterbird Census) and others have successfully monitored Arctic-nesting shorebirds and other bird populations along their migration routes for many years in many parts of the world, allowing long-term population indices to be developed for several species, subspecies, and biogeographical populations;  
And realizing that tens of thousands of shorebirds are banded every year by volunteer and professional ornithologists alike, enabling changes in discrete populations to be detected on breeding as well as staging and wintering areas;  
The workshop participants encourage increased monitoring of Arctic-nesting shorebirds, especially in their wintering areas in the Neotropics (Caribbean, Central and South America), Africa, Australasia, Asia, Europe and Oceania. Such monitoring efforts should include delineation of wintering ranges at the species, subspecies and population levels, establishment of monitoring networks and survey protocols, collection of data by local observers, and sharing of data after they are collected. The International Waterbird Census provides a framework within which internationally coordinated counts can take place.
- 2 Workshop participants further recommend that monitoring on staging and wintering sites be strengthened by collating, analyzing and publishing results on shorebird recruitment collected from visual observations and banding operations. Biologists studying several populations of swans, geese and ducks have already undertaken similar efforts. Results from such collaborations should be explicitly linked to thresholds (e.g. specific population sizes and/or trends) that will trigger specific types of directed research and management tasks.

### IWSG Workshop on Monitoring Waders In and Outside the Arctic

As a first step in implementing the objectives of this document, a two-day workshop was held during the IWSG meeting in Papenburg, Germany, on the 4 and 5 November 2004. The first day of the workshop focused on improving and coordinating existing programs that monitor shorebirds in their arctic habitats, including measuring population and demographic parameters of shorebirds, habitat use, prey and predator abundances, and environmental factors. The morning session included a number of speakers who described the geographical and logistical constraints faced by Arctic shorebird biologists around the world, and

methods for conducting intensive demographic/ecological studies and less intensive checklist/density studies. The remainder of the day was spent on developing protocols and standardizing parameters to be recorded in Arctic field situations. These protocols are scheduled for publication in an upcoming issue of the Wader Study Group Bulletin. The second day of the workshop focused on methods for monitoring recruitment and survival of waders outside the breeding season. Additional goals of this workshop included identifying constraints of the various methods, assessing whether it is possible to obtain population-wide parameters for recruitment and survival, and producing guidelines for undertaking demographic monitoring. The morning session featured a number of speakers who discussed monitoring recruitment at stopovers and flyway termini. These presentations were followed by a discussion that emphasized (1) the need to monitor a population throughout its range for accurate assessment of the absolute level of recruitment rather than just an index of relative recruitment from a few sites, and (2) the importance of considering the effect of changes in the local environment when assessing long-term trends in

recruitment. The afternoon session began with a number of speakers discussing survival and population monitoring. Participants addressed the merits and requirements of using individual colour marks and retrapping of individuals during ringing operations to monitor survival. Protocols for monitoring recruitment and survival at staging and non-breeding sites have recently been published (Robinson *et al.* 2005).

### ABSTRACT

Nesting success, rodent abundance and summer temperatures across the breeding ranges of four Arctic waders in eastern Siberia were analysed in conjunction with data on the proportions of juveniles on the non-breeding grounds in south-eastern Australia in 1979-2003 with a view to revealing the response of wader populations to varying environmental conditions during the breeding season. The effect of temperature on the proportion of juveniles was found to increase in the Sharp-tailed Sandpiper *Calidris acuminata*, Curlew Sandpiper *C. ferruginea*, Red-necked Stint *C. ruficollis* and Ruddy Turnstone *Arenaria interpres*, which to some extent corresponds to the increasing severity of their breeding environment. The proportion of juveniles on the non-breeding grounds increased with an increase in rodent abundance across the breeding range in the Sharp-tailed Sandpiper and Red-necked Stint, but not in the Ruddy Turnstone and Curlew Sandpiper. Nesting success measured within the breeding range depended on July temperatures only in the Ruddy Turnstone, and did not depend significantly on rodent abundance in any of the species under investigation. Thus, although the breeding performance of Arctic waders at the level of flyway populations depends on air temperature and rodent abundance during summer, the relative role of these environmental factors differs between species. Mean July temperatures were increasing from 1979 to 2003 across the breeding range of the Red-necked Stint. During this period, the proportion of juveniles was increasing both in this species and the Sharp-tailed Sandpiper.

### INTRODUCTION

Recent research has demonstrated that many populations of waders are declining (International Wader Study Group 2003, Stroud *et al.* 2006). The reasons for these declines are rarely known with certainty, but global climate change is considered to be an important, or even the principal, factor in the declines in Arctic-breeding birds (e.g. Zöckler & Lysenko 2000, Rehfish & Crick 2003, Zöckler *et al.* 2003).

Arctic-breeding waders are known for the pronounced variation in their breeding success caused by variation in breeding conditions. Given that waders are generally long-lived birds with low adult mortality, variations in breeding success can make a critical contribution to population change. Thus, an understanding of the processes that are occurring on the breeding grounds and their effects on recruitment in wader populations is instrumental for the development of adequate conservation measures in the flyways.

Prey-switching by predators has been suggested as an important factor determining the breeding success of tundra birds, first by Roselaar (1979) and then in a number of other studies. Summers & Underhill (1987) were the first authors to relate presumed predation pressure on the Taimyr Peninsula, Siberia, with the proportion of juveniles in wader populations in their non-breeding areas. However, this relationship has never been analysed over a wide geographical area. Climatic variables may also affect the breeding performance of Arctic waders at scales from local to global (the latter was shown for 1992 by Ganter & Boyd 2000), but their role has rarely been assessed from a long-term perspective (Boyd 1992, Boyd & Piersma 2001) and apparently never in conjunction with the impact of predation pressure.

Thus, existing knowledge of the responses of wader populations to environmental factors on the breeding grounds has been limited in time and space, and has highlighted the role of a single factor. To a large extent, this has been due to a deficiency of large-scale and long-term data from the breeding grounds that would allow formal quantitative processing. Monitoring conducted over a period of 16 years from 1988 to 2003 within the framework of the Arctic Birds Breeding Conditions Survey (a project of the International Wader Study Group) has been able to fill this gap, and has provided data on nesting success and certain environmental factors, such as rodent abundance, within the breeding range of many waders. We have analysed these data in conjunction with the available weather data and data on the proportions of juvenile birds on the non-breeding grounds in south-eastern Australia. This study focuses on processes developing in the East Asian-Australasian Flyway, which until now has received much less attention from researchers than the intensively studied East Atlantic Flyway.

The following specific questions were addressed:

1. How conditions on the breeding grounds relate to nesting success and productivity measured in the non-breeding areas?
2. How the above relations (if any) differ between species?
3. If there are any long-term trends in productivity, and how they relate to possible trends in environmental factors on the breeding grounds?

### METHODS

#### Data on nesting success and rodent abundance

Data on the nesting success of waders and rodent abundance on the breeding grounds were gathered during the course of the

Arctic Birds Breeding Conditions Survey (ABBCS), and included estimates from various localities in eastern Siberia (all original data are available at <http://www.arcticbirds.ru>). The data, which in most cases were not quantitative, were brought to ordinal scale with ranks from 1-3, corresponding to low, average and high estimates of nesting success and rodent abundance. The considerable variation in the precision of the estimates between localities was addressed by ranking the quality of the estimates of nesting success and rodent abundance on a scale of 1-5. These rankings were used for weighting in statistical analyses. Criteria for assigning ranks to estimates of parameters and their quality are explained in Table 1. When quantitative information was lacking, the ranking was based on the mutual agreement of two experts (MYS and PST), who evaluated descriptive information available in the breeding conditions reports. These reports rarely discriminated between species when providing information on nesting success, and the estimates from some localities represented an evaluation of nesting success for the wader community as a whole. Nesting success in this survey was considered strictly as survival of nests, and did not take into account later components of breeding performance, such as the survival of chicks or juveniles.

Relating the information on nesting success and rodent abundance with particular wader species was achieved by interpolating estimates from localities across the ranges of the wader populations under investigation, and averaging the interpolated values. A multiquadratic function with no smoothing (Buhmann 2003) was used for interpolation on a grid with a cell size of 50 km. Averaging the interpolated values resulted in estimates which were no longer ordinal, but still in the same range as the original estimates from point localities (ranks 1-3).

Four species of waders which migrate to south-eastern Australia for the northern winter, and for which good quality data were available for most years, both from the breeding grounds and from the wintering areas, were selected as study species: Ruddy Turnstone *Arenaria interpres*, Sharp-tailed Sandpiper *Calidris acuminata*, Curlew Sandpiper *C. ferruginea* and Red-necked Stint *C. ruficollis*. Delineation of the breeding ranges of the populations of Ruddy Turnstone and Curlew Sandpiper migrating to Australia involved an analysis of long-distance recoveries and flag-sightings, and information from the ABBCS database, Arctic Bird Library at the UNEP World Conservation Monitoring Centre, and Atlas of Breeding Waders of the Russian Arctic (Lappo *et al.* in prep.). The limits of the flyway population of Ruddy Turnstones in the Arctic were set at a point just west of the Lena River delta (120° E) and the Bering Strait (170° W); for the Curlew Sandpiper, the limits were set at Taimyr Lake (100° E) and northern Chukotka (177° E). The flyway populations of the Sharp-tailed Sandpiper and Red-necked Stint encompass the entire ranges of the species.

#### Weather data

Weather data were obtained from the web-site of the World Meteorological Organization (National Climatic Data Center, USA). In this study, analyses of weather variables were restricted to mean air temperatures in June and July, although other parameters (e.g. precipitation, timing of snowmelt) could also have been of major importance. However, temperatures were the only variables for which it was possible to obtain consistent, long-term data for an area of interest extending for over 3 500 km from west to east in eastern Siberia.

**Table 1.** Criteria for assigning ranks to estimates of nesting success and rodent abundance, and for assigning ranks to the quality of these estimates.

Ranks	Nesting success	Rodent abundance
<b>Criteria for estimates of the parameter</b>		
1	<33.3%, if estimated directly as a proportion of hatched nests or using the Mayfield (1975) method; low when based on expert evaluation.	0-3 specimens per 100 trap-days; low when based on expert evaluation.
2	33.3-66.7%, if estimated directly; average when based on expert evaluation.	4-10 rodents per 100 trap-days; average when based on expert evaluation.
3	>66.7%, if estimated directly; high when based on expert evaluation.	11-30 animals per 100 trap-days; high when based on expert evaluation.
<b>Criteria for estimates of parameter quality</b>		
1	Unsupported evaluation by respondent.	Visual evaluation during a period of less than one month, or interview data, or unknown source.
2	Evaluation based on abundance of wader broods.	Visual evaluation during a period of less than one month and interview data.
3	Direct estimates of nesting success with sample of 5-30 nests, or observations of larger numbers of nests terminated before hatching.	Direct counts for a period of less than one month, or visual evaluation for a period exceeding one month, or counts of nests under snow.
4	Combination of two conditions of rank 3, or combination of any condition of rank 3 with condition of rank 2.	Combination of two conditions of rank 3, or combination of any condition of rank 3 with any condition of rank 1.
5	Direct estimates of nesting success with sample exceeding 30 nests.	Direct counts for a period exceeding one month.

We obtained the mean monthly temperatures for June and July for each weather station located to the north of 50° N for the period 1978–2003 (i.e. from the start of cannon-netting for waders in Australia), and then estimated the deviations of these means from the monthly averages over the period 1994–2003. The last 10 years were chosen as a reference period because the available weather data were the most consistent during this period. Deviation values obtained from the weather stations were then interpolated across the whole of the Arctic for each year from 1978 to 2003, and the interpolated values averaged across the flyway population ranges of the four wader species under investigation. The interpolation technique was the same as that used for nesting success and rodent abundance. These average values indicated whether conditions in the respective months across the species' ranges were warmer or colder than the average for the 10-year period 1994–2003.

### Data on proportion of juveniles

The Victorian Wader Study Group has been collecting data on the proportion of juvenile waders in cannon-net catches in south-eastern Australia since 1978. Data on the percentages of juveniles were gathered in 1978–2003 for the Red-necked Stint, in 1979–2003 for the Curlew Sandpiper and Sharp-tailed Sandpiper, and in 1989–2003 for the Ruddy Turnstone. In-depth analyses of the data sampling procedures, possible biases and considerations required during interpretation of data have been published elsewhere (Minton *et al.* 2000). Analyses of the proportions of juveniles in the catches have been made by Minton *et al.* (2001, 2002a, 2002b, 2003a, 2003b, 2004). All catches were made between mid-November and the end of February, except for a few catches of Red-necked Stint and Ruddy Turnstone which were made up to mid-March in some years.

The annual samples of Red-necked Stint and Curlew Sandpiper ranged from several hundred to several thousand birds, while the average annual samples of Sharp-tailed Sandpiper and Ruddy Turnstone were only 180 and 122 birds, respectively. We accounted for the presence of small sample sizes in the latter two species by assigning quality ranks based on the number of birds in the total catches: 1 = <50 birds a year; 2 = 50–99 birds; 3 = 100 or more birds. This scale was chosen to provide the closest match to the previous analyses of juvenile percentage data from the Australian non-breeding grounds, which defined samples below 30 birds as inadequate, and distinguished “small” and “large” catches based on the threshold of 50 birds (e.g. Minton *et al.* 2004).

### Processing and analyses of data

The statistical processing of data was based on fitting regression models, and incorporated weighting of observations with data quality ranks. Outliers were identified using studentized residuals, and excluded from samples when they represented apparently unrealistic values (e.g. 66.7% juveniles in a sample of 66 Sharp-tailed Sandpiper in 1989).

The most general form of dependence of wader productivity on environmental factors was studied by extracting the principal components from two groups of variables: (1) four variables (one per species) corresponding to proportions of juveniles on the

wintering grounds; and (2) eight variables corresponding to July temperatures and rodent abundance within the breeding ranges of the four wader species. This analysis was restricted to the period 1989–2003 for which all data were available for all four species.

Spatial analyses were made using Mapinfo GIS (MapInfo Corp. 1996), while statistical processing employed Systat 7.01 (SPSS Inc. 1997).

## RESULTS

### Effects of temperature and rodent abundance on the breeding performance of waders

The principal results of the statistical testing are summarized in Table 2, while Fig. 1 shows the dependence of juvenile proportions on July temperatures and rodent abundance.

An increase in summer air temperatures within the breeding range resulted in an increase in the proportion of juveniles in the non-breeding grounds in each of the four wader species under consideration. The estimated effect of this increase in temperature, expressed as percentage increase in the proportion of juveniles per one degree of increase in the average June and July temperatures across the range of the species, varied from 3.2 in the Sharp-tailed Sandpiper to 14.0 in the Ruddy Turnstone. The effect was most pronounced for mean July temperatures in all species except Sharp-tailed Sandpiper, in which the effect of July temperature, in isolation, was not significant at  $P < 0.05$ . However, when the average June and July temperatures were combined for this species, the effect was significant.

Summer air temperatures had a significant effect on nesting success across the breeding range only in the Ruddy Turnstone, although the marginally significant effect of July temperatures in the Sharp-tailed Sandpiper is noteworthy.

The proportion of juveniles on the non-breeding grounds in south-eastern Australia increased significantly ( $P < 0.05$ ) with an increase in rodent abundance in the Sharp-tailed Sandpiper, but not in other species, although an examination of the graphs revealed that a good regression in the case of the Red-necked Stint was adversely affected by a single apparent outlier – the low proportion of juveniles in 2000 (Fig. 1). The relationship between nesting success and rodent abundance was, at best, marginally significant in the Ruddy Turnstone.

Summer temperatures across the breeding ranges of the four species of waders were significantly correlated with each other ( $P < 0.05$ , Spearman correlation of ranks =  $S_r$ , below), as were the values for rodent abundance ( $P < 0.05$ ). However, juvenile proportions in Australia were significantly correlated with each other ( $P < 0.05$ ) only in a single pair of species, namely Ruddy Turnstone and Curlew Sandpiper, the only two high Arctic species under consideration.

Extracting the Principal Components<sup>1</sup> from the proportions of juveniles of the four species for the period 1989–2003 aimed at revealing common patterns of variation in the productivity of the different species using a data reduction approach. PC1 explained 54.5% of the total variance of the four variables, and was mostly related to variation in the proportions of juvenile Curlew Sandpiper, Ruddy Turnstone and Red-necked Stint (loadings ranging from 0.68 to 0.94), while correlation with the proportions of juvenile Sharp-tailed Sandpiper was much

<sup>1</sup> A Principal Component Analysis is used to simplify a data set; more formally, it is a linear transformation that chooses a new co-ordinate system for the data set such that the greatest variance by any projection of the data set comes to lie on the first axis (then called the first principal component, PC1), the second greatest variance on the second axis (PC2), and so on.

**Table 2.** Estimates of the effects of environmental parameters on the breeding productivity of waders (response variables), and evaluation of trends. The effects are expressed as percentage change in dependent variable per unit change in independent variable; e.g. in the Sharp-tailed Sandpiper, the proportion of juveniles increases by 7.35% when rodent abundance increases by one unit (from “low” to “average”, or from “average” to “high”). P-values for the corresponding effects are given in brackets, and estimates of effects significant at  $P < 0.05$  are shown in bold.

Parameter	Species			
	Red-necked Stint	Curlew Sandpiper	Sharp-tailed Sandpiper	Ruddy Turnstone
<i>Response variable: juvenile proportion</i>				
June temperature	2.21 (0.198)	1.72 (0.117)	2.10 (0.14)	6.78 (0.40)
July temperature	<b>6.36</b> (0.003)	<b>6.30</b> (0.001)	1.95 (0.066)	<b>11.71</b> (0.018)
Average of June & July temperatures	<b>4.65</b> (0.027)	<b>3.50</b> (0.024)	<b>3.16</b> (0.032)	<b>14.01</b> (0.045)
Rodent abundance	10.68* (0.110)	9.52 (0.168)	<b>7.35</b> (0.016)	16.52 (0.170)
<i>Response variable: nesting success</i>				
June temperature	0.23 (0.220)	0.14 (0.194)	0.08 (0.534)	0.44 (0.182)
July temperature	0.25 (0.125)	0.18 (0.155)	0.17 (0.086)	<b>0.28</b> (0.038)
Average of June & July temperatures	0.29 (0.130)	0.22 (0.099)	0.24 (0.099)	<b>0.41</b> (0.041)
Rodent abundance	0.39 (0.256)	0.40 (0.211)	0.33 (0.369)	0.62 (0.073)
<i>Linear trends with year</i>				
Juvenile proportion	<b>0.51</b> (0.024)	0.32 (0.088)	<b>0.58</b> (0.019)	-0.77 (0.562)
Nesting success	0.01 (0.667)	0.02 (0.500)	0.03 (0.503)	0.004 (0.916)
Rodent abundance	0.02 (0.322)	0.01 (0.650)	0.04 (0.195)	0.04 (0.092)
June temperature (1950–2003)	<b>0.02</b> (0.015)	0.003 (0.778)	0.001 (0.939)	0.01 (0.120)
July temperature (1950–2003)	<b>0.02</b> (0.026)	0.01 (0.183)	<b>0.03</b> (0.020)	<b>0.03</b> (0.001)

\* The effect of rodent abundance on proportion of juveniles increased to 24.3 ( $P < 0.003$ ) after removal of a single apparent outlier in 2000 from the data set.

smaller (−0.34). Variation in the proportions of juveniles in the latter species was accounted for by PC2 which explained 26.6% of the total variance (loading 0.84 for the Sharp-tailed Sandpiper, and loadings in the range −0.40 to +0.39 for the other three species).

PC1 extracted from the eight environmental variables explained 62.8% of their total variance (loadings in the range 72.1 to 83.6). PC2 explained 24.4% of the total variance, and separated temperature variables (loadings >0.25) from variables of rodent abundance (loadings <−0.45). There is a fairly good linear relationship between PC1 extracted from data on juvenile proportions and corresponding to wader breeding performance, and PC1 extracted from environmental variables on the breeding grounds (Fig. 2), and this is also statistically significant ( $P < 0.05$ ,  $Sr = 0.621$ ).

### Trends in environmental factors in Siberia and the proportions of juveniles in south-eastern Australia

Mean July temperatures increased significantly during the period 1950–2003 at a rate of 0.017–0.029°C per year across the breeding ranges of all species except Curlew Sandpiper, while mean June temperatures increased significantly only in the range of the Red-necked Stint (Table 2). To allow comparison with the trends in breeding performance, we analyzed trends in July temperatures during the periods for which data on juvenile proportions were available for each of the four species. This analysis yielded a highly significant ( $P < 0.003$ ) increasing trend (at a rate of 0.053°C per year) across the breeding range of the Red-necked Stint, and a marginally significant ( $P = 0.057$ ) increasing trend (at a rate of 0.1°C per year) across the breeding range of the Ruddy Turnstone.

**Fig. 1.** Percentage of juveniles in four species of waders in south-eastern Australia in relation to deviations in July temperature and rodent abundance on the breeding grounds in eastern Siberia.

In south-eastern Australia, the proportion of juvenile Red-necked Stints and Sharp-tailed Sandpipers increased significantly ( $P < 0.03$ ) at an average rate of 0.51% and 0.58% per year, respectively. However, no significant trend was found in the period 1988–2003 either for rodent abundance or wader nesting success across the ranges of the four species, although in the case of the Ruddy Turnstone, the marginally significant value for the effect of year on rodent abundance suggested some tendency for increase. This was probably not confirmed because of the short time series and extremely high variation of the variable.

## DISCUSSION

In this study, we have revealed the relationships between the breeding performance of four Arctic-breeding waders and

**Fig. 2.** Environmental factors within the breeding ranges of four species of waders in eastern Siberia (PC(1)-environment) and the percentage of juveniles on the wintering grounds in south-eastern Australia (PC(1)-juveniles).

some environmental variables within their breeding ranges. The magnitude of the effect of June and July temperatures on breeding performance increased with an increase in the severity of environmental conditions. Thus, the Sharp-tailed Sandpiper (which shows an increase of only 3.2% in the proportion of juveniles per degree Centigrade rise in temperature) inhabits southern and typical tundra sub-zones (as defined by Chernov 1985), mires and floodplain habitats with abundant sedge vegetation. This corresponds to the least severe environment compared with that of the other three species. The effects of summer temperatures on the proportions of juvenile Red-necked Stint and Curlew Sandpiper were similar to one another (increasing by 6.4% and 6.3% per degree, respectively). The former species primarily inhabits upper slopes and watersheds in southern and typical tundra, while the latter inhabits slopes and watersheds in typical and Arctic tundra. The severity of the environment in the breeding habitat of these two species is probably, therefore, comparable. Finally, the Ruddy Turnstone inhabits typical and Arctic tundra, but in typical tundra, its breeding range is mostly restricted to the sea coast, where the possibility of adverse weather is considerably higher than in inland areas.

The proportions of juvenile Red-necked Stint, Curlew Sandpiper and Ruddy Turnstone were more strongly correlated with July temperatures than June temperatures, while in the Sharp-tailed Sandpiper, the percentage of juveniles was correlated with June and July temperatures combined. A stronger effect of early summer (June) temperatures seems natural in a species with a southerly distribution. Given that chicks of Arctic waders hatch primarily in July, the greater influence of July temperatures on juvenile production in most species is probably explained by the higher sensitivity of the chicks to adverse weather conditions, especially recently hatched chicks, compared with clutches of eggs. The hypothesis that the

primary impact of summer temperatures on breeding performance is via mortality of chicks is also supported by the virtual absence of any relationship between nesting success (up to hatching) and summer temperatures (the Ruddy Turnstone, which inhabits the most severe environment, being the only exception in this study).

The absence of a significant relationship between wader nesting success across the breeding ranges and rodent abundance contradicts the predictions of the Roselaar-Summers prey-switching hypothesis. Our small sample size (16 seasons) and the low quality of data in many years, in particular the data on nesting success, could be a reason for this failure to demonstrate a statistical relationship between these two parameters. The relationship between proportions of juveniles and rodent abundance found in the Sharp-tailed Sandpiper and Red-necked Stint indicates that prey-switching is likely to affect productivity in at least some of the species under consideration, but the reasons why only these species showed a significant relationship are not as yet clear.

The effects of rodent abundance on the nesting success of waders and production of juveniles are less pronounced than the effects of weather. We hypothesize that this is due to the abundance of alternative prey during the incubation period, while temperatures have most effect at the later stage of chick-rearing and thus have a more direct influence on the proportions of juveniles in the population.

The correlation of environmental factors (temperatures and rodent abundance) within the ranges of different species of waders with each other is not surprising given the considerable overlap in the waders' ranges. The absence of a strong correlation in juvenile proportions among most species of waders indicates that the response of waders to similar environmental factors on their breeding grounds differs between species. In particular, the response of the Sharp-tailed Sandpiper to environmental factors differs from that of other species. This may be due to the smaller extent of the Sharp-tailed Sandpiper's breeding range and its more southerly distribution.

Although there are differences between wader species in their response to the Arctic environment, there are also certain similarities. There were years (e.g. 1989 and 1992) in which the combined effects of low summer temperatures and low rodent abundance resulted in very poor breeding performance of all, or nearly all, species, while in other seasons (e.g. 1991) superb environmental conditions resulted in very high reproductive success in all species (Fig. 2). Deviations from this relationship require special consideration. Good environmental conditions in 2000 failed to ensure high breeding performance by waders (Fig. 2). This apparent anomaly was probably the result of an unusual pattern of July air temperatures in eastern Siberia in this year. The very high July temperatures responsible for the relatively high averages across eastern Siberia occurred mostly in eastern Yakutia and western Chukotka – an area which is not inhabited at high density by any of the species under consideration. Conversely, July was cold in western Yakutia, Taimyr and eastern Chukotka, and this probably resulted in the low breeding performance recorded in Australia. Thus, accounting for heterogeneity within the breeding range can greatly aid in the interpretation of results, but the required data have yet to be collated.

In the four species under investigation, the most pronounced long-term increasing trend in juvenile proportions was in the

Red-necked Stint, and this corresponds to the most pronounced increasing trend in July temperatures, which occurred within the breeding range of this species. This tallies well with an increase in numbers of Red-necked Stints on the non-breeding grounds, as revealed by monitoring counts in Australia (Minton 2003), and gives persuasive evidence of the long-term impact of processes developing on the breeding grounds on recruitment and numbers in wader populations.

While all the evidence points to the positive effects of increasing summer temperatures on wader breeding performance, certain issues remain unclear and require further research to assess the possible impacts of changes in the environment on population productivity and numbers. The following research topics require further investigation:

- 1 Increasing summer temperatures might, at some point, reach a threshold after which their effect on wader breeding performance will no longer remain beneficial. For example, high summer temperatures could lead to increased dryness of habitats and an associated decrease in the availability of the soil invertebrates on which the waders feed. The consequences for populations of reaching this upper temperature threshold are not known, but could easily be dramatic.
- 2 Trends in the breeding performance of the Curlew Sandpiper require thorough investigation. The Australian non-breeding population of this species has shown a major decline in numbers, with counts in some areas down to 25% of former levels (Minton 2003). Most of the decline has occurred since 1994 (Minton *et al.* 2002a). However, no evidence was discovered of any deterioration in environmental factors across the breeding range of the species during the present study, implying that stable values of the factors under investigation are not sufficient to support stable populations. It is likely, therefore, that other factors are responsible for the decline in the Curlew Sandpiper population, but what these factors are remains unknown.
- 3 While summer temperatures affect productivity of all four species of waders to varying degrees, some species also respond to changes in rodent abundance. The reasons for the differences between species in their response to rodent abundance are unknown, as also are the effects of interactions of rodent abundance with temperature. It is also possible that the indirect effect of the lemming cycle on wader productivity differs in various parts of the Arctic, and may, for example, be especially pronounced on the Taimyr Peninsula (e.g. Underhill 1987, Underhill *et al.* 1989). This issue needs verification.
- 4 The contribution of impacts away from the breeding grounds to changes in juvenile proportions are unknown. Staging sites of migrants in the East Asian-Australasian Flyway are subject to various threats due to intensive development in coastal areas. Studies of population processes in northern Siberia and Australia will hopefully help to interpret correctly those impacts to which birds are exposed on their migration routes.

## ACKNOWLEDGEMENTS

From 1988 to 1996, collection of data on the breeding grounds and data processing were carried out by the Working Group on Waders (Commonwealth of Independent States), while activi-

ties in 1997-2004 were conducted within the framework of the ABBCS and with support from the International Wader Study Group, Working Group on Waders (CIS), the Government of The Netherlands, and Wetlands International. We would like to give our special thanks to the large number of people who contributed their data to the ABBCS over a period of 16 years, and all those who participated in the wader-catching activities of the Victorian Wader Study Group over a period of 26 years. Derek Scott provided valuable comments on the manuscript.

## The Arctic connection: monitoring coastal waders in South Africa - a case study

Doug M. Harebottle & Les G. Underhill

Avian Demography Unit, University of Cape Town, Rondebosch, 7701, South Africa. (email: doug@adu.uct.ac.za)

Harebottle, D.M. & Underhill, L.G. 2006. The Arctic connection: monitoring coastal waders in South Africa - a case study. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 138-139.

This paper discusses population processes of Arctic-breeding waders in light of global climate change and the birds' occurrence and abundance at non-breeding sites at the southern limits of their migratory range. Curlew Sandpiper *Calidris ferruginea* trends from Langebaan Lagoon, South Africa were selected as a case study to demonstrate the strength of assessing change in Arctic-breeding wader populations through monitoring populations at selected non-breeding sites. Preferred and peripheral sites are described to ensure that monitoring is measurable and valuable. Recommendations are provided to guide future global migratory wader research and conservation.

Arctic-breeding waders constitute an important component of wetland communities, and the ecological impact on the health and integrity of wetland systems is unknown should they disappear (Committee for Holarctic Shorebird Monitoring 2004). There is growing international concern that many wader populations are declining (Wader Study Group 2003, Stroud *et al* 2006) and global warming is likely to impact all habitats used in the annual cycle. Breeding grounds will change due to loss of tundra habitat, while inter-tidal wetlands, both in non-breeding sites and along the migration route, will be impacted as sea-levels rise. The dependence of Arctic waders on critical staging sites will thus reflect environmental conditions across the globe.

It has been suggested that population processes of waders breeding in the Arctic tundra can be monitored at the end of the migratory range, e.g. lemming cycles in Siberia can be observed at the foot of Table Mountain (Underhill 2003). South Africa is host to birds from many of the East Atlantic and West Asia/East Africa Flyway migratory wader populations and the opportunity exists to monitor population trends and processes in these non-breeding areas. Currently, three appropriate sites in South Africa have monitoring programmes for arctic waders: (1) Langebaan Lagoon (Harebottle *et al.* 2006, Underhill 1987), (2) Robben Island (Underhill *et al.* 2001) and (3) Dyer Island (Venter *et al.* 2002). Langebaan Lagoon supports the southern-most large concentration of waders on the East Atlantic Flyway and has the longest running monitoring programme of its kind in the southern hemisphere, operating since 1975.

For our case study, we selected Curlew Sandpiper and examined count data from Langebaan Lagoon over the past 28 years. Long-term trends and breeding productivity are presented in Figs. 1 & 2. Data from mid-summer (January/February) was used to establish overall population trends, while southern winter (July/August) counts were used to measure breeding productivity, as most first-year birds do not migrate (Summers *et al.* 1995). Both numbers of birds and numbers of juveniles at the lagoon have been decreasing over the past 28 years.

The Curlew Sandpiper results from this study have demonstrated that population monitoring at non-breeding sites can be a useful measure of population processes at the breeding grounds.

Fig. 1. Summer (solid line) and winter (broken line) counts for Curlew Sandpiper *Calidris ferruginea* at Langebaan Lagoon, South Africa from 1975-2003. Trend lines (dark blue) are shown for each count series.

Fig. 2. Breeding productivity of Curlew Sandpiper measured at Langebaan Lagoon, 1976-2003. Figures based on the percentage of winter count of first-year birds versus the previous summer count. Trend line shown in black.

However, it is important that the correct sites are selected for monitoring to be effective. Generally, monitoring sites should be unlikely to undergo any long-term development changes. As such, there is a need to identify preferred and peripheral sites. Preferred sites are those that have roughly the same number of birds each year (e.g. Langebaan Lagoon), while peripheral sites are those that are not occupied every year, or have large annual fluctuations of birds (e.g. Robben Island and Dyer Island).

Based on this case study, the following recommendations are provided for future migratory wader research: (a) the need for improved, coordinated circumpolar monitoring of arctic wader populations to assess their status and population trends, (b) the establishment of networks of preferred and peripheral sites throughout the species' migratory range and (c) the provision of adequate funding to establish monitoring programmes at selected sites, particularly in poorer countries.

We acknowledge financial support from the National Research Foundation.

### ABSTRACT

Regular wader counting and trapping activities were initiated in the Dutch Wadden Sea about 30 years ago by a group of pioneering ornithologists/ecologists including Jan Rooth, Arie Spaans, Gerard Boere, Ebel Nieboer and Piet Zegers. Since the first count in 1963, there have been over 100 simultaneous counts throughout the Dutch part of the Wadden Sea. Most trapping activities began around 1970, and since then, over 32 000 waders have been trapped. The major aim of the counts and trapping has been to monitor changes in the populations of the wader species occurring in the Wadden Sea, and to obtain insight into changes in the composition of these populations. This paper focuses on the numerical trends and changes in population composition of seven Arctic-breeding waders that occur regularly in the Wadden Sea. Special attention is given to the composition and breeding origins of the populations of Grey Plover *Pluvialis squatarola*, Red Knot *Calidris canutus*, Dunlin *C. alpina* and Bar-tailed Godwit *Limosa lapponica*, as determined by morphometric analysis of wing and culmen lengths.

### INTRODUCTION

When the Arctic breeding season comes to an end, the wader populations from north-eastern Canada in the west to central Siberia in the east begin their migrations to the wintering grounds along the eastern shores of the Atlantic Ocean (e.g. Boere 1977, Smit & Wolff 1981, Smit & Piersma 1989, Meltotte *et al.* 1994, Van de Kam *et al.* 1999, Reneerkens *et al.* 2005). The first step to western Europe is a maximum of about 5 000 km. Nearly all waders in this migration system stay for a shorter or longer period in the international Wadden Sea. Here, western and eastern breeding populations mix. Many birds stay

only for a few weeks, this being long enough for them to refuel for another non-stop flight of 3 000-5 000 km to wintering areas along the coast of West Africa. Those birds that moult in the area stay for a period of between two and four months. Once the moult has been completed, some of the birds migrate to distant wintering grounds in Africa, whilst others depart to winter in coastal regions of south-western Europe and the British Isles. Relatively few waders remain throughout the winter in the Wadden Sea, especially during harsh winters when the area may become devoid of waders. Reverse movements take place in March, April and May, when migrating waders again gather in the Wadden Sea prior to their departure to the breeding grounds. Once again, the area is filled with massive numbers of Arctic-breeding waders.

In order to understand the migrations of these Arctic waders, regular counting and trapping activities were initiated in the Dutch Wadden Sea (Fig. 1) about 30 years ago by a group of ornithologists/ecologists including Jan Rooth, Arie Spaans, Gerard Boere, Ebel Nieboer and Piet Zegers. These pioneers laid the foundations for the organization of regular counting and trapping activities (Fig. 2). The first count was organized by Jan Rooth in 1963, and since then there have been over 100 simultaneous counts throughout the Dutch part of the Wadden Sea. Gerard Boere and Ebel Nieboer started most trapping activities around 1970, after they had been inspired by the trapping activities of Clive Minton and Hugh Boyd on the island of Vlieland in the Dutch Wadden Sea. Since then, over 32 000 waders have been trapped and analysed, resulting in a string of publications, e.g. Nieboer (1972), Boere *et al.* (1973), Boere (1977), Smit & Wolff (1981), Boere *et al.* (1984) and Van der Have *et al.* (1984). Nearly all the younger Dutch ornithologists and ecologists

Fig. 2. Chronology of wader trapping activities in the Dutch part of the Wadden Sea.

working in the Wadden Sea today became inspired while being involved in these counting or trapping activities in the area. Many of them have since exported their experience to other parts of the world.

Throughout the years, the major aim of organizing counts and trapping activities has been: (1) to monitor changes in the populations of the wader species occurring in the Wadden Sea, and (2) to obtain insight into changes in the composition of these populations. This aim was, and still is, of utmost importance for an understanding of how best to protect the area as a whole. This paper focuses on numerical trends and changes in population composition of seven Arctic-breeding waders that are regularly present in the Dutch Wadden Sea during the non-breeding season. These are: Common Ringed Plover *Charadrius hiaticula*, Grey Plover *Pluvialis squatarola*, Red Knot *Calidris canutus*, Sanderling *C. alba*, Dunlin *C. alpina*, Bar-tailed Godwit *Limosa lapponica* and Ruddy Turnstone *Arenaria interpres*. Some of these species have populations which breed in low Arctic or temperate zones and are regularly present in the Wadden Sea. These populations have also been included in the analyses. Another Arctic species, the Curlew Sandpiper *Calidris ferruginea*, has been excluded because of its restricted occurrence in the Wadden Sea.

Morphometric studies make it possible to produce quantitative estimates of the population composition of mixed wader populations. These estimates are produced with the aid of multivariate data analysis, which includes a comparison of the measurements of birds in the mixed Wadden Sea population with measurements of birds in the breeding populations. Migrant waders in the international Wadden Sea have a mixed breeding origin, but the degree of mixing differs for each species. Measurements of migrants in the Wadden Sea were used to test these new multivariate methods in order to estimate the proportional occurrence of the various breeding populations in the Wadden Sea during the migration seasons and in winter.

## RESULTS

In total, over 32 000 waders have been trapped since the early 1970s. The number of birds trapped annually has fluctuated between 500 and 3 500. In addition, the whole of the Dutch part of the Wadden Sea has been counted three to five times each winter since the early 1970s. P. Zegers and G.C. Boere co-ordinated these counts until 1975 (Boere & Zegers 1974, 1975 & 1977). Zegers continued with the co-ordination until 1992

(Zegers 1985, Zegers & Kwint 1992), and since 1993, SOVON, the Dutch organization for bird monitoring and research, has been responsible for co-ordination (Koffijberg *et al.* 1999, De Boer *et al.* 2001, Kleefstra *et al.* 2002, Van Roomen *et al.* 2002, 2003, 2004, 2005).

## Trends

Most of the Arctic wader species present in the Dutch part of the Wadden Sea show an increasing trend in numbers (Fig. 3). The Red Knot and Ruddy Turnstone have suffered serious declines in the area, but the Ringed Plover, Grey Plover, Sanderling, Dunlin and Bar-tailed Godwit have been increasing in numbers. The early 1980s were characterized by relatively low numbers of Ringed Plover, Sanderling, Dunlin and Bar-tailed Godwit. In the second half of the 1980s, numbers started to recover, with the recovery in Dunlin starting somewhat earlier than in Ringed Plover, Sanderling and Bar-tailed Godwit. The numbers of Red Knot peaked in the first half of the 1990s and have declined since then. Ruddy Turnstone numbers were in continuous decline until the winter of 1999/2000. Since then, numbers have been recovering slowly. Once the trends of mixed populations have been established, it is necessary to unravel them: which populations are on the increase and which are not?

## Population composition in the Wadden Sea

Increases or decreases may be triggered on the breeding grounds, somewhere along the migration routes, on the wintering grounds, or even during the migratory flights. A better understanding is therefore required of population composition throughout the non-breeding season with reference to variability in time and space. When birds are counted, absolute numbers are obtained, resulting in estimates throughout the non-breeding season and a series of index values (Table 1). Conversely, estimates of the composition of populations result in proportional estimates, and can only be obtained when measurements of individual birds are available. Since juveniles and first-winter birds are not fully grown when they arrive in the Wadden Sea, they cannot be compared with samples of adult specimens from the breeding grounds. Thus, in the accounts for Grey Plover, Red Knot, Dunlin and Bar-tailed Godwit that follow, attention is focused on the adult populations.

By comparing the wing and culmen lengths of breeding populations with each other and with those of birds in the mixed

**Fig. 3.** Increasing index values of five Arctic wader species in the Dutch part of the Wadden Sea: 1975/76 - 2001/02. 100 = average over all years.

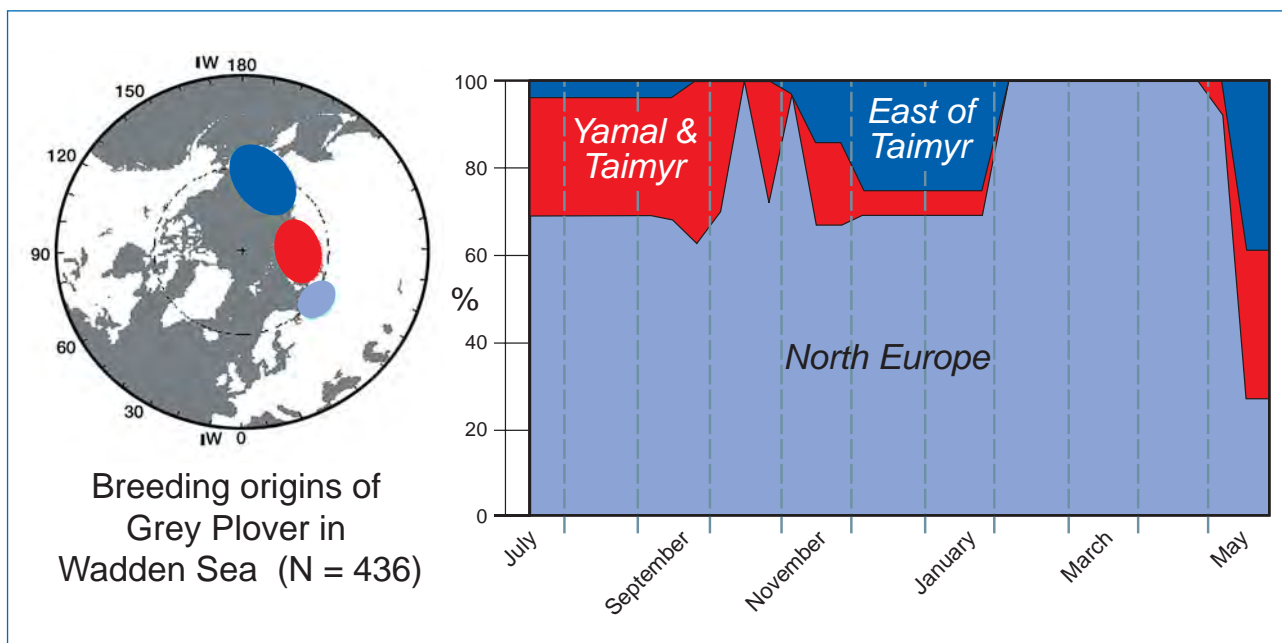

populations in the Wadden Sea, it is possible to produce estimates of the composition of the wader populations in the Wadden Sea. The methods of comparison are described in Engelmoer (1995), Engelmoer & Roselaar (1998) and Engelmoer (in prep.). Here we focus on the results.

#### Grey Plover

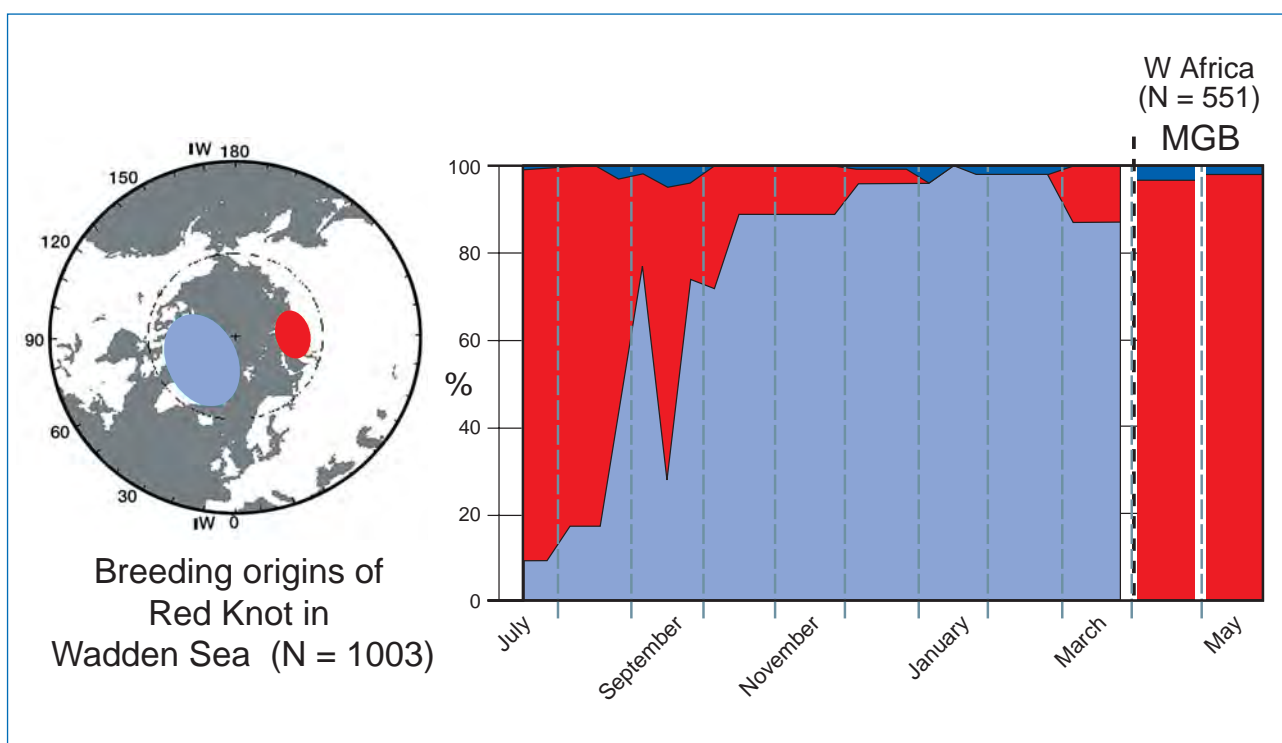

Morphometric studies have resulted in the recognition of three different breeding populations of potential relevance to the Wadden

**Fig. 4.** Composition of the non-breeding Grey Plover *Pluvialis squatarola* populations in the Dutch part of the Wadden Sea, based on morphometric analysis of wing and culmen lengths.

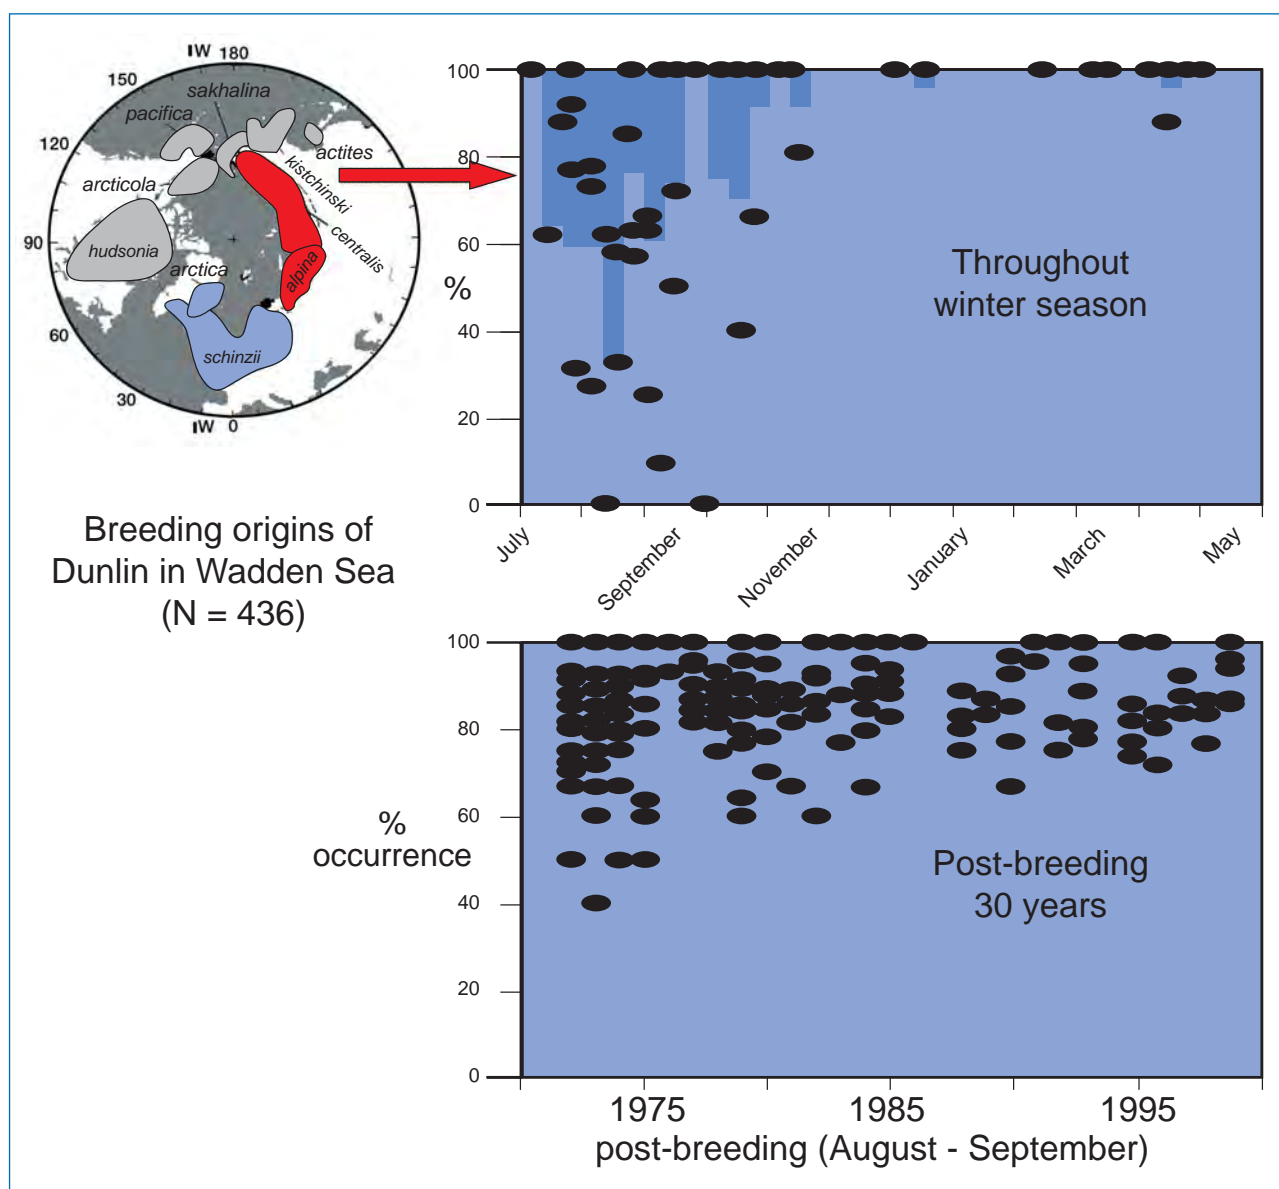

**Fig. 5.** Composition of the non-breeding Red Knot *Calidris canutus* populations in the Dutch part of the Wadden Sea, based on morphometric analysis of wing and culmen lengths. Explanation of patterns: islandica (grey); nominate *canutus* (hatched); *piersmai* (black). M = wintering population in Mauritania (WIWO-expeditions, Ens *et al.* 1990); GB = wintering population in Guinea-Bissau (WIWO-expedition, Zwarts 1988).

Sea populations. From west to east, these are: (1) the breeding population in northern Europe; (2) the breeding population in Yamal and Taimyr; and (3) the breeding population east of Taimyr.

The majority of the Grey Plovers in the Wadden Sea apparently belong to the westernmost population breeding in northern Europe (Fig. 4). This breeding population has increased in numbers (Hagemeijer & Blair 1997). The numbers wintering in

western Europe have also increased (e.g. Meltofte *et al.* 1994, Pollitt *et al.* 2003, Van Roomen *et al.* 2004, Engelmoer in prep.), but it is possible that birds from other breeding areas might be involved as well. Grey Plovers from Yamal and Taimyr occur in the Wadden Sea, particularly in July/August and May, and the estimates from the Wadden Sea persistently show the occurrence of a small proportion of Grey Plovers originating from breeding areas east of Taimyr.

**Fig. 6.** Composition of the non-breeding Dunlin *Calidris alpina* populations in the Dutch part of the Wadden Sea, based on morphometric analysis of wing and culmen lengths. The upper right figure shows the average estimated proportion of the two larger subspecies, *alpina* and *centralis*, in the population by ten-day period throughout the year (dark grey shading). Black dots represent individual samples. The lower right figure shows the change that has occurred over the last 30 years in the proportion of the two larger subspecies in individual samples collected during the post-breeding period.

### Red Knot

Morphometric studies have resulted in the recognition of three breeding populations of potential relevance to the Wadden Sea populations. From west to east, these are: (1) the population of *islandica* breeding in north-eastern Canada; (2) the population of *canutus* breeding in Taimyr; and (3) the population of *piersmai* breeding in the New Siberian Islands.

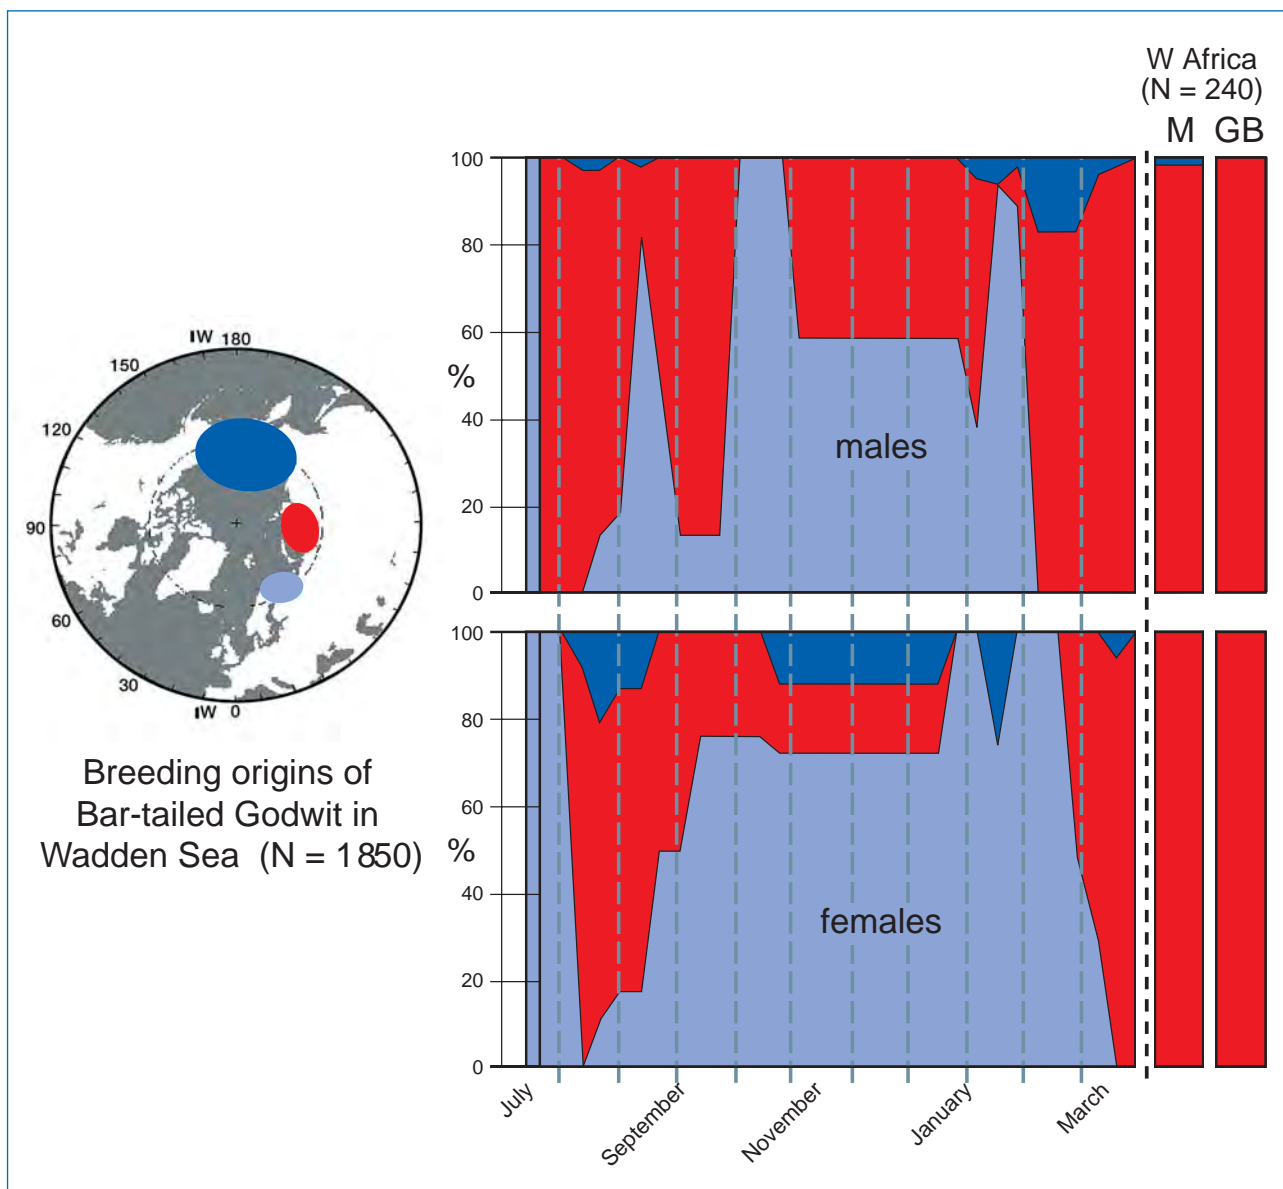

The majority of Red Knots occurring in the Wadden Sea are the Nearctic subspecies *islandica*, particularly during winter (Fig. 5). Siberian *canutus* are most numerous during July/August and in May, but this subspecies is also regularly present during September/October and March/April. Small numbers of *piersmai* (representing <5%) have been identified in the Wadden Sea in August/September and January/February.

### Dunlin

Four subspecies of Dunlin occur in the Wadden Sea: *arctica* breeding on East Greenland; *schinzii* breeding in north-west

Europe; nominate *alpina* breeding in northern Europe east to Yamal; and *centralis* breeding from Yamal east to 85°E. However, there is overlap in the breeding ranges, as shown by DNA analyses (Wenink 1994), and also overlap in the measurements of the subspecies. The two smallest subspecies, *arctica* and *schinzii*, can easily be separated from the largest subspecies, *centralis*. The measurements of male *alpina* are similar to those of the two smaller subspecies, while female *alpina* are similar in size to *centralis*.

The Dunlin in the Wadden Sea are most often *alpina* or *centralis* (Fig. 6). *Arctica* and *schinzii* occur only during the post-breeding period, with their proportional presence decreasing from July/August to September/October. *Arctica* seems to occur somewhat more regularly than *schinzii*. The late summer occurrence of the two small subspecies, *arctica* and *schinzii*, has decreased markedly since the 1970s in favour of *centralis* and *alpina*. The positive trend in Dunlin numbers since the second half of the 1980s is thus related to larger numbers of *centralis* and *alpina* staging in the Wadden Sea.

**Fig. 7.** Composition of the non-breeding Bar-tailed Godwit *Limosa lapponica* populations in the Dutch part of the Wadden Sea, based on morphometric analysis of wing and culmen lengths. Explanation of patterns: nominate *lapponica* (grey); *taymyrensis* (hatched); *menzbieri* or further east (black). Ma = wintering population in Mauritania (WIWO-expeditions, Ens *et al.* 1990); GB = wintering population in Guinea-Bissau (WIWO-expedition, Zwarts 1988).

### Bar-tailed Godwit

Morphometric studies have resulted in the recognition of three breeding populations of potential relevance to the Wadden Sea populations. From west to east, these are: (1) nominate *lapponica* breeding in northern Fenno-scandia; (2) *taymyrensis* breeding from Yamal east to the delta of the Anabar River; and (3) *menzbieri* breeding from the Lena Delta east to Chaunsk Bay.

In July and August, immediately after the breeding season, a relatively large proportion of the Bar-tailed Godwits occurring in the Wadden Sea originate from Taimyr, and this is particularly the case amongst the males (Fig. 7). The proportion of *taymyrensis* then decreases during September and October in favour of north European *lapponica*. About 80% of the wintering population of Bar-tailed Godwits in the Wadden Sea are *lapponica* and about 20% *taymyrensis*. Birds from populations breeding east of Taimyr, such as *menzbieri*, occur regularly,

especially females, but always in proportions of less than 10%. *Taymyrensis* is the dominant form again in May, especially amongst the males.

### CONCLUSION

Over the past 30 years, important changes have occurred in the Wadden Sea. Evidence of this has been found from the counting and trapping of Arctic-breeding waders. The combination of counting and trapping has provided quantitative insight into the composition of wader populations with respect to breeding origins, juvenile percentages, and the moulting and refuelling functions of different parts of the area. It has now become clear that the international Wadden Sea should not be considered as a single system for wader migration. Rather, the various areas in the Wadden Sea have different roles and functions for migratory wader populations.

Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 147-153.

## ABSTRACT

The Spoon-billed Sandpiper *Eurynorhynchus pygmeus* is a globally threatened species currently classified by IUCN as Endangered. Four expeditions to various parts of the breeding range in Chukotka, eastern Siberia, in 2000-2003 have revealed a sharp decline in numbers. The total population does not exceed 1 000 pairs, and is most likely much lower. The main staging and wintering areas are poorly known, and little information is available on habitat requirements and threats. An analysis of two stable isotopes (deuterium and oxygen-18) in feathers taken from adult birds on the breeding grounds in 2003 indicates wintering areas in the Ganges-Brahmaputra Delta region and South China Sea. Very few of the birds ringed and colour-flagged on the breeding grounds have been re-sighted, and none of the 30 chicks flagged in a core breeding area in 2001 was re-sighted in this area in 2003, suggesting that the main pressures on the species are along the migration route. Various possible reasons for the decline in the species and low return rate of young birds to the breeding areas are discussed. Other migratory waterbirds in the East Asia-Pacific Flyway are undergoing similar declines, and may be affected by the same threats. It is concluded that more effort needs to be given to internationally co-ordinated research and conservation activities if the Spoon-billed Sandpiper is to be safeguarded from extinction.

## INTRODUCTION

The Spoon-billed Sandpiper *Eurynorhynchus pygmeus* is considered to be a globally threatened species and is classified as Endangered (BirdLife International 2004). Four expeditions between 2000 and 2003 to different parts of the breeding range in Chukotka, Russia, revealed a sharp decline. The total population does not exceed 1 000 pairs and is most likely to be much lower (Tomkovich *et al.* 2002, Zöckler 2003, Syroechkovskiy *et al.* in prep.). However, the exact population size and the main wintering sites are not fully known, although there are scattered observations of Spoon-billed Sandpipers in south and south-east Asia. This information and a knowledge of the habitat requirements and threats along the flyway are essential in understanding the recent decline and in implementing the necessary steps towards the protection and safeguarding of a viable population.

The breeding range of the Spoon-billed Sandpiper is confined to the coastal tundra of Chukotka and northern Kamchatka (Figs. 1 and 2). An initial investigation of the three major breeding grounds visited during the surveys did not indicate any specific reasons for the decline in the breeding areas. Although in some of the sites visited, predation of nests and

chicks was very high, in other sites hatching success was very high. There may, however, be other important factors affecting the birds on the breeding grounds, and further research is required to investigate the possible impacts of climate change and other global drivers on conditions in the breeding areas. However, much of the evidence points to threats along the migration route or in the wintering areas.

On migration, the species regularly passes along the coasts of Kamchatka, Sakhalin, Japan and Korea. However, only in Korea are there recent records of the species in substantial numbers, i.e. between 100 and 200 birds annually (Lethaby *et al.* 2000, Jin-Young Park *in litt.*). There have been observations of Spoon-billed Sandpipers in suitable staging and wintering sites in Thailand, Malaysia and Vietnam (Collar *et al.* 2001). Little information is available on staging or wintering areas in Myanmar, Bangladesh and eastern India, and this is often only historical (Howes & Parish 1989, T. Inskipp pers. comm., S. Balachandran pers. comm.). Since 1990, very little information has been received from the wintering grounds, and there have been no observations of groups of more than 20 birds. All this information gives further support to the conclusion that the species is in strong decline.

Unanswered questions on the status of the species still include the exact size of the population and the main wintering areas. The latter is vital in understanding the main reasons for the decline. In view of the paucity of ringing recoveries from potential wintering areas, new technologies are required to reveal the major wintering and stopover sites. In addition to ringing and colour-flagging, the use of stable isotope technology has been demonstrated to be useful in determining the geographical origin of individuals in a population of a species (Hobson & Wassenaar 1997, Marra *et al.* 1998, Webster *et al.* 2002, Atkinson *et al.* in prep.). This technology is now being applied to the Spoon-billed Sandpiper – the first time that a stable isotope analysis has been used on any wader in the Asia-Pacific Flyway. It promises to provide further insight into the location of the pre-breeding moulting areas and the major wintering areas of the Spoon-billed Sandpiper.

## METHODS

### Breeding sites and ringing

Between 2000 and 2003, four expeditions were made to different sites in Chukotka, under the leadership of E.E. Syroechkovskiy, Jr., to investigate the situation of the Spoon-billed Sandpiper on its breeding grounds (see Fig. 2). Breeding densities, hatching and fledging success and various other features of the breeding biology were recorded and compared with the findings of

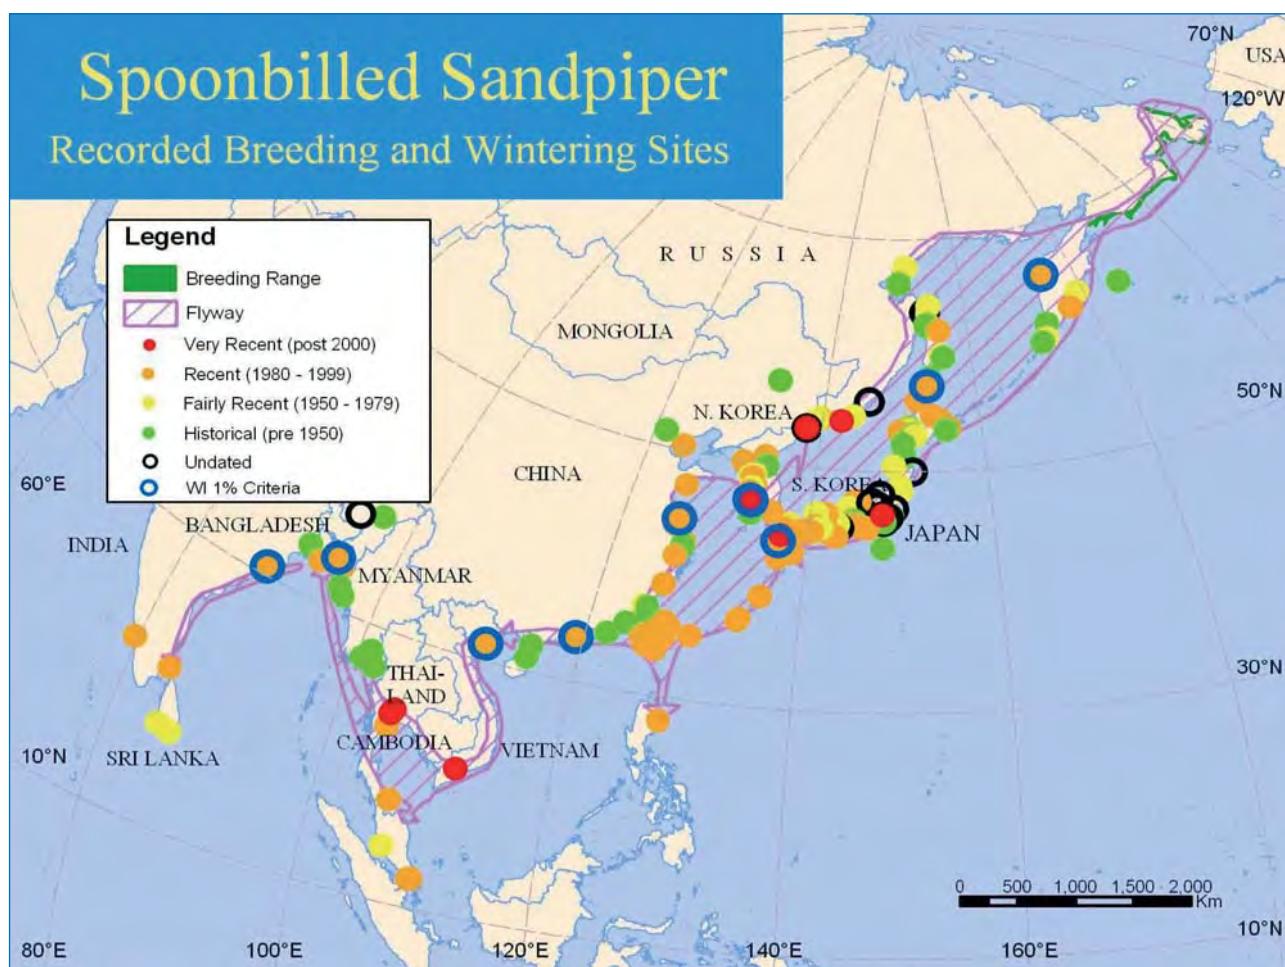

Fig. 1. The distribution of the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*, showing the presumed flyway to south-east Asia.

previous visits. The results of this research will be published elsewhere (Syroechkovskiy *et al.* in prep.). In addition, a number of birds were ringed and colour-flagged. Whenever possible, both members of a breeding pair of Spoon-billed Sandpipers were caught with traps set at or nearby the nest. The adult birds were sexed, and most were ringed and individually colour-flagged. The chicks were also ringed and colour-flagged with light blue flags in North Chukotka and light green flags in South Chukotka.

### Stable isotopes

In the 2003 season, feather samples were collected for subsequent analyses of stable isotopes. Samples were taken from 28 adult Spoon-billed Sandpipers and one Red-necked Stint *Calidris ruficollis* caught on or near the nest between 13 June and 5 July. Only one or two of the central tail feathers or a couple of scapular feathers were sampled so as not to affect the birds' mobility.

Stable isotopes vary regionally, and the distribution of  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  are promising geographical markers. These isotopes could narrow the location of the species' pre-breeding moulting sites to a smaller geographical region than is currently known. Feather samples from adult breeding birds are assumed to be generated on the wintering grounds, based on a knowledge of closely related species such as other sandpipers (Prater *et al.* 1977), and should therefore bear the signature of the wintering location. At present, the results from the analysis of nine feather

samples are available. Funding for a full analysis of all 29 samples is still lacking.

For the oxygen-18 analysis, 1 mg amounts of feather were weighed into silver capsules. Samples were measured using IAEA-CH-6 (sucrose,  $\delta^{18}\text{O} = 36.4\text{‰}$  vs V-SMOW) as a reference. IAEA-CH-6 and IAEA-C-3 (cellulose,  $\delta^{18}\text{O} = 32.2\text{‰}$  vs V-SMOW) were run as quality control check samples during batch analysis of the samples. IAEA-CH-6 and IAEA-C-3 are inter-comparison materials distributed by the International Atomic Energy Agency, for which the values reported above are generally agreed by the stable isotope analysis community. Both standards and samples were oven-dried at  $60^\circ\text{C}$  for more than 72 hours prior to analysis, to remove moisture.

The oxygen isotope analysis was conducted by total conversion at  $1080^\circ\text{C}$  in a quartz reactor tube lined with a glassy carbon film, filled to a height of 170 mm with glassy carbon chips and topped with a layer of 50% nickelized carbon (10 mm deep). Carbon monoxide and nitrogen were separated on a GC column packed with molecular sieve 5A at a temperature of  $54^\circ\text{C}$ . The isotope ratio mass spectrometer used was a Europa Scientific Geo 20-20 with triple Faraday cup collector array to monitor the masses 28, 29 and 30.

For the deuterium analysis, 1 mg amounts of feather were weighed into silver capsules, and equilibrated with laboratory air moisture for more than 96 hours prior to analysis (Wassenaar & Hobson 2002). Samples were measured using IA-R002 (ISO-Analytical mineral oil,  $\delta^2\text{H} = -111.2\text{‰}$  vs V-SMOW) as a refer-

**Fig. 2.** The breeding distribution of the Spoon-billed Sandpiper *Eurynorhynchus pygmeus* and location of sightings during four expeditions to the breeding grounds in 2000-2003.

ence. IA-R002 and IAEA-CH-7 (polyethylene,  $\delta^2\text{H} = -100.3\text{‰}$  vs V-SMOW) were run as quality control check samples during batch analysis of the samples. IAEA-CH-7 is also an inter-comparison material distributed by the International Atomic Energy Agency with an internationally accepted  $\delta^2\text{H}$  value.

Correction for the exchangeable hydrogen in the feather samples was applied by comparative equilibration of the feathers with BWB-II (whale baleen from the University of Alaska,  $\delta^2\text{H} = -108\text{‰}$  vs V-SMOW). The mean measured  $\delta^2\text{H}$  value for BWB-II was  $-101.17\text{‰}$  vs V-SMOW, providing a comparative equilibration correction factor of 1.0675.

The hydrogen isotope analysis was conducted by total conversion at  $1080^\circ\text{C}$  in a quartz reactor lined with a glassy carbon film, filled to a height of 180 mm with glassy carbon chips. Hydrogen was separated from other gaseous products on a GC column packed with molecular sieve  $5\text{\AA}$  at a temperature of  $30^\circ\text{C}$ . The isotope ratio mass spectrometer used was a Europa Scientific Geo 20-20 with a Faraday cup collector array to monitor the masses 2 and 3.

The oxygen-18 and deuterium analyses were carried out by Iso-Analytical Ltd., Cheshire, UK.

#### Database of sightings

To support information derived from the stable isotope analyses described above and to provide as much insight as possible into the wintering behaviour of these rare and widely dispersed birds, a database of sightings is being developed. This is directly linked to a GIS system in order to provide a range of map outputs at various scales. These can, in turn, be used for a range of

purposes from giving an overall picture of recent sightings (Fig. 1) to more detailed uses such as planning expeditions and assessing probable threats at the local level.

The database was based on information from Collar *et al.* (2001), but now also includes more recent sightings derived from a range of published and unpublished sources. Two new sites, one in the Gulf of Thailand and one in the Mekong Delta, have recently been included. Additional information from a Wetlands International report (Watkins *et al.* in prep.) has also been added to highlight those sites at which numbers exceeding 1% of the total population have been recorded (blue circles on Fig. 1). Anyone with information on recent sightings, especially of flagged birds, is requested to send it to the authors as well as to the relevant ringing authorities.

**Table 1.** Present and past population estimates of the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*.

Population estimate (in pairs)	Source	Comments
2 000-2 800	Flint & Kondratiev 1977	Extrapolation from known breeding grounds.
<1 000	Tomkovich <i>et al.</i> 2002	Based on decline in number of known sites.
560-900	Syroechkovskiy <i>et al.</i> in prep.	If population declined by a factor of 3-5.
400-500	This study	Based on known numbers and calculated estimates.

**Table 2.** The results of ringing of Spoon-billed Sandpipers *Eurynorhynchus pygmeus* during the expeditions to the breeding grounds in 2000-2003.

Year	Adults	Chicks	Sightings
2000	8	7	-
2001	1	28	-
2002	29	30	1 juv.
2003	55	88	1 juv.
Total	93	153	2

## RESULTS

### Population estimates

Based on information acquired during the four expeditions in 2000-2003 (see Fig. 2), it is concluded that the total population does not exceed 560-900 pairs, and may be no more than 400-500 pairs (Table 1). For more details, see Syroechkovskiy *et al.* (in prep.).

### Ringing

During the four breeding seasons 2000-2003, a total of 246 birds were ringed and colour-marked with light blue (2002) and light green flags (2000, 2001 and 2003) (Syroechkovskiy *et al.* in prep., Zöckler 2003). Most of these were chicks, but 93 adult birds were also ringed and colour-flagged (Table 2).

### Migration and recoveries

Since the first birds were ringed in 2000, there have been only two re-sightings. A juvenile ringed on 9 July 2002 on Belyaka Spit was sighted in Japan on 25 September 2002, and a juvenile ringed in Meinypil'gyno in 2003 was seen on the mudflats of Saemangeum in South Korea in September 2003, 2.5 months after ringing.

Birds returning to the breeding grounds included two breeding birds re-captured on Belyaka Spit in 2002; these had been ringed in 1988, one as a chick, the other as an adult breeding bird. The site at which the latter individual was breeding was only 200 m away from where it had been ringed 14 years previously (Tomkovich & Soloviev 2000, Tomkovich 2003). This is a remarkable record for two reasons. Firstly, it confirms the high site fidelity of this species on its breeding grounds (Tomkovich 1992, 1995), and secondly, it constitutes the longevity record for the species. Unfortunately, none of the chicks ringed in 2001 was re-sighted in 2003 in Meinypil'gyno.

However, the only adult bird ringed in 2001 was found breeding again in 2003, only a few hundred metres from where it had been ringed.

### Stable isotopes

The stable isotope analysis has so far only been carried out on eight Spoon-billed Sandpipers and one Red-necked Stint. Table 3 shows the results obtained from these nine birds. For comparative purposes, the eight samples from Spoon-billed Sandpipers were compared with that from the Red-necked Stint, a species which is known to follow a different migration route. Hobson & Wassenaar (1997) pointed out that isotope values in feathers differ from those in precipitation. Only about 30% of hydrogen in feathers is derived from drinking water; the remainder (c. 70%) is derived from dietary intake.

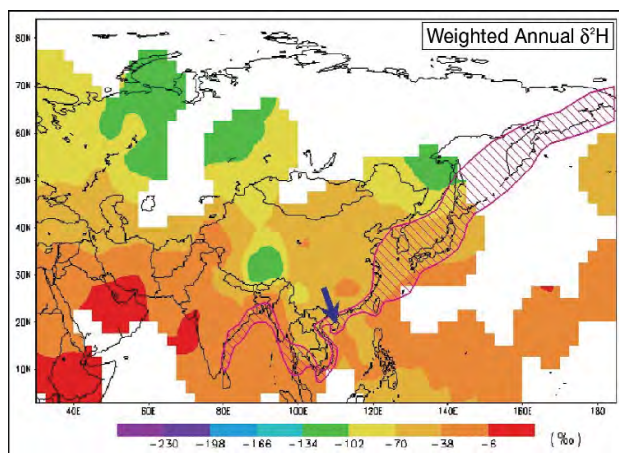

Lott *et al.* (2003) have shown that, regardless of species and trophic level, the difference between the values of  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$  in precipitation and feathers remains constant at about 18 and 21‰, respectively. According to their research, coastal feeders have a mean value of 36.4‰ (Lott *et al.* 2003). The preferred foraging habitat of the Spoon-billed Sandpiper is coastal lagoons and deltas. This would suggest that there is a high proportion of freshwater or brackish water intake that might reduce the value further towards the freshwater difference. As we do not know enough about the species' diet during the winter months, we have to assume a mix of both deuterium offset values (25‰ and 35‰), resulting in a mean offset of 30‰ of  $\delta^2\text{H}$  to be added for further approximation. There is no established offset between oxygen-18 in precipitation and feathers. However, taking into account that oxygen-18 in plants is on average 27‰ higher than in precipitation, and in mammals the offset of oxygen-18 is intermediate between that in plants and precipitation, we suggest that oxygen-18 in feathers is very roughly 15-20‰ higher than in precipitation and this needs to be subtracted from the values.

These adjusted values can be compared with the values generated from various research stations as displayed by IAEA (2001) and superimposed with the flyway of the Spoon-billed Sandpiper (see Figs. 3 and 4 for deuterium and oxygen-18, respectively).

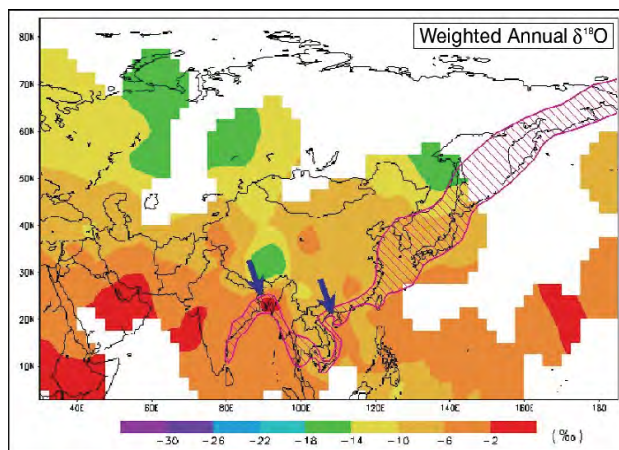

If we consider the adjusted  $\delta^{18}\text{O}$  values of five birds (numbers 2, 3, 4, 24 and 25 in Table 3) and the oxygen-18 distribution within the flyway, we can see that the values coincide well in the Ganges-Brahmaputra Delta region (indicated in

**Table 3.** Feather samples from eight Spoon-billed Sandpipers *Eurynorhynchus pygmeus* and a Red-necked Stint *Calidris ruficollis* obtained during the 2003 expedition to Meinypil'gyno, South Chukotka. All isotope values are expressed in terms of ‰ vs V-SMOW (‰). Adjusted ? values estimate the original precipitation during feather growth.

Sample No.	Nest No.	Date	Sex	Ring No.	Ref	$^2\text{H}$	Adjusted $^2\text{H}$	$^{18}\text{O}$	Adjusted $^{18}\text{O}$

**Fig. 3.** Distribution of annual mean  $\delta^2\text{H}$ , based on IAEA (2001), with overlapping flyway of the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*. The blue arrow points to possible areas of overlapping values and location of the pre-moulting areas

**Fig. 4.** Distribution of annual mean  $\delta^{18}\text{O}$ , based on IAEA (2001), with overlapping flyway of the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*. The blue arrows point to possible areas of overlapping values and location of the pre-moulting areas.

red in Fig. 4) and suggest that this is the wintering area of the birds in question. Two birds (numbers 5 and 8 in Table 3) show values in the next lower category (red-brown in Fig. 4) which covers a large area including all the west coast of India, all of Myanmar, Thailand, Malaysia and the area around Hainan in southern China. The value of the first bird sampled (number 1 in Table 3) goes well beyond the values of the others but is still within the range for this second category. Bird 26 in Table 3 shows the only positive value not displayed in the map in Fig. 4. As this sample refers to a different species (Red-necked Stint), the widely differing value of this sample fits quite well with the occurrence of this species in a different flyway.

The values for deuterium vary quite considerably within the nine samples, ranging from  $-18\text{‰}$  to below  $-80\text{‰}$ . Furthermore, the deuterium precipitation map (Fig. 3) does not show as much variation as the  $\delta^{18}\text{O}$  map (Fig. 4). Only one value coincides with the red-brown range, indicating that the Ganges-Brahmaputra Delta region might be the wintering area of the bird. At the same time, this value could equally refer to the rest of India, Myanmar, Thailand and southern Vietnam. All other

values fall within the next category, which covers an area ranging from central Vietnam north along the Chinese coast as far as North Korea. The only other region of overlap is the area between northern Vietnam and Hainan in southern China, where six of the lower deuterium values in Table 3 overlap with two of the oxygen-18 values (see dark blue arrows in Figs. 3 and 4).

## DISCUSSION

### Stable isotopes

Stable isotopes can be powerful geographical markers. The oxygen-18 values seem to point to the area of the Ganges-Brahmaputra Delta as a wintering area for the Spoon-billed Sandpiper, while overlap in the deuterium and oxygen-18 values of two samples indicates a wintering area in the South China Sea. Both areas are previously known to have held large numbers of Spoon-billed Sandpipers (Collar *et al.* 2001).

However, the results can only be interpreted with caution, as the sample size is very small, the variation within the deuterium values too large, and the scale of the simulated maps very coarse. The results can only be seen as a first approximation, and we hope that funds can be generated to increase the sample size in order to verify these preliminary results.

### Threats during migration

On the basis of our four-year research programme, we can conclude that the Spoon-billed Sandpiper is in serious decline. At the moment, we still do not know what is causing this decline. Compared with all other major flyways, there are particularly serious conditions for waterbirds in the East Asia-Pacific Flyway, with almost all populations declining and many threats recognized (BirdLife International 2003, Syroechkovskiy 2003, Barter 2006, Crosby & Chan 2006). In the Yellow Sea, about 40% of the inter-tidal area has vanished since 1950, and land claim of a further 45% of the remaining area is planned (Barter 2006).

The fact that none of the 30 chicks ringed in 2001 returned to the breeding areas could be interpreted as support for the theory that the main reasons for the decline are to be found on the migration routes or in the wintering areas. However, there are four other possible explanations:

- the birds are still in the wintering areas after two years;
- the returning birds disperse more widely over a larger area and have been overlooked as they spread away from the ringing site;
- the birds did not survive to migrate, which agrees with the very low breeding success observed in Korea (1–2%, Moores 2001); or
- the rings fall off because they were not properly fixed, or the flags harm the birds, increase their vulnerability to predation, or hamper their flight on migration.

In his research on Belyaka Spit in northern Chukotka, Tomkovich (1992, 1994, 1995) found some one- and two-year old birds returning to the vicinity of the ringing site. He noticed that first-time breeders dispersed more widely than older adults, and re-captured two females that had been ringed as chicks 1.5 and 5.5 km from the ringing site, respectively (P.S. Tomkovich *in litt.*). In 2003, we surveyed a 50–60 km stretch of suitable habitat in Meinopil'gyno without finding any ringed birds other than a single breeding bird that had been ringed as an adult and

had returned to within a few hundred metres of its ringing site. Although some birds might have been overlooked or moved further away from their natal area, it seems unlikely that all 30 chicks would have been missed, and this again supports the theory that the reasons for the decline are to be found along the flyway or within the breeding area just after hatching.

The possibility that the rings fall off or the flags harm the birds cannot be fully excluded, but most experience with rings and flags in other species of waders has demonstrated that recoveries or re-sightings can be obtained, in some cases, even after 15 years (Tomkovich 2003). There is no research indicating that birds with flags are less well camouflaged or more visible, and thus exposed to a higher risk of predation, than birds without flags. Expeditions to the breeding grounds in 2004 and 2005 should provide further clues, and if young birds are again under-represented among the returning birds, the flagging methods will need to be reviewed.

However, there are some indications that the possible reasons for the decline are to be found in the breeding areas. The most likely is increased predation as a result of changes in the abundance of predators. Climate change and socio-economic changes that have occurred since “perestroika” have led to an increase in the numbers of Arctic Foxes *Alopex lagopus*, and this might have altered the fine balance between lemmings, voles and their predators. No direct research has been carried out yet, and so there is a clear need for further research activities.

It is quite possible that the threats to the Spoon-billed Sandpiper also affect other species within the same flyway. The continuing decline in the population of Dunlin *Calidris alpina* wintering in Japan (M. Kashiwagi *in litt.*) may be relevant here. However, little information is available for other wader populations migrating along the same flyway through south-east Asia. If the widespread declines are a result of the same threats, many wader populations and other migrating species might benefit from conservation efforts for the globally threatened Spoon-billed Sandpiper.

### Future research

We conclude that there is a need for further field expeditions to the breeding areas to monitor the breeding situation and breeding success. However, there is also a need for expeditions to the suspected wintering areas, to investigate wintering numbers, feeding habits and potential threats.

Much more effort needs to be given to internationally co-ordinated research and conservation activities if the species is to be safeguarded from extinction. High priority should therefore be given to the development of a co-ordinated action plan for the species.

### ACKNOWLEDGEMENTS

We are grateful to Steve Brookes and Ian Begley from Iso-Analytical Ltd., Richard Bevan from the University of Newcastle, Phil Atkinson from the British Trust for Ornithology and others for their help and support, and Steve Brookes for comments on the first draft. We would also like to thank Ivan Taldenkov and Vladimir Morozov for providing us with additional feather samples and supporting our surveys, as did Axel Bräunlich, Minoru Kashiwagi, Heikki Karhu, Chris Kelly, James McCallum, Mikhaela Pavlicek, Remo Probst, Chris Schenk, Pavel Tomkovich, Manfred Trobitz and Liu Weiting. We would also like to thank our driver Roman, who brought us to so many remote

places, and also many of the other local people who supported our efforts in search of Spoon-billed Sandpipers. The study was supported by the German Ornithological Society (DO-G), the Keidanren Nature Conservation Fund and the Toyota Foundation.

## Declines in breeding waterbirds following a redistribution of Arctic Terns *Sterna paradisaea* in West Greenland

Carsten Egevang<sup>1</sup>, Kaj Kampp<sup>1</sup> & David Boertmann<sup>2</sup>

<sup>1</sup> Greenland Institute of Natural Resources, PO Box 570, DK-3900 Nuuk, Greenland. (email: egevang@natur.gl)

<sup>2</sup> National Environmental Research Institute, Dept. of Arctic Environment, Frederiksborgvej 39, PO Box 358, DK-4000 Roskilde, Denmark.

Egevang, C., Kampp, K. & Boertmann, D. 2006. Declines in breeding waterbirds following a redistribution of Arctic Terns *Sterna paradisaea* in West Greenland. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 154.

The archipelago of Grønne Ejland, consisting of many skerries and four major islands, hosts the largest colony of Arctic Terns *Sterna paradisaea* in Greenland, but the population has undergone some radical changes over the last decades with the decrease in breeding numbers. Arctic Terns inhabited all four major islands twenty years ago but today they are only found on two. The disappearance of the terns from the most easterly island was probably a consequence of Arctic Foxes being present. However, egg harvesting by humans appears to be the main reason why the total tern population has declined. Their disappearance from two islands was followed by a general impoverishment of the islands' birdlife, and the Red Phalarope *Phalaropus fulicarius* disappeared completely after a few years, although numbers remained largely unchanged on the islands still inhabited by terns.

The Red-necked Phalarope *P. lobatus*, on the other hand, still breeds on the islands abandoned by the terns, although some reduction in numbers of pairs has occurred. The response of the Red Phalaropes, and their general co-occurrence with Arctic Terns in West Greenland, suggests that the presence of terns is a necessary condition for Red Phalaropes to breed in this marginal breeding area.

Colonial terns defend their nests and chicks fiercely against avian and mammalian predators, and other birds may benefit from this behaviour by breeding in association with the colonies. Arctic Tern colonies can attract a number of bird species, resulting in both higher species diversity, as well as in higher breeding densities, compared with areas without terns. The Red Phalarope is known to associate with Arctic Tern colonies, but several other species, like ducks and shorebirds, will also occasionally do so. The Red Phalarope is a scarce breeder in West Greenland and all confirmed breeding sites here have been associated with colonies of Arctic Tern.

Six years of data on breeding birds on the four major islands of Grønne Ejland (numbered 1, most westerly, to 4, most easterly, in Tables 1 and 2) from 1980 to 2003 provides estimates of breeding Arctic Tern numbers for 1996, 2002 and 2003 based on line transect analysis, and a rough estimate for 1980 based on extrapolation of breeding densities.

Red Phalaropes were recorded at potential breeding sites; both breeders and migrants feed at the ponds of Grønne Ejland, but breeders were identified by their attachment to a certain area, by their alarm calls, or by direct observation of broods. Breeding Red-necked Phalaropes and other waterbirds were recorded from inspection of the many small ponds of the islands.

Arctic Terns have now abandoned the two easternmost islands (islands 3 & 4, Table 1). For Island 4 this seems to have

**Table 1. Distribution and numbers (breeding pairs) of Arctic Terns *Sterna paradisaea* on the four islands of Grønne Ejland (+ = present, ? = no information).**

Island	1980	1990	1996	2002	2003
1	+	?	900	3300	900
2	+	?	2.800	12.300	19.300
3	+	+	1100	0	0
4	10.000	0	0	0	0
Total	c. 25.000	-	4.800*	15.600	20.200

\* The actual number is probably higher but was difficult to estimate due to heavy egg harvesting

**Table 2. Distribution and numbers (pairs) of Red Phalaropes *Phalaropus fulicarius* on Grønne Ejland (? = unknown status).**

Island	1979	1980	1990	1996	2002	2003
1	?	?	?	0	1	1
2	ca. 10	?	?	12	8	7-8
3	2-3	0	?	1	0	0
4	10-20	10-11	1-2	2	0	0

happened between 1982 and 1989. The neighbouring Island 3 was not abandoned until after 1996.

Numbers and distribution of Red Phalaropes on Grønne Ejland have also changed over the last few decades (Table 2), and the species has disappeared from its former stronghold of Island 4. It has also abandoned Island 3, where it was never very numerous. However, on Island 2 the population has been stable or, at most, experienced a moderate decrease. Even the Red-necked Phalarope appears to have decreased on Island 3 and 4, although the earlier counts of this species are less accurate than for Red Phalaropes.

Mallard *Anas platyrhynchos* and Red-breasted Merganser *Mergus serrator*, bred on all the islands, but Long-tailed Duck *Clangula hyemalis* only bred on one island in the central parts of the tern colony.

Our data show that the disappearance of the Arctic Tern from the easternmost islands (Islands 4 and 3) was followed by a gradual but relatively swift disappearance of the Red Phalarope, and supports the view that the Red Phalarope in West Greenland is strongly dependant on breeding Arctic Terns at their breeding site.

## Long-term study of Bewick's Swans *Cygnus columbianus bewickii* nesting in the Nenetskiy State Nature Reserve, Russia: preliminary results and perspectives

Rees, E.C. & Belousova, A.V. 2006. Long-term study of Bewick's Swans *Cygnus columbianus bewickii* nesting in the Nenetskiy State Nature Reserve, Russia: preliminary results and perspectives. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 155-156.

### INTRODUCTION AND METHODS

A long-term collaborative study of Bewick's Swans *Cygnus columbianus bewickii* breeding on the Russki Zavorot peninsula in the Nenetskiy State Nature Reserve was undertaken by WWT (UK) and ARRINP (Russia) over an eleven year period, from 1991-2000 inclusive and in 2003. Observations were made within a 25 km<sup>2</sup> study area at Khabuicka, on the east coast of the Russki Zavorot peninsula (68°32'N 53°54'N). The main aim was to determine the extent to which environmental factors (weather, habitat on the breeding territories and predator levels), and also factors relating to individual birds (breeding experience and duration of the pair bond), explain annual variation in breeding attempts, breeding success, and thus recruitment to the population as a whole. Individual swans were identified by the variation in their black-and-yellow bill markings, and by reading the codes on their leg-rings and neck-collars. Nesting density, occupancy of territories and the turnover of pairs on each territory were recorded each year. The breeding success of each pair was measured by recording clutch size, the number of cygnets hatched and the survival of those cygnets through the first 10 days of life. The behaviour of nesting pairs, and of parents with young in the first few days after hatching, was also observed.

### RESULTS

Observations showed that Bewick's Swan *Cygnus columbianus bewickii* pairs occupy the same breeding territories over several summers (Shchadilov *et al.* 1998). Of 184 pairs where both male and female were identified between 1991 and 1995, two (1.1%) were pairs where both members remained together in all five years, eight (4.3%) were birds paired for a minimum of four years, 22 (12.0%) were together for at least three years and 39 (21.2%) for two years. The remaining 113 pairs were seen on territories that they had not occupied in a previous season, and were thought to be newly-formed pairs. Pairs generally returned to the same territory used in the previous year, unless ousted by an incoming pair.

The onset of laying dates ranged from May 23 in 1995 (an early spring) to June 6 in 1994 and 1997 (late springs). Weather conditions influence the timing of arrival on the breeding territories, breeding density and clutch size. The major influence of the timing of the spring thaw on the swans' breeding programme, by reducing the number of breeding pairs and clutch size in late years, agrees with observations of Bewick's Swans on Vaygach Island, which additionally found that cold weather during incubation following an early spring had a detri-

mental effect on hatching success (Syroechkovskiy *et al.* 2002). Preliminary analyses of the Khabuicka data suggest that the effect of previous breeding experience upon brood size at the end of July (by which time the cygnets are about 3-4 weeks old) is more important in some years than in others. This supports observations made in the wintering range, which also found that the number of years that a pair had been together had a greater influence on breeding success (i.e. the number of cygnets associating in winter) in some years than in others (Rees *et al.* 1996).

### CONSEQUENCES AND FUTURE PERSPECTIVES

The long-term Bewick's Swan research programme, together with other ecological studies undertaken in the region in recent years (e.g. van Eerden 2000) have had the positive effect of raising the awareness of local people to the importance of the wildlife in their area. Most of the Russki Zavorot peninsula and the adjacent Korovinkaiya Gulf was designated as a State Nature Reserve (the Nenetskiy zapovednik) by the Russian Government in December 1997 (Kotkin 2000). Scientific staff of the zapovednik are now monitoring biodiversity at the site, and also promote local interest in waterbird conservation through the media and by facilitating education programmes.

Future collaborative programmes planned within Russia include:

- continuing the monitoring programme within the *zapovednik*, with the benefit of modern technology (e.g. GIS) and analyses;
- involving local amateurs in waterbird monitoring, especially during migration;
- raising the awareness of administrators of joint ventures and local enterprises (mainly gas-oil exploitation), to ensure that waterbird conservation and impact assessment is a priority in their business development strategies; and
- the establishment of a network for monitoring waterbird migration (especially Bewick's Swans) along the European flyway.

Further monitoring data will make it possible to develop an inventory of key sites and habitats used by the swans within Russia, and provide guidelines for establishing a network of protected sites. It will also provide a sound scientific foundation for the development of the Russian Bewick's Swan Action Plan, and make a major contribution to a Flyway Management Plan for the species.

## 3.2 Waterbirds in the Neotropics. Workshop Introduction

Melanie Steinkamp<sup>1</sup> & Roberto Schlatter<sup>2</sup>

<sup>1</sup>Atlantic Coast Joint Venture, 11510 American Holly Drive, Room 206C, Laurel, Maryland 20708, USA.

<sup>2</sup>Instituto de Zoología, Universidad Austral de Chile, Casilla 567, Valdivia, Chile. (email: rschlatt@uach.cl)

Steinkamp, M. & Schlatter, R. 2006. Waterbirds in the Neotropics. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 157.

In some regions of the world there is a long history of survey and monitoring of waterbirds, leading to a well-developed understanding of distribution of waterbirds, their status and trends, and the locations of important sites. Throughout the Neotropics however, knowledge of waterbirds, their habitats and ecology, is much more limited, as a consequence of much less data and information.

Many of the papers presented in this workshop describe essential surveys that describe the distribution and numbers of waterbirds so that appropriate conservation measures can be developed. These include surveys in Costa Rica (Quesada), Panama (Sánchez *et al.*), Colombia (Naranjo *et al.*), Brazil (Kober), and Chile (Aparicio).

Generally, a major issue in the Neotropics is a major lack of funding for basic surveys and population monitoring. However, opportunities for funding surveys and conservation can vary between taxa. Whilst significant attention has been focussed on the needs of long-distance, intercontinental migrants, there has been much less research and conservation activity on waterbirds that migrate solely *within* South America. Many of these intra-continental migrant species, and non-migratory waterbirds have poor conservation status and largely unknown populations trends. This is especially the case for Neotropical migrant and resident waterbirds (especially waders) since international sources of funding are not readily available for monitoring, research and conservation.

The progressive development of the Western Hemisphere Shorebird Reserve Network has been an important initiative to raise awareness of the importance of key sites. The role of such areas, their identification and conservation is described from Mexico by Vega *et al.*, for Colombia by Naranjo *et al.*, with the recent development of a more strategic national approach for waterbird conservation in Argentina outlined by Goldfeder & Blanco. The recently established Hemispheric Steering Group for migratory waterbirds, established following the Western Hemisphere Migratory Bird Conference in Chile in 2004, has considerable potential to drive forward conservation activities.

The Symposium presented an overview of existing actions for waterbird flyways in central and South America, and discussed progress to date. A general point which was stressed was an urgent need to update IUCN Red-listings for South America to better reflect the current situation.

Vega, X., González, M.A. & Muñoz del Viejo, A. 2006. Potential new Ramsar sites in northwest Mexico: strategic importance for migratory waterbirds and threats to conservation. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 158-160.

Northwest Mexico supports a critical series of coastal wetlands that sustain vast numbers of resident and migratory waterbirds using the Pacific Flyway in their annual migrations. These key habitats therefore qualify for possible designation as Ramsar sites. However, there is a need to further investigate and document these areas in order to protect them. This note presents the locations of potential new Ramsar sites in Northwest Mexico, the species and numbers of birds and the potential threats for their conservation.

Mexico has a coastal shoreline of more than 11 122 km which includes numerous habitats critical for various types of flora and fauna (Riviera-Arriaga & Villalobos, 2001). Northwest Mexico is formed by four States: Baja California Sur, Baja California, Sonora and Sinaloa. It has a shoreline of approximately 5 140 km representing more than 46% of the total coastline of Mexico. Its existence and location along the Pacific Flyway make this region one of the most important and critical areas in the Americas for migratory and neotropical birds (Engilis *et al.* 1998). The coast supports a rich diversity of habitats and high numbers of waterbirds that use the area as a stop over, resting or wintering site during migrations. Additionally, there are non-literal shorelines of lagoons and wetlands that are important parts of these biological corridors but are currently under represented because of a lack of systematic studies and evaluation or documentation to warrant their Ramsar nomination (Pérez-Arteaga & Gaston 2004).

According to CONABIO (1997) there are 32 priority wetlands in Mexico, eleven located in Northwest Mexico (Engilis *et al.* 1998). However, Pérez-Arteaga *et al.* (2002) indicated that there are 34 wetlands in Mexico that qualify under Ramsar site-selection Criteria 5 and 6. These wetlands are: Ensenada de Pabellones; Bahía de Santa María; Bahía de Topolobampo; Bahía de Agiabampo; Bahía Santa Barbara; Isla Tobarí; Estero de Lobos; Laguna San Quintín; Laguna Ojo de Liebre and Bahía de San Ignacio. Recently the Mexican Government designated 34 new Ramsar sites, three of which are in the Pacific Northwest Region. There are additional wetlands that may qualify as Ramsar sites, but either there is not yet sufficient scientific information or the Federal Government is not aware of their potential importance (Table 1 over).

The Northwest Pacific Coast represents key habitats for several resident and migratory waterbirds, but economic development with pressure to develop new urban centers is a serious threat. Some of the pressures leading to a loss in bio-productivity follow.

### Aquaculture industry (shrimp farms)

The national production of farmed shrimp reached 16 000 tons in 2000. Of that production, 95% was from the states of Sinaloa and Sonora (Investigación y Desarrollo 1999). The approximate

total surface area for shrimp farming was 35 000 ha. Unfortunately most shrimp farms are under-regulated environmentally and several have been constructed in fragile ecological ecosystems such as mangroves, intertidal areas, and marsh areas. Effluent contaminated with organic matter and chemical runoff has been pouring directly into adjacent bays as well as altering the natural drainage.

### Agriculture and livestock

Several areas near to the coast have been opened up for agricultural or cattle ranching, developments utilizing large applications of agrochemicals with runoff draining directly into adjacent bays. Livestock have been known to cause nesting failure in waterbird colonies (Muñoz & Vega 2002).

### Tourism

Recreational and vocational activities along coasts are major factors of nesting failure and disturbance among waterbirds. Boats, ATVs and pets use these areas without any regulation. A mega-project is proposed by an agency of the Federal Government (Escalera Náutica) for the Northwest region, and several yacht marinas are planned in some of the most important waterbird areas.

### Fishing

The constant influx of new inhabitants into the coastal areas and the development of more “cooperativas” (associations of fishermen) have been the principal cause of overexploitation of the bays and coastal areas.

### OTHER ISSUES

In Northwest Mexico, resident and migratory birds are also affected by egg consumption by local people, killing of chicks for bait for crab fishing, building developments and feral animals around breeding colonies and colony disturbance by tourists and fishermen.

### CONCLUSIONS

Although the Federal Government recently designated 34 new Ramsar sites in Mexico, there are other potential sites important for resident and migratory waterbird species. There is a need to establish permanent and systematic monitoring programs in these areas to include wintering and reproductive studies and conservation programs.

Unfortunately, there is a lack of technical and economic resources to undertake such activities. Mexico has partial financial support from the North American Wetland Conservation Act

(NAWCA) by the Government of the United States of America for non-governmental organizations and institutions to work on wetland conservation projects. However, the funds are inadequate to support much needed additional scientific research.

The potential Ramsar sites included in this presentation represent the efforts of ornithologists monitoring a diverse array of conservation activities in the Pacific Northwest but whose information has unfortunately not been published or used by the Mexican Government for conservation purposes. There is need to plan, conserve and manage the coastal areas that can help to protect important and crucial waterbird areas; otherwise, the coastal wetlands and waterbirds are going to be further imperiled.

## The importance of Costa Rica for resident and migratory waterbirds

Ghisselle M. Alvarado Quesada

National Museum of Costa Rica, Natural History Department, PO Box 749-1000, San José, Costa Rica. (email: museohn@racsa.co.cr)

Alvarado Quesada, G.M. 2006. The importance of Costa Rica for resident and migratory waterbirds. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 161-165.

This paper presents a compilation of the available information on Costa Rica's waterbirds: their diversity, distribution, important breeding and wintering areas, nationally and regionally threatened species, and threats to wetland habitats. Costa Rica's waterbird fauna is composed of 167 species in 26 families, and represents 19 percent of the country's total avifauna. Fifty-nine percent of waterbird species are purely migratory, 34% are resident, and 7% have both resident and migratory populations. Costa Rica has over 350 wetlands. The most significant of these for waterbirds (as stopover sites, breeding areas and wintering areas) are Tortuguero, Palo Verde, Cocos Island and Caño Negro, all of which are Ramsar sites. In general, waterbirds use wetlands in the lowlands of the Pacific and Atlantic coasts, and on the north slope, although some waterbirds use small wetlands in the interior of the country, such as the small lakes in the Central Valley. Several islands along the Pacific coast host breeding colonies of colonial waterbirds. Six species of waterbirds are at risk of extinction in Costa Rica, and 12 are considered to be of "High Concern" in the North American Waterbird Conservation Plan.

### INTRODUCTION

Costa Rica is located in the heart of Central America and hosts an abundance of waterbirds, both resident species and migrants that use the many wetlands as stopover points and wintering areas. Most waterbirds occur in the lowlands of the Pacific, Atlantic and North slopes, although some species, including the Snowy Egret *Egretta thula* and Fasciated Tiger-Heron *Tigrisoma fasciatum*, can be found at elevations of up to 2 000 m above sea level (Stiles & Skutch 1989).

Costa Rican waterbirds include seabirds, shorebirds and other freshwater species. Most of the seabirds breed far away from Costa Rica, in places such as New Zealand, Antarctica and Siberia. The migratory waterfowl (Anatidae) and other freshwater species breed in North America, while migratory shorebirds breed mainly in Siberia, Alaska, and north and central Canada (Stiles & Skutch 1989).

Costa Rica has over 350 wetlands, situated both in the lowlands and the highlands; ten of these have been designated as Ramsar sites (Wetlands of International Importance). The Ramsar sites of Palo Verde National Park, Caño Negro, Tortuguero and Cocos Island are the most important for waterbirds. Thousands of cormorants, boobies, herons and egrets, storks, ducks, shorebirds, gulls and terns use these sites for wintering or reproduction.

This paper is a compilation of available information on the waterbirds of Costa Rica: their diversity, distribution, and important breeding and wintering areas; their conservation status at national and regional level; and the threats to their wetland habitats.

### METHODS

The results presented here are based on a review of published literature, as well as bird lists produced by regional experts and

unpublished field data held at the National Museum of Costa Rica. For well-studied areas such as the National Parks, comprehensive bird lists are available (e.g. Stiles & Lewis 1980). However, for some areas, information sources had to be combined in order to include all or at least most of the waterbirds occurring there. Maps were created with Arc View 8.2.

### RESULTS AND DISCUSSION

#### Waterbird biodiversity

Costa Rica's waterbird fauna is composed of 169 species, representing 19% of the country's total avifauna. These species belong to 26 families, with most species belonging to the Scolopacidae (29), Laridae (27), Ardeidae (18), Anatidae (15) and Rallidae (15). Of all waterbird species, 59% are migratory (passage migrants, winter residents and year-round migrants, with no breeding populations), 34% are resident throughout the year, and 7% have both resident and migratory populations (Table 1).

Osa	82	27 (33%)	45 (55%)	10 (12%)

### Waterbird distribution

Most waterbirds occur in wetlands in the lowlands of the Pacific and Atlantic coasts, and on the north slope. The Pacific coast is more topographically irregular than that of the Atlantic and is characterized by many different habitats, such as beaches, mangrove forests and swamps, which provide excellent foraging areas for waterbirds (Stiles & Skutch 1989). Some herons, ducks, rails, sandpipers and gulls also occur at elevations below 1 800–2 000 m in the Central Valley.

Costa Rica is divided into ten Conservation Areas (including Cocos Island). Fig. 1 shows the numbers of wetlands and waterbird species in Costa Rica by Conservation Area. The Pacifico Central Conservation Area has the greatest species richness, followed by Osa Conservation Area. A higher proportion of waterbirds in the Pacifico Central Conservation Area is migratory than in other parts of the country, with the exception of Cocos Island and Osa (Table 2).

### Ramsar sites important for waterbirds

Costa Rica has 10 Ramsar sites (Wetlands of International Importance). Four of these are extremely important wintering, stopover and breeding areas for waterbirds: Palo Verde National Park, Caño Negro National Park, Tortuguero National Park and Cocos Island (Fig. 2, Table 3). Cocos Island is especially important for seabirds, such as species of Procellariidae and Hydrobatidae, and most of the waterbird fauna here is migratory. These four Ramsar sites are important for waterbirds due to their wetland characteristics (providing opportunities for feeding, breeding and wintering) and because they are located near or along migratory flyways.

### Important breeding sites

Our knowledge of the breeding colonies of waterbirds in Costa Rica is still incomplete. However, some important breeding sites have been identified for species such as the Brown Pelican *Pelecanus occidentalis*, Brown Booby *Sula leucogaster*, Anhinga *Anhinga anhinga*, Magnificent Frigatebird *Fregata magnificens*, Great Egret *Egretta alba*, Cattle Egret *Bubulcus ibis*, Black-crowned Night-Heron *Nycticorax nycticorax*, Boat-billed Heron *Cochlearius cochlearia*, Wood Stork *Mycteria americana*, American White Ibis *Eudocimus albus*, and Bridled Tern *Sterna anaethetus* (Fig. 3). For example, Isla de

Pájaros, located in the lower basin of the Tempisque River, is the most important island for breeding waterbirds in Central America. It is just 2.4 ha in area, and is used as a breeding site by at least eight species of waterbirds: Neotropic (Olivaceous) Cormorant *Phalacrocorax brasilianus*, Anhinga, Great Egret, Cattle Egret, Black-crowned Night-Heron, Boat-billed Heron, Wood Stork, and Roseate Spoonbill *Platalea ajaja*. Cocos Island is used by several breeding seabirds such as Red-footed Booby *Sula sula*, Great Frigatebird *Fregata minor*, Brown

R = resident; M = migratory; R-M = resident and migratory.

Noddy *Anous stolidus*, Black Noddy *A. minutus* and White Tern *Gygis alba*.

#### Important stopover sites and wintering areas

Many thousands of waterbirds pass through Costa Rica during their southward or northward migrations, using river mouths, beaches, swamps, salt ponds and lakes as stopover sites. Most of these move along the Atlantic coast during the southward migration, and along the Pacific coast during the northward migration, with a large number wintering at wetlands in Costa Rica. Many immature herons and egrets, shorebirds, gulls and terns remain year round in Costa Rica until they reach sexual maturity (Stiles 1983), and this is very important in terms of the conservation of these species. Fig. 4 shows some important stopover sites and wintering areas along the Atlantic and Pacific coasts of Costa Rica.

#### Threatened species and threats to wetlands

Of the 16 bird species threatened with extinction in Costa Rica, six are waterbirds: Jabiru *Jabiru mycteria*, Roseate Spoonbill,

Red-billed Tropicbird *Phaethon aethereus*. Photo: Albert Chipps.

Sunbittern *Erypyga helias*, Sungrebe *Heliornis fulica*, Fulvous Whistling-Duck *Dendrocygna bicolor* and White-faced Whistling-Duck *D. viduata* (Reglamento a Ley de Conservación de la Vida Silvestre 1997). All of these are resident species. The Costa Rican population of the Jabiru is under 90 individuals, while that of the Roseate Spoonbill is estimated at 300 pairs.

The North American Waterbird Conservation Plan (Kushlan *et al.* 2002) provides a status assessment for 166 colonial waterbirds occurring in the Plan area (from the Arctic to Panama, including the Caribbean Islands and islands of the Pacific). Of the species ranked as “High Concern” (populations are known or thought to be declining, and have some other known or potential threat), 12 occur in Costa Rica: Red-billed Tropicbird *Phaethon aethereus*, Brown Booby, Magnificent Frigatebird, Tricolored Heron *Egretta tricolor*, Little Blue Heron *Egretta caerulea*, Snowy Egret, Bare-throated Tiger-Heron *Tigrisoma mexicanum*, Wood Stork, Jabiru, Gull-billed Tern *Sterna nilotica*, Bridled Tern and Black Skimmer *Rynchops niger*.

Several wetlands in Costa Rica are threatened, the primary threats being human disturbance, industrial and agricultural contamination, sedimentation, drainage and habitat destruction.

## CONCLUSION

Costa Rica is very important for waterbirds, both resident and migratory species. Additional study and careful management of the country’s Ramsar sites, conservation areas, migratory flyways, and threatened species are necessary for the health of waterbirds in Costa Rica and throughout the Americas. This compilation is intended to provide a foundation for these actions, which are best carried out within the context of an international initiative, such as Waterbird Conservation for the Americas ([www.waterbirdconservation.org](http://www.waterbirdconservation.org)).

## ACKNOWLEDGEMENTS

I wish to thank Jennifer Wheeler who assisted with the English translation and provided helpful comments on this manuscript, Joaquín Sánchez who made the maps, the National Museum of Costa Rica and in particular Cecilia Pineda for giving me the time to do this work, the Waterbird Council for their letter of support, and the Joint Nature Conservation Committee and organizers of the Waterbirds around the world Conference for financial support to participate in the Conference.

### ABSTRACT

The Republic of Panama occupies an important geographical position connecting North and South America; it hosts an extremely high number of migratory shorebirds in a very restricted area. Within Panama, the Upper Bay of Panama supports enormous numbers of shorebirds during migration. The area qualifies as a globally Important Bird Area; it has been declared a Wetland of International Importance under the Ramsar Convention, and qualifies as a Hemispheric Reserve under the Western Hemisphere Shorebird Reserve Network (WHSRN). This study, conducted by the Panama Audubon Society with support from the Canadian Wildlife Service, collected data on shorebird abundance in the Upper Bay of Panama through aerial and ground surveys during the autumn migration in 2003. The conclusions of the study were as follows: (1) for meaningful comparisons between surveys taken in different years, extended surveys covering the entire migration period are needed; (2) tidal flats within a 30 km stretch to the east of Panama City are extremely important for small shorebirds; (3) studies of productivity, nutrient input and other factors in the inter-tidal zone need to be undertaken to determine why the mudflats between Panama City and the Pacora River are so attractive to shorebirds.

### INTRODUCTION

Shorebirds are among the most migratory of all birds, and spend most of their annual cycle on wintering grounds and migratory staging areas. The viability of their populations thus depends not only on the availability of suitable breeding grounds, but also on the availability and health of highly productive non-breeding areas (Watts 1998). Recent studies indicate that many species concentrate in a small number of essential sites both during migration and in wintering areas. Many shorebird species depend on a network of migration stop-over sites and habitats during their non-breeding season to complete their annual cycles. For conservation to be successful, entire networks, crossing political borders, need to be preserved. Shorebird conservation thus represents an international challenge (Myers 1983, Myers *et al.* 1987, Morrison & Myers 1989), the importance of which is emphasized by recent declines in North American shorebird populations (Morrison *et al.* 2001).

The Republic of Panama occupies an important geographical position connecting North and South America. Due to its position, it hosts an extremely high number of migratory birds in a very restricted area. Aerial surveys by the Canadian Wildlife Service have documented the importance of Panama as a wintering and staging area for shorebirds (Morrison *et al.* 1998). In January 1993, Panama supported a population of 255 000 Nearctic shorebirds; 80% of these birds were within the Upper Bay of Panama. These numbers, concentrated in a very small area, highlight the

crucial importance of Panama for shorebirds. During southward migration in October 1991, counts were even higher, and Morrison *et al.* (1998) counted over 369 000 shorebirds in the Upper Bay alone. Aerial and ground surveys conducted by Watts (1998) during the autumn migration in 1997 found 370 000 shorebirds in a single day. These numbers exceed 100 000 birds annually, and thus qualify the area as a site of international significance under the Western Hemisphere Shorebird Reserve Network (Morrison *et al.* 1995). Based on turnover, Watts estimated that nearly 1.1 million Western Sandpipers *Calidris mauri* alone passed through the area. These estimates of turnover during autumn migration far exceed the WHSRN criterion of 500 000 birds annually, and qualify the Upper Bay of Panama as a site with the highest status under WHSRN (Morrison *et al.* 1995).

Since 1998, as part of the Important Bird Area (IBA) program, the Panama Audubon Society (PAS) has worked to protect this area. Based on a proposal and other information provided by the PAS, ANAM, Panama's National Authority for the Environment, decided to designate part of the area as a Wetland of International Importance under the Ramsar Convention. The site was officially declared a Ramsar site (no. 1 319) on 20 October 2003. It would be beneficial to have this site recognized as a WHSRN Hemispheric Reserve – status that would afford the area further international recognition as a hemispherically important link in a network of important shorebird areas.

The purpose of this study was to conduct additional aerial surveys of the Upper Bay of Panama during the autumn migration of 2003, to build upon the data on abundance, distribution and phenology previously collected by Morrison *et al.* (1998) and Watts (1998), and to conduct extensive ground surveys at five sites (two of which were not previously surveyed).

### STUDY AREA

This study was conducted along the northern shore of the Upper Bay of Panama from Panama Viejo at the eastern edge of Panama City to the Maestra River Estuary, a total distance of 80 km. The study area encompasses the new Ramsar site, which protects all remaining mangroves between Tapia River and the Maestra River Estuary. The area was surveyed by dividing the shoreline into eight 10 km sectors (Fig. 1) which correspond approximately to the sectors used by Watts (1998) and sectors 61 and 62 as designated by Morrison *et al.* (1998). The area consists of mangroves and spectacular inter-tidal mudflats, primarily composed of fine silt and organic compounds, bordering a narrow coastal plain.

Based on criteria established by BirdLife International, the Upper Bay of Panama was determined to be an IBA of global importance (Angehr 2003) and includes 17 000 ha of mangroves and 22 000 ha of mudflats. The mudflats, exposed to seven metre tides, extend out several kilometres from the shore at low

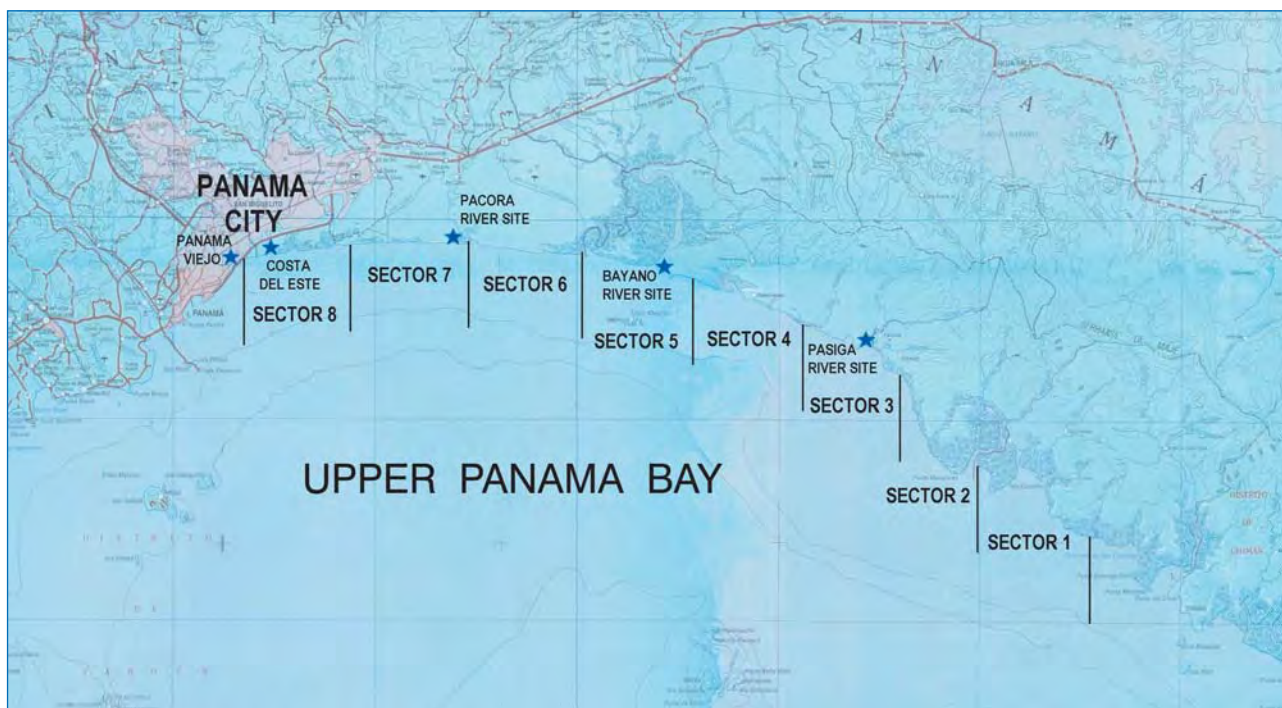

Fig. 1. The eight 10 km survey sectors in the Upper Bay of Panama.

Fig. 2. Spatial distribution of all shorebirds along aerial transects in the Upper Bay of Panama. Sectors are numbered from east to west

tide. The mangroves lie east of the mudflats most heavily used by shorebirds. The prevailing long-shore current flows from east to west, suggesting that mangroves may provide much of the nutrients found in these mudflats (Watts 1998). The western end of the Upper Bay of Panama IBA, a 30 km stretch between the eastern edge of Panama City and the mouth of the Bayano River, harbours the highest density of birds.

## METHODS

The groups of species included in ground and aerial counts were: ducks (Anatidae); raptors, including Ospreys (Pandionidae), hawks (Accipitridae), and falcons and caracaras (Falconidae); long-legged wading birds, including herons and egrets (Ardeidae), ibises and spoonbills (Threskiornithidae), and storks (Ciconiidae); coastal seabirds, including pelicans (Pelecanidae), cormorants (Phalacrocoracidae), frigatebirds (Fregatidae), gulls (Laridae), terns (Sternidae), and skimmers (Rhynchopidae); shorebirds, including jacanas (Jacanidae), oystercatchers (Haematopodidae), stilts (Recurvirostridae), plovers and lapwings, (Charadriidae); sandpipers and relatives (Scolopacidae); and kingfishers (Alcedinidae).

## Ground surveys

Ground surveys were conducted at five sites between 8-27 September 2003. Sites were visited on a rotating basis; however, because of difficult access, the Pasiga River site was visited only once and the Bayano River site only twice. At each site, surveys were carried out with binoculars and telescopes when the tide was 70% to 100% full. The same stretch of shoreline was surveyed each time.

The Panama Viejo site (9°00'21"N, 79°29'14"W) is located on the eastern edge of Panama City and was easily accessed on a paved road. The site comprises a broad mudflat with soft black mud, flanked to the east by a tourist centre and to the west by a rocky outcrop. An elevated highway, the Southern Corridor, runs offshore over the outer mudflats, and may have changed tidal circulation patterns since its construction in the late 1990s. The survey was conducted within a 1 km strip of the inter-tidal mudflat and adjacent rocks.

The Costa del Este site (9°00'40"N, 79°27'31"W), at the eastern end of Panama City, is located 3 km east of the Panama Viejo site and was easily accessed on a paved road. It comprises broad mudflats, flanked to the west by the Matías Hernández River and to the east by mangroves. The landward side of the mudflats is flanked by a concrete seawall built to protect a new housing development. This survey included a 3 km stretch of inter-tidal mudflat plus an occasionally flooded 700 m x 300 m area of grassland.

The Pacora River site (9°01'24"N, 79°18'09"W) is 25 km east along the shore from Costa del Este. The area was accessed by four-wheel drive vehicle on a dirt road through privately-owned rice fields to within 500 m of the coast, and then on foot. The site comprises broad mudflats of soft black mud, flanked inland successively by savannah-like grassland with scattered trees and extensive rice fields. The survey included a 2 km stretch of the inter-tidal mudflat, plus some irrigated rice fields surveyed from the road.

The Bayano River site (8°59'54"N, 79°06'18"W), at the

**Table 1.** Summary of information on aerial surveys in Panama in 2003.

Date	Aircraft	Survey time	Estimated time of high tide	Estimated height of tide (in feet)	Weather
7 Sept.	Cessna 152	11:58-13:03	13:14	14.7	Light haze, light wind, 30°C
18 Sept.	Cessna 152	07:16-07:50	08:17	13.3	Overcast, light wind, 22°C
26 Sept.	Cessna 152	15:00-15:33	16:39	17.4	Clear, light wind, 32°C

mouth of the Bayano River, is located 25 km east of the Pacora River site, is accessed by boat from the Bayano River, and comprises a sandy beach. A 2 km stretch of the beach was surveyed on foot, and a 15 km stretch of mangrove forest was surveyed by boat en route to the site.

The Pasiga River site (8°55'16"N, 78°55'14"W) is located 25 km east of the Bayano River site and can only be accessed via the Bayano River and a four hour boat trip by sea. The site comprises a 1 km undisturbed inter-tidal gravel, sand and silt flat at the mouth of Pasiga River.

All five sites are subject to up-welling during the dry season, when westerly winds blow warm surface water offshore and draw cooler, nutrient-rich bottom water to the surface near the coast. Up-welling increases invertebrate activity and reproduction, and makes inter-tidal areas particularly rich in invertebrates which are used as food by shorebirds (Morrison *et al.* 1998).

Counts derived from ground surveys were used to ground-truth the counts obtained during aerial surveys. Since some species were difficult to distinguish from the air, they were counted according to size class (small, medium and large) during the aerial surveys. The number of each species was then estimated by extrapolating from its proportion in flocks based on ground surveys, since the latter provided a more accurate determination of the species composition of large flocks. However, even on ground surveys, some very similar species, such as Semipalmated Sandpiper *Calidris pusilla* and Western Sandpiper, were difficult to distinguish, so they were treated as a single category "peeps". Small shorebirds included peeps (Western and Semipalmated Sandpipers), Least Sandpiper *Calidris minutilla*, Semipalmated Plover *Charadrius semipalmatus* and Wilson's Plover *C. wilsonia*; medium shorebirds included Short-billed Dowitcher *Limnodromus griseus* (the Long-billed Dowitcher *L. scolopaceus* is rare in Panama and has not been recorded in inter-tidal habitats), Red Knot *Calidris canutus*, Black-bellied Plover *Pluvialis squatarola* and Ruddy Turnstone *Arenaria interpres*; large shorebirds included Whimbrel *Numenius phaeopus*, Marbled Godwit *Limosa fedoa* and the two yellowlegs, Greater Yellowlegs *Tringa melanoleuca* and Lesser Yellowlegs *T. flavipes*. Based on habitat similarities, the proportions observed on ground surveys from Pasiga River were used to extrapolate counts for sectors 1-3, the proportions from Bayano River for Sectors 4-6, the proportions from Pacora River for Sector 7, and the proportions from Costa del Este for Sector 8.

### Aerial surveys

Low-altitude aerial surveys were conducted to determine the abundance of shorebirds during September 2003 (Table 1). Flight dates were selected to try to represent bird numbers at the beginning, middle and end of the survey period. Although it would have been ideal to separate surveys by an equal number

of days, weather conditions and the timing of tides prevented this. Flight times were chosen so that surveys took place when the tide was 70% to 90% full, a time when shorebirds are highly concentrated in a narrow band along the shoreline and are easily surveyed (Watts 1998).

All surveys began at the mouth of Matías Hernández River, at the western edge of the Costa del Este housing development, and ended at the Maestra River Estuary. Methods described in Morrison *et al.* (1998) were followed as closely as possible, using a Cessna 152 (HP1241AS) high-winged aircraft, flying at about 20-30 m above ground level and at a speed of approximately 180 km/hr, depending on bird numbers, habitat, and the directness of the flight path. The flight path was about 25 m offshore from the water's edge, with one observer (DMB) looking inland from the seat behind the pilot, and one observer (AIC) looking forward and seaward from the co-pilots seat. For each sector, DMB also recorded qualitative habitat descriptions which were later used to judge habitat changes since the surveys of Morrison *et al.* (1998) and Watts (1998). All observations were recorded directly into a tape recorder for transcription after the flight.

## RESULTS

### Habitats

Major changes in habitat since the surveys of Morrison *et al.* (1998) in 1988, 1991 and 1993 and of Watts (1998) in 1997 have occurred primarily in Sectors 7 and 8 (see Table 2 over). The most obvious change has been the replacement of the Costa del Este marshlands with a housing complex. Additional changes include the loss of most of the sandy beach in Sector 7 due to sand extraction for use in construction, and the construction of the Southern Corridor highway, which now runs across the seaward side of the Panama Viejo mudflat. In addition, the area inland from the Juan Díaz and Tocumen mangroves has become increasingly urbanized, resulting in increasing pressure on these coastal ecosystems, even though development has not yet reached the coast itself. In the Bayano Estuary, a fisherman reported recent cutting in the mangroves for the expansion of a cattle farm, and this was confirmed on the next aerial survey. Since all mangroves are protected in Panama, this cutting is illegal, although the regulations are difficult to enforce in remote areas.

### Abundance

The 12 ground surveys at five sites resulted in a cumulative total of 307 803 bird observations. Within this cumulative total, shorebirds accounted for 97.0% of all birds, with small shorebirds by far the most numerous (93.6% of total shorebirds). Medium shorebirds accounted for 3.8% of all shorebirds and large shorebirds for 2.6%. Within small shorebirds, peeps, at 90.8%, were by far the most abundant. Watts (1998) calculated

**Table 2.** Major habitats occurring in survey sectors in the Upper Bay of Panama. Breaks in habitat are indicated with diagonal strokes with the first section describing the inter-tidal habitat, the second section describing habitat immediately behind the inter-tidal zone heading inland, and, if necessary, a third section describing habitats further inland. Sectors are numbered from east to west.

Sector	Habitat Description
8	Broad mudflat with soft black mud / concrete seawall and housing project on western edge and mangroves to the east / housing projects, industrial buildings and Tocumen Airport.
7	Broad mudflat with soft black mud / savannah scrub forest and grassland with scattered small houses / agricultural land (mainly rice fields) Note: Almost all sandy beaches have been removed by sand trucks. Only a small sandbar at the mouth of Río Pacora remains undisturbed.
6	Broad mudflats with firmer mud, sand beach / cattle pasture with scattered trees.
5	Sand and mudflats with some sand beach at the west end of the sector, mangroves up to the water at the mouth of Río Bayano, sand beach at the east end of the sector / some cattle pasture with savannah scrub forest and grassland at the east end of the sector.
4	Sand beach, flooded mangroves / mostly mangroves, some cattle pasture with savannah scrub forest and grassland at the west end of the sector.
3	Sand beach, flooded mangroves / mostly mangroves, some cattle pasture with savannah scrub forest and grassland at the west end of the sector.
2	Muddy flats, sand beach, flooded mangroves / mangroves and some low forest.
1	Muddy flats, sand beach, flooded mangroves / mangroves and some low forest.

through mist-netting that Western Sandpipers accounted for 86.9% of peeps. When applied to this study, this proportion would indicate that Western Sandpipers make up 78.9% of small shorebirds and 73.8% of all shorebirds counted.

Non-shorebird species were dominated by gulls and terns, which accounted for 43.7% of the total. Also very abundant were Neotropic Cormorants *Phalacrocorax brasilianus* (23.3%), Brown Pelicans *Pelecanus occidentalis* (17.4%), and long-legged wading birds (11.2%). Magnificent Frigatebirds *Fregata magnificens*, ducks and raptors were rarer at 2.1%, 1.9% and 0.4% of the total respectively.

The three aerial surveys resulted in a cumulative total of 645 791 bird observations, and shorebirds accounted for 97.7% of this total. Shorebird observations were dominated by small shorebirds, which accounted for 91.2% of the shorebird total, while large shorebirds made up 6.1% and medium shorebirds 2.7% of the total. Non-shorebird species were dominated by Neotropic Cormorants (37.3%), Brown Pelicans (29.5%), and gulls and terns (22.4%). Less abundant were long-legged wading birds (8.4%), Magnificent Frigatebirds (1.8%), Black-bellied Whistling-Ducks *Dendrocygna autumnalis* (0.4%) and raptors (0.2%).

### Distribution

Shorebird concentrations were by far the greatest at Costa del Este and Río Pacora, which together had 98% of the shorebird total (45.6% and 52.4%, respectively). All shorebird size classes were concentrated in these two sites, although the concentration of small shorebirds was most pronounced. For small shorebirds, 99% were found in these two sites, whereas medium and large shorebirds were slightly more dispersed, with 85.3% of the medium shorebirds and 84.5% of the large shorebirds being found at Costa del Este and Pacora River. Buff-breasted Sandpipers *Tryngites subruficollis*, Pectoral Sandpipers *Calidris*

*melanotos*, Upland Sandpipers *Bartramia longicauda* and Southern Lapwings *Vanellus chilensis* were only seen in the flooded grassland of Costa del Este.

Non-shorebird species were also concentrated in Costa del Este and Río Pacora, but to a lesser degree, with 40% of the total in Costa del Este, 30% in Río Pacora, 20% in Panama Viejo and 5% in both Río Bayano and Río Pasiga. Again, the habitats present in each site were important for species composition. Cinnamon Teals *Anas cyanoptera* and Savannah Hawks *Buteogallus meridionalis* were only seen in the flooded grassland of Costa del Este. Wattled Jacanas *Jacana jacana*, Rufescent Tiger-Herons *Tigrisoma lineatum*, Muscovy Ducks *Cairina moschata* and Pearl Kites *Gampsonyx swainsonii* were seen only in the rice fields of Río Pacora. Both the flooded grassland of Costa del Este and the rice fields of Río Pacora were important for Wood Storks *Mycteria americana* and White-tailed Kites *Elanus leucurus*. Finally, Black-bellied Whistling-Ducks were seen in large numbers in the flooded pastures along the Bayano River, and in smaller numbers in the Costa del Este flooded grassland.

### Phenology

Collectively, shorebird numbers increased with each successive flight, and also during the course of the ground surveys at Costa del Este and Río Pacora (the two centres of concentration). This was also true for small, medium, and large shorebirds considered separately. For all sizes, peak counts were on the latest survey date. This is similar to the results of Watts (1998), who found that in 1997 counts of medium and large shorebirds peaked in late September and the numbers of small shorebirds were still increasing at the beginning of November. All previous counts in the area indicate that numbers of small shorebirds peak in early to mid-November in Panama. The counts of non-shorebird species remained fairly stable across flights and ground surveys.

## DISCUSSION

### Habitats

The six years between the autumn migration of 1997, when Watts (1998) conducted his surveys, and that of 2003 have seen large changes in shorebird habitat on the eastern edge of Panama City, as urbanization has sprawled eastward, bringing housing complexes, roads and factories. Changes have included the filling-in and paving-over of the Costa del Este marshes for housing, the building of the Southern Corridor highway across the seaward side of the Panama Viejo mudflats, and construction of new factories on the rivers which feed the Upper Bay. The effects of this urbanization are not fully known, and shorebird counts, although very important for monitoring shorebird numbers, are not sufficient to examine fully the effects of urbanization. Further studies on the specific effects of urbanization are needed. For example, chemical studies of sediments are needed to assess whether the paving-over of marshes changes the chemical make-up of the adjacent mudflats, and whether the nutrients that support the food resources used by shorebirds come not only from mangroves and marshes but also from Panama City's untreated sewage. Radio-tracking studies would be helpful in discovering the locations (if they exist) of new high-tide roost sites when (as in Costa del Este) previous sites are paved over. Furthermore, chemical studies on the waste products of factories located on rivers which feed into the Upper Bay are needed to investigate possible reasons for fish kills reported by local people in the area.

### Abundance and phenology

Our aerial counts correspond well with those of Watts (1998). In terms of species composition, our figures are nearly identical, with shorebirds making up well over 90% of total birds, and within shorebirds, small species making up over 90% of the total, large shorebirds around 6%, and medium shorebirds around 2%. Our total counts also matched well. Watts (1998) counted 183 840 shorebirds on 5 September, 216 431 on 20 September, and 254 318 on 27 September, while we counted 141 938 shorebirds on 6 September, 198 730 on 18 September, and 290 536 on 26 September. As a whole, the Upper Bay supported approximately the same number of shorebirds in September 2003 as it did in September 1997. However, the migration of 2003 apparently started somewhat more slowly than in 1997, and there was a large increase in numbers between 18 and 26 September.

Our peak count for small shorebirds was much lower than that of Watts (1998) owing to the fact that we were unable to continue surveys into the peak of Western Sandpiper migration in November. Our peak counts for medium and large shorebirds were also slightly lower than those of Watts (1998), although our survey covered peak dates for all medium and large species except the Willet *Catoptrophorus semipalmatus* (which peaked on 4 October in 1997).

Because Morrison *et al.* (1998) performed aerial surveys at different times in the migration cycle (in late February 1988, late October 1991 and mid-January 1993), we cannot make a direct comparison with their peak counts. However, our peak count of 290 536 on 26 September falls between the January wintering count of Morrison *et al.* (1998) of 209 703 and their autumn migration peak count of 332 838, indicating that our survey covered a period of active migration and included birds that would stay in Panama for the winter, as well as migrants heading further south.

### Distribution

Our data on shorebird distribution also correspond well with those of Watts (1998). Both studies unequivocally indicate the importance of the 30 km stretch of shoreline immediately east of Panama City, especially for small shorebirds. High counts of these birds appear to be linked to the mudflats, composed of soft black mud, that extend from the city's eastern edge to the mouth of the Río Pacora. East of the Río Pacora, the mud becomes firmer and shorebird numbers drop dramatically.

Such high numbers of birds are almost certainly linked to high food productivity due to high nutrient input into these mudflats. The source of this input is not definitely known. Sources may include sediments from rivers, adjacent mangrove forests and dry-season up-welling (Butler *et al.* 1997, Morrison *et al.* 1998). Studies to determine the organic and chemical content of these mudflats and their productivity are necessary to determine exactly why they are attractive to shorebirds.

Ground surveys highlighted fine-scale differences in species distribution between habitats in the Upper Bay of Panama, emphasizing the need to protect a variety of habitats in order to maintain species diversity. The mudflats at all ground sites except for Panama Viejo are protected within the Ramsar site, and although Panama Viejo may not be as important for overall abundance as Costa del Este or Pacora River, it is in some way attractive to medium shorebirds. This is exemplified by the Red Knot. A flock of approximately 100-200 Red Knots was consistently found during surveys at the Panama Viejo site from January to mid-April 2002 (Buehler 2002) and appeared as expected in November 2003. This species was not seen consistently in such numbers at any other ground site.

The Upper Bay of Panama is an extremely important area for shorebirds and other coastal species, and the sheer number of birds that the area supports gives it international importance. The region is diverse and beautiful. To the west, urbanization is encroaching, but to the east, it remains one of few relatively undisturbed habitats in Panama. The bay is important not only biologically, but also socio-economically, providing, among other things, fish and shrimp that are used not only directly by humans as food, but also as feed for the country's chicken industry. Continued monitoring as well as further studies on the effects of urbanization will be needed to understand and protect the Upper Bay of Panama for future generations of shorebirds and humans alike.

## SUMMARY OF CONCLUSIONS AND RECOMMENDATIONS

- 1) For meaningful comparisons between surveys, long-term surveys which cover the entire migration period are preferred. We recommend that aerial surveys cover all of the autumn migration (August to the end of November) and, if possible, the spring migration (January to the end of April) in order to draw solid conclusions about inter-annual variability between counts. The timing of migration, and thus peak numbers, varies from year to year. Future surveys, which cover the entire migration period and ensure that peak numbers for all categories and species are recorded, will provide a better means for monitoring shorebird abundance in the Upper Bay of Panama.
- 2) The tidal flats within the 30 km stretch to the east of Panama City are extremely important for small shorebirds. Areas not

included in the Ramsar site (the mudflats of Costa del Este, the Panama Viejo area and the Juan Díaz mangroves) should be protected. Furthermore, protection in areas such as the mangroves of Bayano must be enforced.

- 3) Studies should be undertaken to determine the factors, especially nutrient flows, which make the mudflats between Panama City and Rfo Pacora so attractive to shorebirds.

#### ACKNOWLEDGEMENTS

This study was funded by a grant from the Canadian Wildlife Service to the Panama Audubon Society. Research would not have been possible without the assistance of many people. Rosabel Miró, current President of PAS, gave the opportunity to work on this project and provided essential logistical and financial assistance. Dr. George Angehr of the Smithsonian Tropical Research Institute provided much needed maps, advice and editing. Carlos Díaz of the Albrook Flight School was a skilled and fearless pilot who kept the project team airborne during low-altitude survey flights. Juan Ramon provided logistical support in obtaining flight permits. Finally the people of Boca de Pacora, Chepo, Puerto Coquira, and Pasiga opened their property and their hearts to the team and provided valuable local information.

Mugica, L., Acosta, M., Denis, D., Jiménez, A., Rodríguez, A. & Ruiz, X. 2006. Rice culture in Cuba as an important wintering site for migrant waterbirds from North America. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 172-176.

### ABSTRACT

Rice is the second most important crop in Cuba. The main plantations are along the south coast, near natural wetlands. Because rice fields are seasonal and temporary wetlands, they may have an important role as substitute habitat for waterbirds. We studied the bird community associated with rice culture in several plantations in Cuba, and found that 70 bird species were using the paddies mainly as feeding areas, and consuming about 46 different food items. Migrant birds (mainly ducks and shorebirds) comprised 74% of the birds reported; 37% were winter migrants and 37% were species with resident and migratory populations. Most waterbirds utilize both paddies and coastal wetlands as wintering sites. Habitat use during the rice cycle was determined for each of the main guilds in the bird community. The daily consumption of the bird community was determined throughout the year and the rice cycle. In winter, because of the influence of the migrant duck population, daily consumption was five times greater than in summer. We concluded that rice-farming areas in Cuba are playing a key role in the conservation of migratory waterbirds in winter. Cooperative efforts are necessary to understand the complex ecological interactions that are taking place in the paddies and to enhance this important waterbird habitat.

### INTRODUCTION

Rice paddies are among the most productive and dependable agricultural systems devised by humans (Odum 1993), and may be important ecological areas acting as alternative habitat for wetland wildlife (Fasola & Ruiz 1997). Alternating periods of flooding and drying during the rice-growing cycle create a structurally complex habitat which retains many features typical of natural ecosystems. Because waterbirds, with their specific habitat requirements, may be most likely to use those newly created habitats which are most similar to their natural habitat (Cody 1981), the unusually high degree of structural complexity of the rice agro-ecosystem should promote high avian diversity, especially in areas with low usage of pesticides.

After sugar cane, rice is the crop occupying the second highest acreage in Cuba, where it is grown in five provinces. Because of the shape of the island, most of the rice-growing areas are near the south coast. In most places, the coastal belt between the rice fields and the sea is natural wetland, and so the coastal wetlands and paddies may act as a conservation unit for waterbirds. Furthermore, there has been a drastic reduction in the use of chemicals by Cuban farmers in recent years because of the economic crisis, with a consequent increase in the availability of food for waterbirds in the rice-growing areas.

The importance of these areas for wintering waterbirds is enhanced by the fact that Cuba is in the middle of two important

bird migration corridors, the Atlantic and the Mississippi flyways. Thus, Cuba is not only an important wintering area for migrants from North America, but also a very important staging area for birds that are migrating further south. The rice-growing areas may play a key role in the conservation of these species (Mikuska *et al.* 1998).

Although the cultivation of rice is an ancient agricultural practice and rice is now considered the second most important crop in the world (Hoffman 1993), relatively little attention has been given to the complex interactions between the bird community and the rice crop. Some recent studies include those by Fasola & Ruiz (1996), Day & Collwell (1998), Elphick & Oring (1998), Elphick (2000) and Tourenq *et al.* (2001).

Using all of the information collected during a decade (1992-2003) of field studies by the Bird Ecology Group of the University of Havana, our main aims in this paper are: firstly, to summarize data on the diversity, abundance and habitat use of migratory waterbirds using rice fields in Cuba; and secondly, to draw attention to the need for an integrated approach to rice farming that will take into consideration its importance in the conservation of migratory waterbirds.

### STUDY AREAS

The rice-growing regions are huge (c. 20 000 ha), flat areas, usually divided into fields of one hectare. Along the south coast, there is usually a 1 to 5 km wide belt of natural coastal wetlands between the paddies and the sea. During the rice cycle, the development of the rice plant changes with the water regime, and eight different field types have been identified on the basis of water level and vegetation cover (Mugica *et al.* 2003). Samples of the birds using each of these eight field types were taken separately. As the sowing period is spread over several months, many different field types are available at any one time.

### METHODS

We compiled published and unpublished information on the importance of rice fields for migrant birds in Cuba. Most data were collected between 1992 and 2000 during a study of the bird community in the Sur del Jíbaro rice fields in Sancti Spiritus, Cuba (21°35'-21°45'N, 79°5'-79°25'W). Additional data were gathered by sampling the coastal wetlands associated with the rice-growing areas and two other rice-growing areas: Los Palacios, Pinar del Río, in western Cuba, and Amarillas Rice Culture, Matanzas, in central Cuba.

In order to estimate densities of waterbirds and habitat use, the counts were conducted during the first four hours after sunrise (the period of maximum bird activity and relatively low air temperatures) by walking along two transects in each field using a stratified sampling method (each of the eight stages of

**Table 1.** Birds observed during transect counts in rice fields in Cuba, showing annual mean density in birds/ha (MD) with  $\pm 95\%$  confidence limits (CL), frequency of occurrence (FO), and months in which the birds were present. Asterisks indicate those species with enough feeding data to be included in the feeding analysis (from Mugica *et al.* 2001).

the rice cycle was counted independently). Separate tallies of the energetic requirements and 95% confidence intervals were estimated using the allometric equations established by Nagy (1987) for birds (see Mugica 2000 for details of the methodology). The daily consumption of the waterbird community was estimated, taking into account the birds' breeding and non-breeding seasons and the estimated densities of birds in the fields in each month and stage of the rice-growing cycle.

## RESULTS

To date, 97 bird species have been reported using the rice fields and surrounding areas, with the heaviest use of the paddies occurring in winter. Of the 97 species reported, 70 were recorded during transect counts, including 26 species that are migrants and 26 species that have both migrant and resident populations in Cuba (Mugica *et al.* 2001). Thus, 74% of the species recorded in the rice fields are totally or partially migratory, with the migratory populations coming from North America (Table 1). We found that all of the systematic orders of waterbirds reported in Cuba are well represented in the rice fields (Podicipediformes – one species, Pelecaniformes – two spp., Ciconiiformes – 14 spp., Anseriformes – 12 spp., Gruiformes – seven spp., and Charadriiformes – 26 spp.).

The density of waterbirds in the rice fields increased dramatically in winter (Fig. 1) because of the arrival of huge flocks of migrant ducks and shorebirds in October and November. For example, Blue-winged Teal *Anas discors* and Fulvous Whistling-Duck *Dendrocygna bicolor* made up 63% of the birds present in October, whereas in November, the same two species contributed 86% to the total.

Fig. 2. Composition, by guild, of the waterbird community in the Sur del Jibaro rice fields, Sancti Spiritus, Cuba, based on annual mean densities (from Acosta *et al.* 2002).

Fig. 3. Annual mean densities of waterbirds, by guild, using each stage of the rice-growing cycle in the Sur del Jibaro rice fields, Sancti Spiritus, Cuba (from Mugica *et al.* 2003).

## GUILD ANALYSIS

The annual mean density was calculated for each guild of waterbirds occurring in the rice fields (Fig. 2). Migrant ducks included in the vegetarian guild accounted for more than half of the annual density. The guild of shallow probers, which contains all of the shorebirds, was the second-most important guild, comprising 18% of the annual density. Those guilds containing species with both resident and migratory populations, such as wading birds (herons and egrets) and deep probers (ibises), were next in importance. The differences in density between the guilds were highly significant (Kruskal-Wallis:  $H = 50.2$ ;  $p < 0.001$ ).

There was marked segregation between the guilds in relation to habitat use (Fig. 3). Ducks preferred those fields flooded after the rice crop had been harvested, as there were many seeds available in the water because of loss during mechanical harvesting. Ibises were most abundant in mature rice after the fields had been drained in preparation for harvesting, particularly in winter, when Glossy Ibises *Plegadis falcinellus* feed mainly on rice seeds (Acosta *et al.* 1996). Shorebirds frequented the first stages of the growing cycle. In these fields, the water level is very low and there is an abundance of small invertebrates, simulating the natural mudflats that these birds usually use for feeding. Gallinules and coots took advantage of the middle stages of the rice cultivation cycle; in these stages, the birds found protection in the vegetation, and frequently used these habitats for resting, nesting and feeding. Wading birds were very opportunistic, and made heavy use of the rice fields when machinery was preparing the soil for sowing and large amounts of food were unearthed by their wheels, making it available for the birds.

## Food intake from the rice culture

The waterbird community uses the rice fields for resting, nesting and feeding. Of these activities, feeding is the most important, because many birds only use the paddies for the time required to meet their daily nutritional needs. Our results have demonstrated that the waterbird community uses at least 46 different food items (Acosta *et al.* 1988, 1990, 1994, 1996, Acosta 1998, Denis *et al.* 2000, Mugica 2000). Most of these food items are plants (58%), with rice playing the key role, followed by about 22 seed-producing species and an aquatic plant *Elodea*. Animal prey includes invertebrates (30%; mainly mollusks, insects and crustaceans) and vertebrates (12%; mainly fishes, frogs and rodents).

**Fig. 4.** Daily food intake (kg/ha) by the waterbird community in the Sur del Jibaro rice fields, Sancti Spiritus, Cuba, during the rice-growing cycle in the breeding and non-breeding seasons.

A comparison of the different daily intake rates (in kg/ha) during the various stages of the rice cycle in the breeding and non-breeding periods revealed that the main output of matter and energy through the food was during the winter period (Fig. 4). The most important fields for obtaining food were those at the extremes of the rice cultivation cycle, when the fields were being prepared for sowing and when they had been flooded after the harvest. During the winter months (September to March), the intake of the waterbird community (the total daily consumption throughout the non-breeding period) was 1 606 tons, whereas in the summer months (May to August), the intake was 290 tons. Thus, during the winter months, when migratory waterbirds are present, the daily intake of the waterbird community is five times greater than during the breeding season, when only resident birds are using the paddies (Mugica 2000).

## DISCUSSION

Water level, food supply, season of the year, geographical location of the rice-farming areas, and methods of sowing are important factors determining the usage of rice fields by waterbirds in Cuba. The total number of aquatic birds found in the rice fields was similar to, or higher than, the number reported in several natural wetlands in Cuba (Acosta *et al.* 1992), Florida (Breininger & Smith 1990), Italy (Fasola & Ruiz 1996, 1997) and France (Tourenq *et al.* 2001). The reduction in the use of pesticides and herbicides in Cuba is presumably a major factor in the dramatic increase in the populations of species such as Glossy Ibis and Black-necked Stilt *Himantopus mexicanus*, and may be having an important effect on the entire waterbird community. The number of species recorded from Cuban rice fields is greater than the 46 species reported in rice-growing areas in California (Elphick & Oring 1998). Migratory birds are clearly an important component of the community, and no doubt these play a key role in the energy flow and nutrient cycle in the Cuban rice agro-ecosystem. The proximity of Cuban rice cultivation to roosting, resting and refuge areas in the coastal wetlands is also an important factor. That proximity allows the birds to use both ecosystems, natural and man-made, to provide their daily needs with relatively low energetic cost.

With the increasing problems of loss and degradation of natural wetland habitats, waterbirds will depend more and more on rice fields as an alternative habitat. In this case, the bird community is selecting an anthropogenic ecosystem, based on cues that have been historically associated with reproductive success in similar natural environments. We should keep in mind, however, that negative human interference through farming practices has the potential for drastically affecting wildlife associated with this habitat. For this reason, awareness of the issues surrounding waterbirds and the importance of rice culture to them was promoted among farmers and communities near the paddies through a recent environmental education campaign that involved about 8 000 people from two towns in rural areas. Cooperative efforts are necessary to understand the complex ecological interactions that are taking place in the paddies and to enhance this important waterbird habitat.

## ACKNOWLEDGEMENTS

We thank the organizations that financed our field research and environmental education program, including the American Museum of Natural History, Wilson Ornithological Society,

Wildlife Trust, Whitley Laing Foundation, Wetlands International, the Dutch Ministry of External Affairs, and The West Indian Whistling-Duck Working Group. We would also like to thank Jim Wiley for his revision of the manuscript.

Waterbird monitoring and conservation in protected areas of the Colombian Pacific. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 177-180.

### ABSTRACT

Three Colombian protected areas, the Malpelo Sanctuary and the Gorgona and Sanquianga National Parks, hold the largest known concentrations of Pelecaniformes and shorebirds in the country. The Waterbird Monitoring Program in Protected Areas of the Colombian Pacific was launched in order to establish baseline information on the population sizes of waterbirds and the conservation status of their habitats in these protected areas. Monthly estimates of the various species present at each of the three sites and observations of their reproductive activity allowed the identification of major breeding colonies, breeding cycles and factors influencing their local distribution. Sanquianga is the most important stopover site for shorebirds in the Colombian Pacific, with 20 000-30 000 individuals counted in September and October 2003. An estimated 18 000-23 000 Pelecaniformes have been recorded in this area, demonstrating its importance as a foraging and roosting site for both seabirds and shorebirds. The numbers of seabirds in Gorgona during 2003 fluctuated between 1 200 and 19 000, with the largest number occurring in July. Counts of the Nazca Booby *Sula granti* in the Malpelo Sanctuary confirmed that at least a quarter of the global population of this species nests in this virtually undisturbed area.

### INTRODUCTION

Fifty-seven percent of the species of waterbirds occurring in South America have resident populations in Colombia, and 98% of the migratory waterbirds from the Nearctic occur in the country (Naranjo 1997). Thirteen of these species are threatened to some degree: three at global level and ten at national level (Renjifo *et al.* 2002). Even though there is little information available on the population status of most species at local level, in some parts of the country, as many as 10% of the resident waterbird species are threatened to some extent (Restrepo & Naranjo 1987).

The Colombian Pacific coast is one of the most important areas for waterbirds in Colombia. Sixty percent of the species of waterbirds recorded to date in the country are found in this area (Salaman *et al.* 2001), including 71% of the shorebird species found in Colombia (Naranjo *et al.* 1998). The largest concentrations (both of species and individuals) have been recorded in three protected areas in the southern portion of the Colombian Pacific (Pitman *et al.* 1995, Naranjo *et al.* 1998, Johnston 2000, Castillo & Puyana 2005) where several species of Pelecaniformes nest on a regular basis (Johnston 2000, Cadena 2004, Ospina-Álvarez 2004, Cifuentes 2005). Unfortunately, the available information on population sizes and dynamics is

limited, and this has prevented the development of conservation and management plans for the protected areas that take into account the needs of these species.

In order to fill these gaps, in 2003/04 we initiated a waterbird monitoring program in three protected areas along the southern Pacific coast of Colombia. In each protected area, we estimated the population sizes of all seabirds and shorebirds present, and identified the major breeding colonies, roosting sites and foraging sites in each of the different habitats. In this paper, we present some preliminary results of this program and underline future waterbird research and conservation priorities for the Colombian Pacific.

### STUDY AREA

The Colombian Pacific coast is part of the Choco-Darien Eco-region Complex (Dinerstein *et al.* 1995), and stretches for about 1 300 km between 7°27'N and 1°27'N (Reyna & Solano 1996) (Fig. 1). Three National Protected Areas in the southern portion of this vast area cover all wetland types described for the region: sandy and rocky beaches, mudflats, mangroves and estuaries (Naranjo *et al.* 1998).

**Fig. 1.** Location of the three protected areas included in the study: Gorgona and Sanquianga National Parks (PNN) and Malpelo Flora and Fauna Sanctuary (SFF).

The different biophysical characteristics of these three sites, as well as their differing distances from the main harbors, suitability for infrastructure development and management regulations, have given rise to marked differences in resource use and conservation potential for waterbirds. Malpelo is a small

(3.5 km<sup>2</sup>) volcanic island, 500 km off the coast (Prahl 1990); it is permanently inhabited by five marines (Pitman *et al.* 1995). Gorgona is a small archipelago (617 km<sup>2</sup>), about 30 km off the coast (Díaz *et al.* 2001); its largest island (13.3 km<sup>2</sup>) is covered by dense rainforest. Much of the coastline of the main island and a number of small islets have cliffs and tall trees suitable for nesting seabirds. A prison was in operation for several decades on Gorgona Island, but this has been closed down and the archipelago has been declared a National Park; it is currently occupied by less than 20 people on a permanent basis. Sanquianga National Park covers 8 900 km<sup>2</sup> along a 60-km coastal strip, and is largely covered by dense mangroves. Several estuaries open to the sea within the limits of the park, and large mudflats as well as flooded forests are part of this complex mosaic of habitats. More than 10 000 people inhabit the area (Castaño-Urbe & Sguerra 1998).

## METHODS

We plotted the locations of the largest concentrations of waterbirds on 1:25 000 maps of the three protected areas, based on the published literature (Naranjo *et al.* 1998, Johnston 2000, Johnston *et al.* 2000), field surveys and information from local people. During the initial field trips, we carried out a topographical survey of each site using a GPS, and mapped the major habitats at a scale of 1:5 000.

In Sanquianga National Park, we made monthly censuses at one of the sites (Mulatos-Vigía) where we found the largest numbers of shorebirds, and counted birds at low tide in three different habitats (sandy beaches, mudflats and meadows) to determine the habitat preferences of each species.

Between July 2003 and April 2004, we carried out 51 banding sessions, for a total of 1 133 net/hours. We identified each captured bird to species level and, when possible, we also determined its sex, age, and stage of moult using various field guides (Prater *et al.* 1977, Hayman *et al.* 1986, Canevari *et al.* 2001). All birds were banded using US Fish & Wildlife Service metal rings and an individual combination of colour-bands that would allow us to determine the duration of stay of individual birds at selected sites.

We carried out a number of censuses of waterbirds and seabirds at several roosts and colonies located in the three protected areas. We visited Malpelo twice, on board a

Colombian Navy research vessel, and made bird counts from all cliffs accessible on foot (Estela 2003). In Gorgona, we carried out censuses every two weeks from a boat cruising around the nesting colonies (Cadena 2004). In Sanquianga, we made monthly censuses at five roosts/colonies, both in the early morning and before sunset. We also made detailed observations on factors limiting habitat availability for certain nesting seabirds, namely Brown Booby *Sula leucogaster* in Gorgona (Ospina-Álvarez 2004) and in Sanquianga, Neotropic Cormorant *Phalacrocorax brasilianus* (Cifuentes 2005) and Gull-billed Tern *Sterna nilotica*.

## RESULTS

During the 2003/04 winter season, we found 28 species of shorebirds in Sanquianga. As a whole, this area (including the large mudflats located around the northern end of the buffer zone) harbored 20 000–30 000 shorebirds in September/October 2003. Shorebirds were distributed throughout suitable habitats, but were concentrated in two localities: the beaches of Mulatos-Vigía and a sandbar locally known as La Cunita. In these areas, we located three roosts used by Spotted Sandpiper *Actitis macularia* (c. 2 000–5 000), Western Sandpiper *Calidris mauri* (2 000–4 000), Whimbrel *Numenius phaeopus* (>1 000) and smaller numbers of other species.

Mudflats were used by most species, and supported the largest concentrations of shorebirds throughout the field season. Shorebird diversity increased in September and October, when some species made more intensive use of sandy beaches and meadows (Ruiz 2004). We recorded the largest numbers of shorebirds in February 2004, and the highest species diversity in September.

The combined total of Pelecaniformes in the three protected areas in 2003 was in the range 56 455–63 705 (Table 1). The Blue-footed Booby *Sula nebouxii* was much the most abundant species of Pelecaniformes in Gorgona and Sanquianga. The Brown Pelican *Pelecanus occidentalis* also occurred in large numbers at both these sites, while the numbers of Brown Booby were the largest known from any sites on the Pacific coast of Colombia. Gorgona and Sanquianga are only 30 km apart. The main flight directions of the birds and the similar seasonal variation in numbers at both sites suggest that these areas share the same populations, at least in part.

**Table 1.** Estimated numbers of Pelecaniformes at three protected areas of the Colombian Pacific in 2003. Data were collected in July at Gorgona and Sanquianga and in October at Malpelo.

Species	Sanquianga*	Gorgona†	Malpelo‡
Brown Pelican <i>Pelecanus occidentalis</i>	2 000–4 000	4 800–5 200

## DISCUSSION

Our results confirm the importance of the protected areas along the southern part of the Colombian Pacific coast for shorebirds and Pelecaniformes, previously noted by Naranjo *et al.* (1998). Our counts of Nazca Booby *Sula granti* in Malpelo (c. 20 000) support the estimate by Renjifo *et al.* (2002) indicating that a quarter of the world's population nests in this protected area. Even though the numbers of nesting Pelecaniformes in Gorgona and Sanquianga are not particularly large at a global scale, these two areas are still important at regional level, according to the criteria of the Ramsar Wetlands Convention.

As expected from previous work, the largest concentrations of shorebirds were found on extensive mudflats (e.g. Franke 1987, Blanco *et al.* 2000), particularly in and around Sanquianga National Park (Morrison & Ross 1989). However, our data suggest that the local availability of natural meadows and artificial pastures may be important for some shorebird species, at least during exceptionally high tides or just after heavy rains when the number and size of ponds increase (Johnston *et al.* 2000). Both the spatial and temporal diversity of habitats seem to be greater in Sanquianga than in other areas of the Colombian Pacific, explaining the higher diversity and abundance of shorebirds in the National Park than elsewhere.

Our finding of large shorebird roosts in Sanquianga is noteworthy. As Naranjo & Mauna (1996) noted, the location of important shorebird roosts is patchy, and the availability of suitable habitat for roosting may be a factor influencing the population size of wintering shorebirds, even for species that, to our knowledge, have not been recorded roosting in large numbers, e.g. Spotted Sandpiper and Whimbrel.

Judging from previous information, our preliminary results indicate that the populations of migratory shorebirds and resident Pelecaniformes in these three protected areas are stable. However, a number of factors may pose important threats in some areas, and the combined effects of mangrove fragmentation and conversion, marine pollution, urban sprawl, uncontrolled tourism (Naranjo *et al.* 1998) and hunting (Johnston 2000, Cifuentes 2005) need to be evaluated, if we wish to ensure the continued survival of these important populations of seabirds and shorebirds.

Baseline information obtained during our project points in this direction, and can be used to strengthen local capacity to foresee and solve environmental problems. The three protected areas all meet several of the criteria necessary for their designation as Important Bird Areas (IBAs), and we have used our results to promote the adoption of this conservation category. At the same time, it is necessary to initiate the process leading to the inclusion of Sanquianga and the Cunita area within the Western Hemisphere Shorebird Reserve Network. Our data indicate that this area is a regionally important stopover for the largest number of shorebird species in Colombia. Several barrier islands and mudflats at the Guapi-Iscuandé river mouths close to Sanquianga National Park are important roosting and breeding sites both for Pelecaniformes and shorebirds. These areas are not protected and call for urgent attention.

## ACKNOWLEDGEMENTS

We thank local officers of the Colombian National Parks Unit in Malpelo, Sanquianga and Gorgona, local residents at Mulatos, La Vigía and Amarales, and the Colombian Navy for their logistic support and their hospitality. Help from several volunteers was

vital to the success of the field trips. This project is supported by the Colombian National Parks Unit and the Colombian Environmental Action Fund. R. Johnston-González's participation in the Waterbirds Around the World Conference was made possible thanks to financial support from the organizers, the government of Belgium and the Colombian Environmental Action Fund.

Naranjo, L.G., Aparicio, A. & Falk, P. 2006. Important areas for waterbirds on the Pacific coast of Colombia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 181-182.

From late 1996 to early 1998, an assessment of waterbird populations on the Pacific coast of Colombia was carried out in order to identify important breeding areas for resident species, foraging and roosting sites for migratory shorebirds, and potential threats to the habitats used by waterbirds along the coast. The most abundant resident species were Brown Pelican *Pelecanus occidentalis*, Neotropical Cormorant *Phalacrocorax brasilianus*, Magnificent Frigatebird *Fregata magnificens* and Brown Booby *Sula leucogaster*, while Semipalmated Plover *Charadrius semipalmatus*, Wilsons' Plover *C. wilsonius*, Whimbrel *Numenius phaeopus*, Spotted Sandpiper *Actitis macularia*, Western Sandpiper *Calidris mauri*, Ruddy Turnstone *Arenaria interpres*, Laughing Gull *Larus atricilla* and Royal Tern *Sterna maxima* were the most abundant migratory species. Major threats identified included habitat conversion, pollution, and disturbance from human activities.

Colombia has a high diversity of bird species, including many wetland dependent species. Of South American waterbirds 57% have resident populations in the country and 98% of migratory North American waterbirds use Colombian wetlands.

Previous studies have shown the regional importance of the Colombian Pacific coast for the conservation of coastal birds. Of shorebirds wintering in Colombia, 75% use the Pacific coast, and 83-92% of species are concentrated in the mangroves south of this coast (Morrison & Ross 1989). It has been suggested that this area is of hemispherical importance at least for Spotted Sandpiper (Hernández 1996). The biggest breeding colony of Brown Pelican *murphyi* in Colombia is on Gorgona Island off the southern coast. One of the biggest breeding colonies of Masked Booby *Sula dactylatra* is on Malpelo Island together with populations of Red-footed Booby *S. sula*, Brown Noddy *Anous stolidus*, Black Noddy *A. minutus* and Swallow-tailed Gull *Creasurus furcatus*. However, much of the available evidence is anecdotal, old, or without a rigorous system of data collection.

This study reviewed 24 sites (10 marine and 14 estuarine wetlands) along the Colombian Pacific coast between late 1996 and early 1998. Wetlands were characterized and counts made along the coast during the austral and boreal winters. Human pressures on the wetlands were identified from interviews with local communities, and classified according to the categories listed in Ramsar Convention protocols.

Eighty species of 16 families were recorded. Most waterbird species recorded were non-breeding residents with only 11% of these species nesting in the region. Proportionately, 26% of species came from the interior of North America, 23% from the Arctic, and only 3% from the North American Atlantic seaboard. Eight key breeding areas for seabirds were identified as were four foraging areas for shorebirds. Three major types of potential

Red-footed Booby *Sula sula*. Photo: Allan Drewitt.

Masked Booby *Sula dactylatra*. Photo: Allan Drewitt.

threats to waterbirds were recognised:

- human activities that change the landscape, e.g. infrastructure construction and mangrove deforestation. The sites most severely disturbed were Buenaventura Bay and Tumaco, both key foraging areas and roosts for shorebirds;
- pollution, e.g. oil spills, insecticides used in malaria eradication programs, heavy metals from gold and silver mines and organic discharges, with Buenaventura and Tumaco bays and the complex Naya estuary-Timbiquí most severely affected; and
- disturbance by human activities that directly and immediately affect waterbird populations, e.g. boat movements, fisheries, hunting and unregulated tourism.

Winter residents included almost all shorebird species from Alaska and the Canadian Arctic, the interior of the United States and Canada, and from the Atlantic coast of North America. Most tern species recorded have breeding populations in other Pacific regions as well as in Central America and the Caribbean area. The presence of species from the Atlantic on the Colombian Pacific coast indicate that the Gulf of Mexico flyway is linked with the Pacific flyway through birds moving across the Panama isthmus.

Climatic variations such as the El Niño - Southern Oscillation event (ENSO) affect the distribution and reproductive success and cause mortality in some species. The presence of species such as Guanay Cormorant *Phalacrocorax bouganvilli*, Peruvian Booby *Sula variegata* and Inca Tern

*Larosterna inca* in some years, the massive mortality of Blue-footed Booby *Sula nebouxii* and the almost total absence of shorebirds in some localities in 1997, can be attributed to ENSO effects. Although ENSO is a natural cyclic phenomenon, it can be a severe threat to waterbirds when its effects are combined with the other pressures described above.

Further research to fill information gaps, particularly monitoring specific populations over time are recommended to:

- determine the status of residence of oceanic species;
- determine the factors that affect the reproductive success of resident waterbirds;
- evaluate the populations' responses to environmental stress; and
- monitor the phenology and population numbers of migratory species threatened on a global or regional scale.

The results of this study show the importance for collaboration in the region to understand migratory patterns of species using the Pacific Flyway.

## Status of the Black-necked Swan *Cygnus melancorypha* and Coscoroba Swan *Coscoroba coscoroba* in the south of Brazil

Joao Oldair Menegheti<sup>1</sup> & Joao Carlos Dotto<sup>2</sup>

<sup>1</sup>National University of the Rio Grande do Sul, Brazil. (email: meneghet@ufrgs.br)

<sup>2</sup>State Foundation of Environmental Protection of the Rio Grande do Sul, Brazil. (email: dottojc@terra.com.br)

Menegheti, J.O. & Dotto, J.C. 2006. Status of the Black-necked Swan *Cygnus melancorypha* and Coscoroba Swan *Coscoroba coscoroba* in the south of Brazil. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 183-184.

Rio Grande do Sul is the southernmost state of Brazil, situated between 27°03' to 33°45'S and 49°42' to 57°40' W. It has a transitional tropical and subtropical climate, and borders Argentina and Uruguay. Often, in the austral winter, incursions of polar air abruptly change the temperature, rainfall and relative humidity. There is no dry season and rainfall is distributed throughout the year.

This study provides an overview of the current status of the Black-necked Swan *Cygnus melancorypha* and Coscoroba Swans *Coscoroba coscoroba* in the south of Brazil. The Black-necked Swan occurs from Chile and Argentina up to Rio Grande do Sul state, Brazil, occasionally reaching the south of Sao Paulo state and Rio de Janeiro state; the Coscoroba Swan occurs from Patagonia and Chile to Paraguay and Brazil (Nascimento *et al.* 2001).

Annual transect surveys, each lasting about 16 hours, were conducted by helicopter throughout the Coastal Plain of southern Brazil, in late September and early October from 1995 to 2003. Both artificial and natural water bodies were fully surveyed and each was treated as a counting point. The mean annual length of transect was 1 201.56 km, with a 3.15% variation in length between years. The mean annual surface area of water body counting points was 72.72 km<sup>2</sup>, with a 6.62% variation between years. For big flocks of swans, the number of individuals was estimated, with photographs taken for later verification.

Cox-Stuart tests were used to assess trends, but probabilities associated with the tests indicated an insufficient number of pairs of annual counts ( $p=0.625$ ) with only four early-later total counts per species being derived. However, a semi-quantitative approach suggests an increasing trend in numbers of both Black-

necked and Coscoroba Swans in southern Brazil, since three times as many count pairs showed an increase as showed a decrease. It appears that neither species is decreasing in Rio Grande do Sul. This is consistent with the biogeographic population status assessments made by Schlatter and Canevari in Wetlands International (2002).

In the Rio Grande do Sul Coastal Plain, Black-necked Swans were more abundant than Coscoroba Swans in six of the nine years between 1995 and 2003 (Table 1). Both species are considerably more abundant in the Coastal Plain than other regions of Rio Grande do Sul, but both also occur in the western and southwestern parts of the state (Table 1). However, there were more Black-necked Swans in the southwestern region than in the western region, where it was recorded in only one year (1996), it probably reaches the southwestern region via the Jaguarão river from the coastal plain. The Coscoroba Swan was common in all three regions, but in the western region largely occurred on a single large water reservoir, Sanchuri, where 149 birds were counted in September 2003. This species is known to colonize new water bodies, and the completion of the Rio Negro dam in Uruguay soon attracted Coscoroba Swans (Sick 1972). It is unclear why the Black-necked Swan has not colonized Sanchuri reservoir, since evidence from Chile indicates that the species is also an opportunistic colonizer, e.g. following an earthquake in 1960 a new wetland (Rio Cruces Sanctuary) formed which was soon colonized by Black-necked Swans which had previously been absent from the region (Schlatter *et al.* 2002).

Elsewhere in their range, relative abundance varies but Black-necked Swans are mostly more abundant than Coscoroba Swans. In Uruguay Black-necked Swans were far more abundant

**Table 1.** Total aerial counts of the Black-necked Swan *Cygnus melancorypha* and Coscoroba Swan *Coscoroba coscoroba* in the Coastal Plain, Western and Southwestern regions of the Rio Grande do Sul state, Brazil in austral spring (late September/early October) from 1995 to 2003.

1999	289	4 074	2 904	11 866

in October 1987 (8 900 birds compared to only 319 Coscoroba Swans, counted by plane – Gambarotta unpublished); and most of the estimated total of 4 000 swans counted on the Laguna de Rocha were Black-necked (Morrison & Ross 1989). Similarly, in Chile Black-necked Swans were consistently the more abundant species in both the austral winter and summer in the 1990s (Table 2), although coverage in some parts of the range of the Coscoroba Swan (Araya & Millie, 1996) was poor. However, in Argentina whilst Black-necked Swans were often the more abundant species in summer, in winter Coscoroba Swans were considerably more abundant in all years from 1990-1999 (Table 3).

## Opportunism required – migratory shorebirds at variable tidal flats in the northeast of Brazil

Kerstin Kober

Center for Marine Tropical Ecology, Fahrenheitstr. 6, 28359 Bremen, Germany. (email: [kkober@gmx.de](mailto:kkober@gmx.de))

Kober, K. 2006. Opportunism required – migratory shorebirds at variable tidal flats in the northeast of Brazil. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 185.

In contrast to the widespread assumption that tropical tidal flats provide a stable food stock for wintering shorebirds (Wolff 1991), recent investigations demonstrate that the abundance of prey in the tropics may show considerable variability (de Goeij *et al.* 2003). Nevertheless, birds which prepare for migration rely on sufficiently abundant and regularly available food stocks. How do they cope with such tropical variability?

This study describes investigations of shorebird ecology on the tropical tidal flats of the Bragantian peninsula on the northern coast of Brazil between January and June in 2001/2002. Methods of this PhD study are described in Kober (2004). The studied section of the coast is regarded as part of one of the most important wintering areas in South America and shorebirds use this area in spring to accumulate reserves prior to a transoceanic flight to North America (Morrison & Ross 1989).

The tidal flats of the Bragantian peninsula are characterized by strong variability. Powerful tidal currents with a heavy sediment load generate a small scale mosaic of fluctuating sediment conditions. The pore water salinity of the sediments is altered significantly through the input of fresh water during the rainy season. Presumably as a result of these fluctuations and disturbances, total densities and biomasses of the benthic organisms are low in comparison with other tropical areas. Moreover, a large fraction of the benthic biomass is provided by large molluscs and crustaceans which are too large to be eaten by most shorebirds. Consequently, the food stock available to the birds is extremely low. In addition, the abundance of individual benthic taxa showed high temporal and spatial variability, such that most benthic taxa were frequently unavailable to the birds.

Bird abundance varied seasonally since the majority of the birds were North American migrants, present only during the

northern winter. Although their spatial distribution was associated with specific locations, there was noticeable variation which was only weakly related to abiotic factors and prey abundances. Shorebirds showed preferences for certain prey groups, but diets were generally broad. It is assumed that birds in such a poor and variable environment have to forage opportunistically on a large variety of prey items in order to avoid food shortages and the risk of starvation.

Azpiroz, A.B. & Rilla, F. 2006. Biodiversity and conservation in the Bañados del Este, southeastern Uruguay. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 186-187.

Uruguay, in south-eastern South America, lies within a biogeographical crossroad (*sensu* Spector 2002), where several typical South American biomes meet: the Pampas, the Chaco and the Paranaense forests. The south-eastern part of the country, known as Bañados del Este (BDE), is characterized by extensive freshwater and coastal ecosystems of very significant regional importance. Aquatic habitats include a long strip of Atlantic seashore, coastal sand dunes, coastal lagoons (both freshwater and brackish), mudflats, numerous rivers and streams, inland marshes, and palm swamps. Additionally, the landscape supports extensive areas of grasslands and forests, the latter developing along fast flowing water courses (gallery forests) and on hilly sierras ("bosque serrano"). These form a complex mosaic providing a large variety of habitats for both resident and migratory species, supporting approximately 75% of the country's bird species (Azpiroz 2001).

Although BDE harbours a diverse array of migratory animals, including cetaceans, birds, turtles, fish, and crustaceans (PROBIDES 1999), birds are by far the best studied group, with at least 170 taxa identified. Migratory birds include: 1) Austral migrants breeding in Patagonia and Southern Atlantic islands during the austral summer, moving northwards for the winter. These include several Patagonian passerines and many marine birds (e.g. penguins, albatrosses, petrels) that make extensive use of wet grasslands, and coastal waters. 2) Nearctic species, most of which breed in northern North America during the boreal summer and migrate to South America during the austral summer. Most are shorebirds using mudflats surrounding coastal brackish lagoons, seashores and grasslands as feeding grounds. Some species stay in BDE for the whole wintering season, others also use higher latitude destinations. 3) Neotropical migrants

The White-rumped Sandpiper *Calidris fuscicollis* is probably the most common Nearctic shorebird species in the Bañados del Este. Photo: Adrian Azpiroz.

The Band-tailed or Olrog's Gull *Larus atlanticus*, a globally threatened species, is one of many austral migrants that use the Bañados del Este coastal habitats during the austral winter. Photo: Adrian Azpiroz.

breeding in this region during the austral summer and flying northwards for the winter. Most species are insectivorous passerines using diverse terrestrial habitats (Azpiroz 2001). In addition to these "latitudinal" migrants, several other species of waterfowl (e.g. swans and ducks) make regular "horizontal" movements between the large wetland habitats of South America's southern cone (Argentina, Brazil, Chile and Uruguay) (Belton 1984, Arballo & Cravino 1999). The brackish lagoons located along the coast are South America's most important coastal site for American Golden Plover *Pluvialis dominica* (Morrison & Ross 1989). Upland and wet grasslands provide breeding habitat for several threatened capuchino seedeaters *Sporophila palustris*, *S. cinnamomea*, *S. zelichi* (Stattersfield *et al.* 1998, Azpiroz 2003). The large water bodies, scattered throughout the region, offer feeding, resting and breeding habitat for many regional migratory waterfowl, such as Coscoroba Swan *Coscoroba coscoroba* and Black-necked Swan *Cygnus melanocoryphus* (Vaz-Ferreira & Rilla 1991).

The importance of the region has been nationally and internationally recognized. It has a Biosphere Reserve (UNESCO), a Wetland of International Importance (Ramsar Convention) and is being considered for addition to the Western Hemisphere Shorebird Reserve Network (WHSRN), which would recognize BDE as a crucial link within the set of key sites of continental importance for migratory shorebirds (Rilla 1993, Blanco & Carbonell 2001).

Although relatively large expanses of pristine habitats still remain, the region is threatened by human activities that have already caused considerable habitat loss and fragmentation. Wetlands have been drained for large-scale development of rice

The Marsh Seedeater *Sporophila palustris* is one of the many globally threatened species that inhabit the region. This species breeds in the Bañados del Este during the austral summer and moves to lower latitudes afterwards. Photo: Adrian Azpiroz.

fields, and cattle ranching has resulted in the replacement of tall grass by short grass species (Bucher & Nores 1988). Agricultural activities and their associated infrastructures (irrigation channels, mini-dams, road networks, etc.) have altered the hydrology (PROBIDES 1999). Forestry activity has increased substantially in recent years, mostly for pulp production, and problems at the coast include tourism encroachment and urban development (Canevari *et al.* 2001) resulting in many illegal settlements. Marine life, in particular sea turtles, is threatened by artisanal and recreational fisheries (López-Mendilaharsu *et al.* 2003).

Although most of Uruguay's effectively protected areas are located within BDE, these are still too few and too small to adequately protect the region's biodiversity. Moreover, the possibility of expanding the current protected area network is particularly limited as most of the land (c. 95%) is privately owned. Thus, the development of conservation activities targeting land-use changes must necessarily involve the active participation of landowners and the private sector.

Substantial additional research is necessary to characterize the processes that maintain the biodiversity values of BDE, and long-term studies are required to establish trends in population sizes and to understand the ecological processes behind species' declines. Finally, the lack of a clear environmental regulatory framework has resulted in contradictory government land-use

policies and limited law enforcement. The implementation of effective conservation measures will largely depend on the ability to address these political issues.

## Abundance, distribution and migration chronology of shorebirds on exposed sandy beaches of south central Chile

Alexandra Aparicio<sup>1,2</sup>

<sup>1</sup> Instituto de Zoología, Universidad Austral de Chile, Casilla 567, Valdivia, Chile.

<sup>2</sup> Present address: Organization for Tropical Studies, Apdo. 676-2050, San Pedro, Costa Rica.

Aparicio, A. 2006. Abundance, distribution and migration chronology of shorebirds on exposed sandy beaches of south central Chile. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 188.

The south-central Chilean coast (c. 38°–42°S) is characterized by sandy beaches alternating with inter-tidal flats and rocky shores (Jaramillo 2000). This diversity of habitats, combined with the abundance of potential prey for shorebirds, suggests that the region can support boreal migratory species during their migration to wintering areas in the south, and austral species in their migration to warmer zones of South America. However, basic aspects of the migration of some of these species, such as how many and which sites are used as stopover areas or distances migrated, are still unknown. It has not been clear whether or not this zone is included in migratory routes. Apart from work by Morrison & Ross (1989) on the hemispheric importance of some areas in central and south Chile, the sandy beaches located on the route between the wintering and breeding areas of some migratory species have scarcely been studied. This study evaluates the use of sandy beaches in south-central Chile as stopover areas for shorebirds. A total of 11 shorebird species were recorded, of which five were boreal migrants. Although the number of boreal species was lower than austral species, boreal species were the greater component of this shorebird assemblage, with significantly more individuals.

The study was carried out on five exposed sandy beaches in the south-central Chilean littoral zone near Valdivia (c. 39°S; Curiñanco, Calfuco, La Misión, San Ignacio and Chaihuín) from October 2000 to December 2001, and February 2002. Fortnightly censuses were conducted on each of the beaches during days with spring tides, four times per day on each beach, from high tide to low tide.

Three groups of species were identified: i) “boreal migrants” (Hayes 1995): Whimbrel *Numenius phaeopus*, Sanderling *Calidris alba*, Baird’s Sandpiper *C. bairdii*, Surfbird *Aphriza virgata* and Turnstone *Arenaria interpres*; ii) “austral migrants” (Hayes 1995): Rufous-chested Dotterel *Charadrius modestus*, Collared Plover *C. collaris*, Two-banded Plover *C. falklandicus*, Blackish Oystercatcher *Haematopus ater* and Magellanic Oystercatcher *H. leucopus*; and iii) residents: American Oystercatcher *H. palliatus*. Although the number of boreal species was lower than austral species, there were significantly more boreal individuals counted ( $t_{129} = 4.74$ ,  $p < 0.005$ ).

The abundance of boreal migrants was highest in late October 2000 and late February 2001. Austral migrants arrived between March and August, with their abundance relatively constant during the migratory season.

Shorebird assemblages were variable due to a) species arriving from the Northern Hemisphere during the austral spring and summer and b) species from the south arriving during the austral autumn and winter. This explains the greater species richness found in austral winter, when austral species were joined with boreal species that remained in the area. The first abundance peak, October, corresponded to birds arriving from

breeding areas in the Northern Hemisphere during the southward migration. The second peak, February, coincides with the return trip of these species to the north of the continent in the northward migration.

Baird’s Sandpiper and Surfbirds are examples of species using different migratory routes. The presence of Baird’s Sandpiper only during the southward migration suggests this species uses one route during its trip south and another during its return northward migration. In contrast, Surfbirds did not stop in the study area during southward migration but during northward migration in February it used this zone for a short stop. Based on the findings of Vilina & López-Callejas (1996), Tabilo *et al.* (1996) and this work, it appears that the migratory population of Rufous-chested Dotterel disperses and winters on an extensive sector of the Chilean coast, and the number of wintering individuals diminishes towards the north. While there is little information about Collared Plover populations, seasonally fluctuating numbers suggest that the individuals recorded in the study area are part of a migratory population.

In general, the greatest number of birds was recorded at the larger beaches close to other habitats, with no significant concentrations of shorebirds on sandy beaches. However, the results suggest the importance of the zone for migratory shorebirds as the region’s system of rivers, inter-tidal beaches and flats offer a diversity of habitats in a relatively small area.

Funding was provided by DID (DID -2001-02), Escuela de Graduados de la Facultad de Ciencias and Instituto de Zoología de la Universidad Austral de Chile, and DAAD (A-98-11018) Doctoral Fellowship. Final analyses and writing were supported with funding from the Barva Transect TEAM Project.

### ABSTRACT

We present a preliminary assessment of the conservation status of migratory species in Argentina, with a focus on waterbirds. This paper will be used as a basis for the organization of the First National Workshop on Migratory Species in 2006. Guidelines for the development of a national conservation strategy will be produced. The present study included a questionnaire survey of experts and an intensive search of the literature. The available information has been compiled and summarized, and the main gaps in knowledge have been identified. A general overview of the results is presented in terms of species distribution, the main flyways, population status (estimates and trends), threats and conservation priorities. We also present some case studies of potential “flagship” species. The experience gained during this first assessment will be used as a basis for the second stage: the National Workshop and its related outputs. The Waterbirds around the world Conference has proved to be an excellent forum for receiving additional input from experts.

### INTRODUCTION

Located in southern South America, Argentina has a wide diversity and abundance of wetlands (e.g. seashores, estuaries, large rivers and associated floodplains, lagoons and marshes, salt lakes, and peatlands) which provide habitat for many waterbird species. Of the 245 species of waterbirds recorded in the country (Mazar Barnett & Pearman 2001), 100 are migrants (41%), and these include many ducks (18 species), flamingos (three species) and shorebirds (29 species).

Nearctic shorebirds that have their main non-breeding areas in Argentina (Canevari *et al.* 2001, Hayman *et al.* 1986) include coastal species (e.g. Hudsonian Godwit *Limosa haemastica*, Red Knot *Calidris canutus* and White-rumped Sandpiper *Calidris fuscicollis*) and grassland species that concentrate in the grasslands of the Pampas (e.g. American Golden Plover *Pluvialis dominica* and Buff-breasted Sandpiper *Tryngites subruficollis*). Moreover, many species migrate within South America, including various Patagonian migrants that have their main breeding areas in Patagonia and main non-breeding sites at lower latitudes (e.g. Magellanic Penguin *Spheniscus magellanicus*, Ruddy-headed Goose *Chloephaga rubidiceps* and Olrog's Gull *Larus atlanticus*) (Yorio *et al.* 1998 & 1999, Madsen *et al.* 2003).

In view of the increase in threats to migratory species in recent years, it has become apparent that there is a need for a national conservation strategy for the conservation of migratory birds. Some efforts have already been made to address biodiversity conservation (SAyDS 2003), and action plans have been

prepared for individual species such as the Ruddy-headed Goose (De la Balze & Blanco 2002) and the Andean flamingos (Caziani *et al.* 2001). However, conservation of migratory species has not yet been addressed comprehensively.

The aim of this paper is to make a preliminary assessment of the conservation status of migratory waterbirds in Argentina as a first step towards the development of a comprehensive strategy for their conservation. Basic information is being gathered for broader consultation and the development of a National Workshop.

### METHODS

In this first assessment, we included the waterbirds and seabirds occurring in Argentina, and took the following steps:

- 1) an intensive literature search to compile background information;
- 2) selection of species;
- 3) identification of experts on particular species;
- 4) questionnaire surveys and telephone interviews; and
- 5) compilation and analysis of data, including identification of the main gaps in information.

Sources of background information that were consulted included the general literature on Argentinean birds (Canevari *et al.* 1991, De la Peña & Rumboll 1998, Mazar Barnett & Pearman 2001, Narosky & Yzurieta 2003) and international publications (Wetlands International 2002, Hayman *et al.* 1986). Scientific articles and the ‘grey literature’ were also reviewed. Species were selected on the basis of the following criteria: a) the species should represent different migration types and taxonomic groups; b) they should have a threatened status; c) they should represent different habitat types and conditions, portraying different conservation problems; d) they should be appealing enough to become “flagship” species; and e) there should be sufficient information available.

Questionnaires on selected species were produced and sent to a number of experts. About 93% of the questionnaires were answered effectively, and these responses were followed by telephone interviews. The main points covered in this consultation were:

- 1) taxonomic information;
- 2) conservation status;
- 3) seasonal and spatial distribution, and migration routes;
- 4) population estimates and trends;
- 5) the available literature;
- 6) banding initiatives;

- 7) threats and the main conservation actions required; and
- 8) the major requirements for a national conservation strategy.

Background information obtained from the literature and data on selected species provided by experts formed the basis for the present analysis. The taxonomy and systematic order follow Mazar Barnett & Pearman (2001). Information on the conservation status of waterbirds in Argentina was taken from García Fernández *et al.* (1997). Unless otherwise stated, information on population size was taken from Wetlands International (2002).

## RESULTS

### Migratory status

About 100 of the species of waterbirds and seabirds occurring in Argentina are migrants. Taxonomic groups including the highest proportion of migratory species are Phoenicopteriformes (100%,  $n = 3$ ), Charadriiformes (61%,  $n = 79$ ), Anseriformes (45%,  $n = 39$ ) and Procellariiformes (36%,  $n = 39$ ) (Fig. 1). Species were grouped in the following categories according to their migration patterns:

- 1) Nearctic migrants: species that breed in the North American tundra and migrate to the Southern Hemisphere during the non-breeding season, reaching Argentina in the austral spring and summer (e.g. Common Tern *Sterna hirundo*, Hudsonian Godwit, Red Knot and White-rumped Sandpiper);
- 2) Mid-latitudinal migrants: species that breed in Argentina and migrate to central and northern South America during the non-breeding season (e.g. American Wood Stork *Mycteria americana* and Spotted Rail *Pardirallus maculatus*); and
- 3) Patagonian migrants: species that breed in Patagonia and migrate to northern Argentina, reaching lower latitudes during the non-breeding season (e.g. Ruddy-headed Goose and Rufous-chested Dotterel *Charadrius modestus*).

Two other categories have also been considered:

- 4) Altitudinal migrants: species that breed in mountainous areas (including the “Puna” region and high plateaux in north-western Argentina) and make seasonal altitudinal migrations, moving to warmer, lower valleys during winter (e.g. the Andean flamingos);
- 5) Opportunistic migrants: nomadic species that make short- to long-distance movements with no regular pattern in search of favourable habitat conditions providing food and suitable nesting sites (e.g. several grebes, ducks and coots). In many cases, the conditions of the habitat are more important than climatic factors and time of year and, given favourable conditions, these species can breed all year round (Canevari *et al.* 1991).

The dominant migratory type varied between the taxonomic groups that were assessed. The Charadriiformes are dominated by Nearctic migrants, while Patagonian migrants dominate in all other taxa except for the Phoenicopteriformes, which include altitudinal and opportunistic migrants (Fig. 1).

### Case studies

Sixteen species were selected to give as comprehensive an overview as possible (Table 1). In some cases, the information

**Fig. 1.** The numbers of migratory waterbird species in Argentina by Order: (A) in relation to resident species, and (B) in each migrant category.

drawn from literature was revised on the basis of interviews with experts. Eight of the species listed in Table 1 are discussed in greater detail below to illustrate the results of the study. The major gaps in information for these eight species are listed in Table 2.

**Magellanic Penguin *Spheniscus magellanicus*:** This is a Patagonian migrant, breeding along the Patagonian coast from September to March. For the rest of the year (April to August), it is pelagic. The non-breeding range may include southern Brazil (P. Yorin *in litt.*), but no information is available on the migration routes.

**Black-browed Albatross *Thalassarche (Diomedea) melanophris*:** This seabird is another Patagonian migrant, breeding from October to March in the Falklands/Malvinas, South Georgia, the South Sandwich Islands and South Orkney/Orcadas Islands. No specific information is available on its non-breeding areas (April to September), although it is known to reach all southern oceans (F. Rabuffetti *in litt.*). Individual birds are highly faithful to their breeding sites.

**Andean Flamingo *Phoenicopus andinus*:** This is an altitudinal and opportunistic migrant. During the breeding season (October to April), it occurs in the “Puna” region of the high Andes in north-western Argentina, as well as in Chile, Bolivia and Perú. It migrates to lower areas during the non-breeding season, reaching as far as the central plains of Argentina and southern Perú (S. Caziani *in litt.*).

**Ruddy-headed Goose *Chloephaga rubidiceps*:** The mainland and Tierra del Fuego population of this Patagonian migrant has a very restricted distribution. Breeding pairs concentrate in the surroundings of Punta Arenas and in the northern portion of Tierra del Fuego (Madsen *et al.* 2003). During winter, the birds occur in a small area in southern Buenos Aires province (Blanco *et al.* 2003).

**Table 1.** Selected species of migratory waterbirds in Argentina, indicating migratory and conservation status, listing in Appendices to the Convention on the Conservation of Migratory Species of Wild Animals (CMS), and experts consulted.

Family	Species	Migratory status	Conservation Status		CMS	Expert consulted

Migratory status: PAT – Patagonian; NEA – Nearctic; OPP – opportunistic; ALT – altitudinal. Conservation Status: CR – Critically Endangered; EN – Endangered; VU – Vulnerable; NT – Near Threatened; NGT – not globally threatened; NLT – not locally threatened. The eight species selected as case studies are indicated with an asterisk.

**Austral Rail *Rallus antarcticus*:** This small rail is an opportunistic as well as a Patagonian migrant, but little is known about its distribution and movements. There are records from Santa Cruz province in Argentina and Region XII in Chile, but breeding has only been reported from Torres del Paine in November and December (J. Mazar Barnett & S. Imberti *in litt.*).

**Red Knot *Calidris canutus*:** This is a Nearctic migrant shorebird. Most individuals of the subspecies *rufa* migrate annually between breeding sites in the Canadian Arctic and their main non-breeding areas in Tierra del Fuego, in Argentina and Chile (Harrington 2001, P. González *in litt.*).

**Buff-breasted Sandpiper *Tryngites subruficollis*:** This Nearctic migrant has its main non-breeding areas in the Río de la Plata grasslands in Argentina, Uruguay and Brazil, where it is present from September to February (Lancot *et al.* 2002).

**Olrog's Gull *Larus atlanticus*:** This Patagonian migrant is endemic to southern South America, and the breeding colonies are restricted to the Atlantic coast of Argentina (Buenos Aires and Chubut provinces). No information is available on migration routes (P. Petracci *in litt.*).

### Threats and conservation actions

The threats to the conservation of the selected species were identified. In decreasing order of importance they are:

- 1) habitat change (either human-induced or natural) and habitat loss;
- 2) pollution (ranging from oil spills to pesticides);
- 3) urban development and tourism; and
- 4) other threats. The latter category includes mining activities,

water management, collection of eggs and guano, overgrazing, pets and feral animals, and biological causes such as low reproductive success and specialized diet during the breeding season.

Further information is given in Table 3 for the eight case studies. Taking into account these threats and the gaps in information that had been identified, a number of conservation actions were suggested by the experts. In decreasing order of importance they were:

- 1) implementation of protected areas;
- 2) habitat and species management (including eradication of alien species);
- 3) education and public awareness;
- 4) law enforcement;
- 5) long-term monitoring; and
- 6) others.

The main conservation actions required for the eight case studies are listed in Table 3.

A major issue identified by the experts was the need for more research (banding studies, determination of flyways) as a necessary input for better implementation of these conservation actions.

### DISCUSSION

This preliminary analysis provides a basis for the development of a national strategy for the conservation of migratory species in Argentina. The process involved the participation of many

**Table 2.** Population size and trend, revised national conservation status (from Table 1) and main gaps in information for eight species of migratory waterbirds in Argentina. Population estimates follow Wetlands International (2002) except for the two marine species and *Chloephaga rubidiceps*, for which the sources of information are specified.

Species	Population size	Population trend	National conservation status (revised)	Gaps in information
<i>Spheniscus magellanicus</i>	964 000 breeding pairs <sup>(1)</sup>	No information available	NLT	- Wintering distribution - Migration routes

<sup>(1)</sup> Yorio *et al.* (1999), <sup>(2)</sup> BirdLife International (2000), <sup>(3)</sup> Blanco *et al.* (this volume)

experts from all around the country who provided updated information on the current status of migratory waterbirds, including natural history, distribution and migration, threats, conservation needs, gaps in information, and so on.

An analysis of the information provided by the experts identified many gaps in information and the need to revise the migratory and conservation status of several waterbird species. There should, in fact, be further discussion regarding the classification of migrants, as several species do not fit into any of the “traditional” categories. In some cases, there is an overlapping of features from different categories. Some species, such as the Black-browed Albatross and Austral Rail, show both Patagonian and opportunistic features, while the Andean Flamingo shows altitudinal and opportunistic characteristics. For many species, basic information on migration patterns is still lacking.

On the other hand, some species are known to be declining, e.g. the Black-browed Albatross. In this case, the available information suggests a decreasing trend for the Falklands/Malvinas colonies, which contain 80% of known breeding pairs (BirdLife

International 2003). The Black-browed Albatross was the main species found in the by-catch on long-line fishing vessels between 1999 and 2001, out of a total of 10 000 albatrosses and petrels counted (M. Favero pers. comm.)

As regards long-distance migrants, many shorebirds are decreasing in South America, including some species that have their main non-breeding areas in Argentina. A particular case is the *rufa* population of the Red Knot, which has been declining significantly for the last two decades, particularly in Tierra del Fuego, where numbers have fallen from 51 000 to 27 000 in 2000-2002, threatening the viability of the subspecies (Baker *et al.* 2004). Another example is the Buff-breasted Sandpiper, which continues to show a declining trend (Lancot *et al.* 2002).

Patagonian migrants also include some species with an unfavourable conservation status. The mainland and Tierra del Fuego populations of the Ruddy-headed Goose have been in serious decline since the 1950s. This species is now considered to be in danger of extinction both in Argentina and in Chile, with the total population in both countries now estimated at

**Table 3.** Main threats and conservation actions identified for eight species of migratory waterbirds in Argentina.

Species	Threats	Conservation actions
<i>Spheniscus magellanicus</i>	Oil exploration Interaction with fisheries Disturbance from tourism	Further research? International co-operation?
<i>Thalassarche melanophris</i>	Interaction with fisheries (including by-catch in long-line fishing, trawling and jigging vessels) Predation by alien species Pollution Disturbance from tourism	By-catch mitigation measures Monitoring breeding colonies Assessment of off-shore distribution and abundance Banding studies
<i>Phoenicopterus andinus</i>	Habitat changes due to irrigation works Human disturbance in breeding colonies (including egg-collecting and tourism) Mining and poaching Agro-chemicals	Long-term programmes to monitor populations Basin management; regulations on water use and law enforcement
<i>Chloephaga rubidiceps</i>	Predation by Patagonian Grey Fox <i>Dusicyon griseus</i> Sport hunting and "pest" control Agro-chemicals Habitat changes	Protection of breeding and non-breeding areas Hunting regulations and law enforcement Education and public awareness campaigns Habitat management
<i>Rallus antarcticus</i>	Overgrazing Irrigation works Alien species?	Management plans for cattle-raising in Patagonian wetlands Water management planning
<i>Calidris canutus</i>	Tourism and unplanned development Potentially also industrial pollution, oil exploration, sea-farming projects	Management planning Law enforcement Education and public awareness campaigns Monitoring activities
<i>Tryngites subruficollis</i>	Habitat loss and changes due to agricultural development in former cattle-raising areas Pollution from pesticides in rice fields	Management of grasslands and cattle Regulations on pesticide use Public awareness campaigns Banding initiatives
<i>Larus atlanticus</i>	Egg-collecting Pollution (heavy metals) Draining works in crab habitats	Improvement of management plans Law enforcement in protected areas Identification of main non-breeding areas and migration routes Protection of the breeding colony at Isla del Puerto

only about 1 000 birds (Madsen *et al.* 2003, Blanco *et al.* in press). However, the Falklands/Malvinas population of this species has a favourable conservation status (Wetlands International 2002).

In some cases, a revision of the National Conservation Status is needed, as in the case of the Black-browed Albatross, which should be amended to Vulnerable (F. Rabuffetti *in litt.*), and the Austral Rail, which should be moved from Critically Endangered to Endangered (J. Mazar Barnett & S. Imberti *in litt.*). In addition, some species such as the Magellanic Penguin and Austral Rail are not included in the CMS Appendices, and thus lack the protection of this international conservation tool.

Moreover, gaps in information have proved to be critical. In some cases, even basic information is lacking (e.g. abundance and distribution, migration routes, wintering areas, habitat use), making the conservation of the species more difficult to accomplish. A lack of knowledge of the distribution and movements of the Austral Rail, for example, prevents the implementation of conservation measures for this species. In the case of the Red Knot, although there is valuable information on the migration of the species (Baker *et al.* 2004), important gaps in knowledge still remain: demographic parameters for the northern South America

and Tierra del Fuego populations, recruitment rates in the breeding areas, late migration and connectivity factors (P. González *in litt.*)

## CONCLUSION

This preliminary assessment has enabled us to collect very valuable information on the migratory waterbirds in Argentina. We have identified many information gaps, the main threats and the main conservation actions required. Furthermore, we have confirmed that a wide consultation amongst waterbird specialists is needed as a next step towards the development of a comprehensive national strategy. With this in mind, a first National Workshop on Migratory Species is planned for 2006.

## ACKNOWLEDGEMENTS

We would like to thank the Secretaría de Ambiente y Desarrollo Sustentable (Argentina), Wetlands International, the Convention on the Conservation of Migratory Species of Wild Animals (CMS), and Colin Galbraith (Chairman) and the Organizing Committee of the Waterbirds around the world Conference.

Our special recognition goes to all those who responded to our questionnaires and provided very valuable information: Carlos Albrieu, Juan Mazar Barnett, Sandra Caziani, Silvia

Ferrari, Esteban Frere, Pablo García Borboroglu, Mariano Gelain, Patricia González, Santiago Imberti, Juan Pablo Isacchs, Mark Pearman, Pablo Petracci, Fabián Rabuffetti, Mauricio Rumboll and Pablo Yorio. We apologize for any omissions.

Blanco, D.E., Matus, R., Blank, O., de la Balze, V.M. & Zalba, S.M. 2006. The Ruddy-headed Goose *Chloephaga rubidiceps* mainland population: a flyway perspective. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 195-196.

### ABSTRACT

The mainland population of the Ruddy-headed Goose *Chloephaga rubidiceps* is currently estimated at around 1 000 individuals and breeds in southern Patagonia, Chile and Argentina, and winters in southern Buenos Aires province, Argentina. Numbers have seriously declined since the 1950s (Canevari 1996), and at present is considered in danger of extinction in both Argentina and Chile (Glade 1993, García Fernández *et al.* 1997). This study provides an overview of the species' ecology and conservation from research carried out by Wetlands International during the last seven years.

The Ruddy-headed Goose exists in two well-defined populations: a sedentary one restricted to the Malvinas/Falkland Islands and a migratory one that breeds in southern Patagonia, Chile and Argentina and during the winter migrates northwards to the southern Pampas in Buenos Aires Province, Argentina. The latter is the "mainland and Tierra del Fuego" population, currently in serious danger of extinction. Throughout this paper it is referred to as the mainland population.

The Ruddy-headed Goose mainland population is migratory, has a small population size and very restricted distribution (Canevari 1996, Blanco *et al.* 2003a.). Breeding areas are located in mainland Chile along the Straits of Magellan from San Juan to Pali Aike, and in the northern portion of Tierra del Fuego Island (Madsen *et al.* 2003). Brood-rearing sites, such as San Gregorio and San Juan, are characterized by swamps and/or open water offering retreat in case of predation attempts by foxes (Madsen *et al.* 2003).

After the breeding season the Ruddy-headed Goose migrates north to Buenos Aires Province, Argentina. The migration route is still unknown, but twice a year geese fly across Patagonia, which separates the breeding and wintering quarters, covering around 1 500 km. Three uncertain records suggest the use of an inland corridor close to the coast (Wetlands International unpubl. data).

During the non-breeding season the species concentrates in San Cayetano and Tres Arroyos districts, in southern Buenos Aires province (Blanco *et al.* 2003a). This region, where they share the habitat with other *Chloephaga* geese (*Ch. picta* Upland Goose and *Ch. poliocephala* Ashy-headed Goose), is predominantly agricultural with a mosaic of crops, mainly wheat and planted pastures.

Recent studies estimated the mainland population size as 900-1 178 individuals from breeding and wintering areas respectively (Madsen *et al.* 2003, Blanco *et al.* 2003), (Table 1). Due to its critical status, the species is listed in Appendices I and II of the Bonn Convention (CMS) and was included in CMS Resolutions 4.2 and 5.1 for "Concerted Actions".

The main cause of the population decline appears to be an increase in nest depredation resulting from the introduction in 1951 of the Patagonian Fox *Pseudalopex griseus* to the island of

**Table 1.** Ruddy-headed Goose status (Wetlands International 2002)

Population	Migration status	Estimate	Trend
Mainland and			
Tierra del Fuego	Migratory	900-1 178 <sup>(1)</sup>	Decreasing
Malvinas /			
Falkland Islands	Sedentary	42 000-81 000	Stable

<sup>(1)</sup> Confidence interval 95%: 491-1865 (Blanco *et al.* 2003b).

Tierra del Fuego (Madsen *et al.* 2003). A further threat is the location of this population's wintering distribution in the main wheat cropping areas of Argentina, where *Chloephaga* (sheldgeese) have been traditionally persecuted by local farmers who do not distinguish the Ruddy-headed Goose from the other two species (Blanco *et al.* 2001, De la Balze & Blanco 2002). To a lesser degree, sport hunting, habitat modification and agro-chemical poisoning are additional threats to the species.

After seven years of studies, Wetlands International and its partners have achieved the following:

- a database with updated information on Ruddy-headed Goose mainland population distribution and numbers;
- a manual and "Action Plan" for the conservation of the species (Blanco *et al.* 2001),
- the creation of the San Juan Reserve, located in the mouth of the San Juan River, 60 km south of Punta Arenas (XII Region, Chile), where Ruddy-headed Goose nests were recently discovered;
- the development of a "Water Management Plan" for the San Gregorio area;
- an intensive public awareness campaign - brochures, magazines articles, posters, etc.; and
- an internet Forum to help track the species during migration.

The critical status of the Ruddy-headed Goose mainland population points to the need for re-categorisation of its status at a global scale. Although more research is needed, there is a possibility that the two populations (mainland and the Malvinas/Falklands) could be different subspecies.

The work was supported by the Convention on Migratory Species of Wild Animals (CMS-UNEP). We thank researchers from Argentina, Chile and Denmark, and especially: Carolina Belenguer, Luis Benegas, Jorge Gibbons, Astrid Knell, Nora Loekemeyer, Jesper Madsen, Gustavo Mateazzi, Flavio Moschione, Pablo Petracci, Germán Pugnali, Silvina Ramírez, Hernán Rodríguez Goñi, Luis Scorolli and Lucas Verniere.

### 3.3 Flyway conservation in North America. Workshop Introduction

**Paul R. Schmidt**

*U.S. Fish and Wildlife Service, Migratory Birds and State Programs, 1849 C St. NW, Room 3250, Washington, D.C. 20240, USA.*

Schmidt, P.R. 2006. Flyway conservation in North America. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 197-198.

Delaware Bay on the east coast of North America is a critical staging area for huge numbers of arctic breeding shorebirds that use the site each spring, 'refuelling' especially on abundant Horseshoe Crab *Limulus polyphemus* eggs. Sustaining populations of Horseshoe Crabs is central to the long-term conservation of dependant shorebirds. Photo: Rob Robinson.

#### INTEGRATED WATERBIRD HARVEST MANAGEMENT IN NORTH AMERICA

Blohm *et al.* describe the integrated cooperative monitoring efforts to set waterfowl harvest regulations and make management/conservation decisions in North America. Treaties have been developed to define the hunting season and the conditions necessary to implement a hunt.

The Migratory Birds Treaty Act authorized the Secretary of Interior to determine when and how to allow hunting, and to adopt regulations to govern it. Harvest must be compatible with the ability to sustain populations – for both under and overabundant species. In the case of subsistence hunting (traditional use) – treaties have been amended to provide for legal subsistence of migratory birds during the closed season, except during peak of nesting season.

Programs monitoring population, productivity and habitat parameters have been developed to collect data needed to set harvest regulations. Breeding wintering and migration surveys are conducted each year. Spring breeding surveys are done by aircraft using transect lines with ground counts at samples along the same transect lines to correct for detectability of birds from air. Approximately 80 000 miles of survey lines are flown each year. Production surveys are conducted in the summer using the same transects but using a smaller sample. Habitat data is collected during these surveys.

Mid-winter surveys are conducted each year and help to determine continental populations. These surveys provide general

information for most waterfowl species, including relative abundance and distribution on the wintering grounds. In Mexico, surveys are conducted cooperatively every three years, with some surveys conducted annually.

Data on productivity is accomplished through large banding programs. Each year, over 200 000 ducks and 150 000 geese/swans are banded. This allows the U.S. Department of Interior to estimate harvest and survival rates. The quality of the data is dependent on band return rates.

Harvest surveys are conducted in the U.S. and Canada where a sample of hunters are asked to provide information particular to their hunt each year. Species specific harvest estimates are conducted and wing surveys provide species age and sex data.

Understanding migration patterns of migratory waterfowl has been the cornerstone of their management. Since 1948, waterfowl species have been managed through four flyways.

Each flyway has a Council with representatives from each province and state in the flyway who develop recommendations about species management. Biologists from the flyways meet a few times annually to review data from surveys and to produce recommendations, which are then presented to for approval. In the U.S., the Assistant Secretary of the Department of Interior gives final approval after review by the U.S. Fish and Wildlife Service. Guidelines or limits on season date, season length, daily bag limits, and shooting hours are set and provided to States who then determine their own hunting regulations within these boundaries.

In the U.S, a process called adaptive harvest management is being used to develop waterfowl hunting regulations. Adaptive harvest management is an iterative process of monitoring, assessment, and decision making designed to reduce the uncertainty associated with waterfowl population estimates.

The most pressing issues and challenges in waterfowl management in North America are:–

- Snow Geese *Anser (Chen) caerulescens* and resident Canada Geese *Branta canadensis* – populations are growing at 14% per year in the Atlantic Flyway and rapidly in other flyways as well. This growth has resulted in overabundant populations. New methods of take have been developed and take is allowed during the “closed” migratory bird hunting season.
- Declining species include Scaup *Aythya marila* and Northern Pintail *Anas acuta*. Bag limits have been reduced in response to declining populations throughout the U.S.

### HABITAT CONSERVATION PARTNERSHIPS AND CONTINENTAL PLANNING

Habitat conservation for waterfowl populations in North America has a 75 year history, the success of which has been characterized by the development of partnerships between national governments, regional governments, and the private sector. The first and most important initiative was the North American Waterfowl Management Plan, which, as described by Wheeler, was adopted in the early 1980s as US government policy and later by Canada and Mexico. The implementation strategy involves prioritization of habitat conservation based on habitat goals derived from population goals. A fund was established to provide matching grants for habitat conservation. Inspired by the approach taken in waterfowl, plans were developed for other groups of birds including land birds (Partners in Flight), shorebirds (US Shorebird Conservation Plan) and waterbirds (Waterbird Conservation for the Americas). This activity provided the impetus to develop a cooperative approach, including common approaches to setting goals and common landscape divisions, called Bird Conservation Regions that cover North America. This approach became the North American Bird Conservation Initiative, incorporating not only the taxon based initiative but also Canada and Mexico. The delivery of habitat conservation through the North American Waterfowl Conservation Act was affected through the development of Joint Ventures, which are landscape specific stakeholder partnerships, and which have recently been expanded to include all wetland depended bird species. These partnerships include the Federal government, state governments, and private organizations and interests, which leverage federal funds. Over six million hectares have been protected, restored or enhanced through the North American Waterfowl activities between 1991 and 2004.

Issues and Challenges Facing Migratory Bird Conservation Programmes in North America, involve a wide range of natural and new anthropogenic challenges. There are four principal components: science, legislative policy, habitat, and international. Birds fall into different conservation categories (such as endangered, hunted, and overabundant), which have different challenges. Science issues are critical, including incomplete knowledge, monitoring failures, and communications requiring the right mix of resources and skills to understand the complexities of bird conservation. Legislation includes migratory bird laws and treaties, endangered species laws and environmental protection and assess-

ment laws and policies. Habitat change is a consistent and often the most important threat to species. Habitat conservation needs include habitat loss, contaminants, and climate change. Lessons learned and future strategies in North America, include coordination of monitoring programs, legal consistency, and developing a cohesive Western Hemisphere strategy.

### AN INTEGRAL APPROACH TO WATERBIRD CONSERVATION, MEXICAN PERSPECTIVE

An integral approach includes population, habitat, and socio-economic issues. About 300 species are shared between Mexico and the US but 16% of Mexican species are endemic. The specific legal framework for conservation involve treaties (such as the Ramsar Convention), international funding programs (such as the US North American Waterfowl Conservation Act), and, importantly, the General Law of Wildlife enacted in 2000. This law increased the ownership stake of the local landowner. Implementation and enforcement is still being developed. Important Bird Areas form the network for bird conservation in Mexico. Important Bird Areas include important sites for waterbirds and these sites include some that hold a large proportion of certain waterfowl. The important NGO partners include Ducks Unlimited Mexico and PRONATURA. There is a need for improved international cooperation through international alliances, long term monitoring programs and assessment, and the North American Species Assessment Model.

### SEARCHING FOR EQUILIBRIUM POINTS

Migratory bird conservation must change to meet the goals of keeping common birds common and helping populations in trouble to improve. However it is clear that many species are in trouble, and therefore the goal is not being met. We must search for a balance between historic programming and modern conservation, between targeted conservation action and research and monitoring, and between historic partnerships and new strategic alliances. Historic programs were based on game birds, but there is a growing emphasis on an all bird, multi-species, habitat based approach, while retaining important attention to hunted species. There is a need to design new programs to meet all-bird needs, not just tweak existing programs. We must articulate conservation goals in terms that make broad sense, and must participate in water conservation issues. There is a need be action oriented and also to have a solid understanding of ecological processes. Both are required. The science must be rigorous, reliable, relevant, and resource efficient and have scientifically valid measurable results and monitoring, and continually test key assumptions, such as the relationship between habitat conservation and populations effects. Approaches to bird conservation, such as those for migratory birds and species at risk, need to be brought together. Management decisions are increasingly vulnerable to scientific challenge. Historic alliances, which have achieved good results, are facing new partners and include those from the resource sector. Traditional partnerships must not be neglected and cohesion within the bird community must be strengthened and non-competitive. We need to strive for “working landscapes,” in which land must also be used for people, which requires additional linkages to agriculture, fisheries, forestry, and other resource sectors. Continuing to go on the same track will get the same result, and the results are not now sufficient, so change is needed.

## Integrated waterfowl management in North America

### ABSTRACT

Waterfowl management in North America has its legal foundation in treaties among the continent's three countries that established guidelines for the cooperative management of migratory birds. Within those guidelines, each country determines its own waterfowl hunting regulations each year, based upon the results of cooperative annual programs that monitor the status of waterfowl populations, habitat conditions, migratory movements, and harvest on a continental scale. In the United States, the process for setting regulations involves a cooperative effort by the U.S. Fish and Wildlife Service, representing the Federal government, and Flyway Councils that represent the State governments. This effort culminates with the annual publication of rule-making documents that provide the legal foundation for the establishment of hunting seasons. The United States has recently implemented an adaptive approach for setting annual duck-hunting regulations. This process, called Adaptive Harvest Management, uses model-driven assessments of the results of monitoring programs to set hunting regulations, whereupon the impacts of those regulations are measured in subsequent monitoring efforts, and the cycle is repeated.

### INTRODUCTION

In North America, migratory birds are an important natural resource, with a rich tradition of economic and recreational use and an aesthetic value shared across international boundaries. However, the transitory nature of migratory birds contributes to a unique set of management challenges, due principally to the large number of species and individuals, their widespread distribution, seasonal migration, habitat requirements, and variation in population attributes. The biological complexity is compounded by the fact that these birds migrate to, and through, many different political jurisdictions throughout the continent each year. Furthermore, there are numerous and sometimes competing interests, both within and among jurisdictions, with regard to the management of these species. Thus, managing recreational use, namely the regulation of harvests on the continent, is probably one of the most complicated examples of allocating a renewable resource.

This paper is an overview of the approaches that have been taken in North America to resolve some of the issues that are inherent to managing waterfowl, i.e. migratory ducks, geese, and swans. We describe the legal foundation for cooperation among the nations that share this natural resource, and we provide an overview of cooperative monitoring efforts that establish the biological basis for making sound conservation decisions. Additionally, we describe the administrative processes that are involved in setting annual waterfowl hunting regulations in the United States, including a brief discussion of the Adaptive

Harvest Management protocol that has been adopted for the management of duck harvests in the past decade. Finally, we discuss some of the current issues and challenges that are facing North American waterfowl managers today.

### LEGAL FOUNDATION

Waterfowl, like most migratory birds, are a shared multinational resource. In North America, the importance each country holds for all or portions of the annual cycle of migratory birds is underscored in the respective treaties between those countries. Guidelines for the cooperative protection and management of waterfowl and other migratory bird species were agreed upon and established through treaties (Bean 1983). The first such treaty was the 1916 Convention for the Protection of Migratory Birds between the United States and Great Britain (on behalf of Canada). In 1936, the United States signed a treaty with Mexico at the Mexico Convention for the Protection of Migratory Birds and Game Mammals. This treaty was amended in 1972. Canada and Mexico cooperate under a separate agreement. The United States later entered similar treaties with Japan in 1972 (amended in 1974) and Russia (then the Soviet Union) in 1976. As a result of these treaties, all of the countries involved are jointly responsible for ensuring that healthy migratory bird populations will be available to future generations for all to enjoy.

The treaties define when seasons for hunting are allowed, the species that may be hunted, and the conditions under which hunting seasons may be considered. Within these general guidelines, each nation may implement its own hunting seasons. Each year, representatives of Canada, the United States, and Mexico meet to discuss a wide spectrum of migratory bird topics in order to fulfill their respective mandates for this shared resource.

In the United States, the Migratory Bird Treaty Act of 1918 is the domestic legislation that implements these migratory bird treaties (Bean 1983). Under this Act, the Secretary of the Interior is authorized to determine when and how hunting of migratory game birds can take place, and to adopt regulations for this purpose. Those regulations are written based on the distribution, abundance, economic value, and breeding and migration habits of migratory game birds, and they are updated annually. The Department of the Interior has delegated the federal authority for managing and conserving migratory birds to one of its agencies, the U.S. Fish and Wildlife Service.

The purpose of hunting regulations is to provide opportunities for hunters to take migratory game birds, while ensuring the welfare and long-term sustainability of populations of hunted birds (U.S. Fish and Wildlife Service 1988). This is the common thread that links regulated hunting activities in all three countries on the North American continent. In the United States, our objectives in setting annual hunting regulations are to provide equitable

hunting opportunities for all who wish to hunt migratory birds, including sport hunters, subsistence hunters, and those who hunt on Indian reservations. However, we must also ensure that the total annual harvest is compatible with the overall goal of maintaining sustainable populations. In some cases, this means using harvest as a tool to help manage over-abundant species.

Hunting with firearms and falconry are the two legal methods of sport hunting for waterfowl in the United States. As established by treaty, sport hunting of waterfowl may only occur from 1 September to 10 March (open period). The Migratory Bird Treaty Act allows State governments to make and enforce laws or regulations about migratory bird hunting, provided that they do not extend beyond the frameworks that are approved by the Secretary of the Interior (U.S. Fish and Wildlife Service 1988). In other words, States always have the latitude to establish more conservative hunting regulations, but never more liberal regulations. Thus, a key feature of the regulations-setting process for hunting migratory birds in the United States is cooperation with the States.

Although the 1916 treaty between the United States and Canada prohibited the taking of migratory birds from 11 March to 31 August (closed period), native residents of northern Canada and Alaska traditionally harvested migratory birds for nutritional purposes during the spring and summer months (Klein 1966). In recognition of this long-standing, traditional use of migratory birds, the governments of Canada, Mexico, and the United States amended their treaties and agreements in 1997. The amendments provide for the legal subsistence harvest of migratory birds and their eggs in Alaska and Canada during the closed period. However, no take is allowed for a 30-day period during the peak of the nesting season for each species or population.

Beginning with the 1985 hunting season, we have employed separate guidelines and administrative processes for migratory game bird hunting regulations on Indian reservations and ceded lands in the United States (U.S. Fish and Wildlife Service 1988). We developed these parallel guidelines in response to tribal requests for our recognition of their reserved hunting rights, and for some tribes, recognition of their authority to regulate hunting throughout their reservations and ceded lands. In all cases, tribal regulations established under the guidelines must be consistent with the provisions of the international migratory bird treaties, including the outside dates for hunting seasons.

## MONITORING EFFORTS

There are five categories of migratory bird monitoring efforts that are conducted annually in North America: population surveys, productivity surveys, habitat surveys, banding and marking studies, and harvest surveys (Smith *et al.* 1989).

Each year, waterfowl population surveys are conducted on breeding, migration, and wintering areas. The May waterfowl breeding population and habitat survey represents one of the most extensive and respected wildlife surveys in the world. This annual aerial survey has been conducted systematically since 1955, and it is a cooperative effort of the U.S. Fish and Wildlife Service, the Canadian Wildlife Service, and numerous state, provincial, and tribal agencies. The area covered by the survey represents more than 5 400 000 square km of the key waterfowl breeding grounds on the continent. In this survey, pilot-biologists survey the number of breeding waterfowl from aircraft by counting breeding birds seen along established transect lines

(Canadian Wildlife Service & U.S. Fish and Wildlife Service 1977, Reynolds 1987). Biologists on the ground also count birds and assess breeding habitats on a sample of the same transect lines during the same period of time. This provides the basis for correcting the aerial counts to account for the fact that not all birds present along the transect lines can be seen from the air. The corrected counts are expanded to provide species-specific estimates of breeding populations for the entire survey area.

The May breeding population and habitat survey is followed by a July production survey later in the summer, during which broods are counted from the air. The July production survey is conducted on a smaller sample of the same transect lines that are flown during the May breeding population survey. In both surveys, habitat information is an important component of data-gathering efforts. The number and types of ponds are of particular importance as predictors of productivity, and are an important component of the population models that are used to help set hunting regulations. Overall, pilot-biologists fly a total of roughly 128 000 km during the breeding population and production surveys.

The mid-winter survey is another survey of continental waterfowl populations. Conducted annually since 1935, this monitoring program is a census of waterfowl on major wintering areas throughout the United States, and is typically carried out during early January. The mid-winter survey yields general information for most waterfowl species, including relative abundance and distribution on wintering habitats. However, the survey does provide the best population data available for some species, including Tundra Swans *Cygnus columbianus*, Black Brant *Branta bernicla nigricans*, and Snow Geese *Chen (Anser) caerulescens*.

The Mexico waterfowl survey is another aerial survey that is conducted cooperatively by biologists from Canada, Mexico, and the United States. This survey began in 1936, and it augments the mid-winter survey in the United States. The survey covers the major waterfowl wintering grounds of Mexico, including the east coast, the west coast, and the interior highlands. Parts of the survey are conducted annually, but the entire survey is carried out at three-year intervals.

Banding is also an important tool of waterfowl management. To date, biologists in North America have banded more than 63 000 000 birds in total, and have accumulated more than 3 500 000 recoveries. In any one year, biologists will band more than 200 000 ducks and nearly 150 000 geese and swans. In addition to delineating migration routes and chronology, biologists can estimate harvest rates and survival rates for some waterfowl species from band recovery data. These harvest and survival rates are critical pieces of information that are used in efforts to model the population dynamics for particular species or populations (e.g. Anderson & Burnham 1976, Burnham *et al.* 1984). Estimating harvest rates from band recoveries requires accurate estimates of band reporting rates, which reflect the willingness of people who recover bands to report this information to the Bird Banding Laboratory. Band reporting rates were studied extensively in the late 1980s (Nichols *et al.* 1991, Nichols *et al.* 1995), but in recent years, use of a toll-free telephone number imprinted on bands has raised reporting rates significantly from the levels reported earlier. In 2002, biologists began a continent-wide investigation to determine current reporting rates and whether they vary by region and species.

Surveys of sport hunters are conducted annually in both Canada and the United States to assess their level of participation and success during the hunting season. These surveys consist of asking a sample of waterfowl hunters to report the number of ducks and geese they harvested during the hunting season (Martin & Carney 1977, Cooch *et al.* 1978). Both countries also conduct annual wing surveys that provide data on species, age, and sex composition. Additionally, a survey of subsistence hunters is conducted in Alaska each year that provides species-specific estimates of subsistence harvest. These survey systems have been in place since 1961 in the United States, since 1967 in Canada, and for subsistence harvest, since 1980 in Alaska. Harvest surveys provide species-specific estimates of harvest, estimates of hunter effort, and age and sex ratio estimates that are used in population modeling efforts.

### ADMINISTRATIVE PROCESSES

Understanding the migration habits of birds is a primary requisite for all nations participating in the management of our shared waterfowl resource. Long-standing analyses of numerous band recovery records show that waterfowl appear to follow distinct, traditional migration corridors or flyways in their annual travels between breeding and wintering areas (Lincoln 1935, Bellrose 1980). Since 1948, we have managed waterfowl by four administrative Flyways that are based on those migration paths: the Atlantic, Mississippi, Central, and Pacific Flyways (Fig. 1). Some of the important waterfowl hunting regulations that are set each year, including season length and daily bag limits, are specific to these individual Flyways.

Fig. 1. The waterfowl flyways of North America.

Each Flyway has a Flyway Council, which is a formal organization that is composed of one member from each State and Province in that Flyway. Recently, Mexico has also provided representation at Pacific and Central Flyway meetings and discussions. The Flyway Councils are involved in many aspects of migratory game bird management, including development of

recommendations for hunting regulations and assisting in research and habitat management activities.

In the United States, the process of establishing annual hunting regulations is a complex merging of biological, administrative, and legal considerations (U.S. Fish and Wildlife Service 1988). Waterfowl biologists within each Flyway meet several times annually to review the biological data from monitoring programs. Following these reviews, they prepare a series of recommendations for the upcoming hunting season that are presented to their respective Flyway Councils. The recommendations that are adopted by the Flyway Councils are then presented to the U.S. Fish and Wildlife Service's Regulations Committee for consideration. The Regulations Committee evaluates each Flyway's proposals and then submits its findings and recommendations to the Director of the U.S. Fish and Wildlife Service. Final approval is given by the Assistant Secretary of the Department of the Interior, representing the Secretary, whereupon the annual hunting regulations are formally adopted after public review and comment. Throughout this process, the general public are provided with ample opportunity to comment on the recommendations and decisions.

Waterfowl hunting seasons must be established by late August for a few species and areas, and by late September for all of the other species and areas. However, most of the biological data are not available until July. Thus, much of the regulations-setting process in the United States occurs during a very compressed time frame. As one would expect, the processes for developing annual regulations in Canada and Mexico differ from this in terms of both procedures and timing (see Boyd 1979).

The U.S. Fish and Wildlife Service develops waterfowl hunting regulations by establishing the frameworks, or outside limits, for season opening and closing dates, season lengths, bag limits, and shooting hours (U.S. Fish and Wildlife Service 1988). States then select their seasons within these frameworks, considering factors such as distribution, abundance, and timing of migration to and/or from their State, as well as other factors important to their hunting communities. Again, States may always be more restrictive than the federal regulations, but never more liberal.

To help improve the overall regulations-setting process in the United States, the U.S. Fish and Wildlife Service and the States worked together in the early 1990s to develop an Adaptive Harvest Management approach for regulating duck harvest (Johnson *et al.* 1993). Adaptive Harvest Management serves as a way for all interested groups to work cooperatively to review

Fig. 2. The monitoring, assessment and decision-making cycle employed annually by the Adaptive Harvest Management process that is used to set annual duck hunting regulations in the United States.

the available biological information and develop as much consensus as possible with regard to setting duck hunting regulations each year. The explicit goal of Adaptive Harvest Management is to optimize long-term hunter opportunity while ensuring healthy waterfowl populations.

Adaptive Harvest Management is an iterative process that each year uses the results of monitoring to inform a series of biological assessments that help establish particular hunting regulations in a given year. The impacts of those regulations are then measured by subsequent monitoring activities, and the cycle is repeated (Fig. 2). The biological assessments are based on statistical models that all parties have agreed to use, which helps promote objective decision-making despite acknowledging an incomplete understanding of the role that harvest plays in duck population dynamics (Williams *et al.* 1996). Annual regulatory decisions about season length and daily bag limits are limited to a fixed set of clear alternatives, and the alternative selected in any given year is based upon the results of the models. The heart of the process is its adaptive nature; when new information is obtained, it is continually incorporated into the process, thereby reducing our uncertainty about the relationship between harvest and duck numbers. This underscores the value of our monitoring programs, and our need to maintain their accuracy and reliability.

The U.S. Fish and Wildlife Service and the States adopted Adaptive Harvest Management in 1995 for regulating duck harvest. Currently, this approach is only used in the United States for the development of duck hunting regulations, particularly for the Mallard *Anas platyrhynchos*. The regulatory alternative that is selected for the Atlantic Flyway is based upon the results of the population models for eastern Mallards, whereas the population models for mid-continental Mallards determine which regulatory alternative is selected for the other three Flyways. Work is ongoing to expand the Adaptive Harvest Management approach to the western Mallard population, recognizing further that stocks vary in their potential to support sport harvest. Additionally, Canada is currently working with the United States to develop an adaptive approach for the harvest of other species or populations of waterfowl besides Mallards, namely, the shared American Black Duck *Anas rubripes* population and the Atlantic population of Canada Geese *Branta canadensis*.

## CURRENT ISSUES

Waterfowl populations typically fluctuate as a function of habitat and environmental conditions; thus periodic increases and decreases are expected. However, the long-term trend information provided by our monitoring efforts indicates that we have cause to be concerned about the status of some species in North America. Results of the waterfowl breeding population survey indicate that Greater Scaup *Aythya marila* and Lesser Scaup *A. affinis* have experienced a long-term decline, particularly since the early 1980s (Afton & Anderson 2001). In response to this decline, the U.S. Fish and Wildlife Service and the Flyway Councils have reduced bag limits for these two species throughout the United States. Contaminants, lower female survival, and reduced recruitment due to changes in the availability of food resources or essential habitats have been suggested as possible reasons for the decline.

The Northern Pintail *Anas acuta* is another species whose numbers have declined significantly. Unlike other prairie ducks, Northern Pintails have not rebounded during the past decade of

generally improved wetland conditions in the prairies of North America. This is probably due to increased vulnerability during the nesting season as a result of modern farming practices, particularly in the grassland areas of the north-central United States and southern Canada (Miller & Duncan 1999). As with Greater and Lesser Scaup, the U.S. Fish and Wildlife Service and the Flyway Councils have reduced the daily bag limit on Northern Pintails to decrease harvest. When low population numbers warrant, they have also reduced the number of days during which hunters may take these birds.

North America is also currently experiencing problems caused by over-abundance of some species. Several populations of Snow Geese and Ross's Geese *Chen (Anser) rossii* have increased dramatically and are causing extensive habitat damage to breeding, migration, and wintering areas (Ankney 1996). To help alleviate this problem, unusual measures have been taken recently to reduce those populations, under the authority of a Conservation Order (U.S. Fish and Wildlife Service 2001). These measures consist mainly of allowing methods of take that previously have been prohibited (e.g. electronic calling) during the period that has traditionally been closed to all migratory bird hunting (i.e. after 10 March). The goals of these efforts are to reduce the Greater Snow Goose *C. c. atlantica* population in the East from 860 000 to 500 000 birds, and to reduce Lesser Snow Goose *C. c. caerulescens* and Ross's Goose populations in the mid-continental region by 50%. These birds number 3 000 000 in mid-winter counts, but estimates from the breeding ground are as high as 5 600 000 birds.

Resident populations of Canada Geese have also experienced high growth rates. These birds reside year-round in much of the United States and parts of southern Canada. Numbers of resident Canada Geese are growing at a rate of 14% per year in the Atlantic Flyway and 6% per year in the Mississippi Flyway, and these geese are increasing rapidly in the Central and Pacific Flyways as well. An over-abundance of these birds has resulted in habitat degradation, crop depredation, and an increasing incidence of conflicts with human activities in urban and suburban areas (Conover & Chasko 1985). Consequently, the U.S. Fish and Wildlife Service is currently considering several alternative management strategies to reduce and control resident Canada Goose populations (U.S. Fish and Wildlife Service 2002).

The results of annual waterfowl monitoring and management efforts in North America are available in a variety of publications and formats, including population status reports, administrative reports, technical reports and scientific papers, proceedings of various conferences and other meetings, and videotapes and DVDs. Reports and other information, including the annual migratory bird hunting regulations, are available on the web sites of the U.S. Fish and Wildlife Service and the Canadian Wildlife Service.

## Summary of the Workplans for 2005 of the Waterbird Conservation Council's committees

Jennifer Wheeler

U.S. Fish and Wildlife Service, Division of Migratory Bird Management,  
4401 N. Fairfax Drive, Suite MBSP, Arlington, VA 22203, USA. (email: jennifer\_a\_wheeler@fws.gov)

Wheeler, J. 2006. Summary of the Workplans for 2005 of the Waterbird Conservation Council's committees. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 204-205.

The Waterbird Conservation Council (Council) is the keeper of the North American Waterbird Conservation Plan (NAWCP) and has responsibility for coordinating, supporting, communicating implementation of NAWCP and other waterbird plans, updating the plans, and facilitating actions for waterbird conservation throughout the Plan area. The Council is structured to accomplish its work through seven working committees that report to an Executive Committee. The role and workplan for 2005 for each Council committee is summarized in this document.

### EXECUTIVE COMMITTEE

Role: Composed of representatives of the major geographic units of the NAWCP area and committee chairs, this committee oversees and facilitates the work of the Council, and in 2005 has oversight over two ad hoc committees, which will:

- Address the commitments associated with NAWCP "Version 2" as discrete tasks by working committees:
  - Continental-scale treatment of marshbirds as a 2005 task for the Technical Services Committee;
  - Fuller treatment of Latin America and the Caribbean: Underway under "Advancing Range-Wide Waterbird Conservation Throughout the Western Hemisphere;" Regional Committee to facilitate creation of relevant regional plans;
  - Revision of status assessments: Technical Services to develop a strategy to account for hemispheric expansion;
  - Increased conservation actions – Regional Committee to facilitate regional-scale implementation of planned conservation activities; Resources Committee to assess funding opportunities; Conservation Action Committee to continue addressing urgent conservation issues; and
  - Printed Communications Piece: Development led by Communications Committee.
- Develop a strategy of "integration" - identifying opportunities and proposing actions for engaging with existing international organizations and programs to advance waterbird conservation; also promoting integration of waterbird conservation needs with other initiatives at regional levels.
- Outline a plan of action with regard to identifying geographic priorities at multiple levels.

### TECHNICAL SERVICES COMMITTEE

Role: To provide leadership and guidance on a number of technical topics of interest to the Waterbird Conservation for the Americas initiative. The Committee will focus on the most pressing needs identified in the NAWCP, but will also provide input on other technical issues as they emerge

- Secure increased participation from the ranks of scientists
- Priority tasks for 2005:
  - Form a task force and complete the continental-scale marshbirds assessment (i.e. status assessment, and documentation of threats, needs, and partners);
  - Complete the monitoring needs framework currently underway by the committee; and
  - Examine and update the method for status assessment reflecting the Council's decision to include the entire Western Hemisphere in its scope.
- The task of developing guidance for setting resource (population and habitat) objectives is expected to arise from analyses and discussion of bird conservation regions (BCR) and among regional planners.

### REGIONAL PLANNING AND IMPLEMENTATION COMMITTEE

Role: To ensure effective regional waterbird conservation planning and implementation.

- Expand its membership and adjust operations to formally include representatives from each of the planning regions.
- Expand its scope, previously focused on Canada and U.S., to all regions in the NAWCP area, now including South America.
- Priority tasks for 2005:
  - Facilitate completion and endorsement of regional waterbird conservation plans;
  - Facilitate initiation of working group for Mexico to advance a technical assessment of waterbird needs in Mexico; and
  - Assist Central American partners in creating a regional plan from the country reports generated under the Council's project "Advancing Range-Wide Waterbird Conservation Throughout the Western Hemisphere."

### RESOURCES COMMITTEE

Role: To acquire resources to fund the work of the Council and support the implementation of the North American Waterbird Conservation Plan.

- Priority Tasks for 2005 are:
  - Fund the operational budget of the Council for 2005; and
  - Analyze funding opportunities for the waterbird initiative (beginning with the Neotropical Migratory Bird Conservation Act (NMBCA) and the North American Wetlands Conservation Act (NAWCA)).

### COMMUNICATIONS COMMITTEE

Role: To provide communication-related services to support the work of the Council, drawing on its expertise and networks to develop the tools and means of reaching out to target groups with selected messages.

Priority tasks for 2005:

- Expand and improve communications within the committee, the Council, and immediate partners;
- Take responsibility for a new “Executive Summary-like” communications piece on the work and progress of the initiative;
- Assist and guide expansion, revision, and maintenance of the Initiative web site; and
- Oversee an ad hoc committee on “Birds and Rice,” which will address A) research needs, B) best practices, C) promotion of “bird-friendly” rice cultivation.

### INTERNATIONAL COMMITTEE

Role: To foster the advancement of the Plan in the widest manner and especially to engage regions in Latin America and the Caribbean.

Priority Tasks for 2005:

- Shift focus from exclusive Latin America/Caribbean areas of initiative to range-wide and cross-boundary issues and make appropriate membership changes;
- Take the lead in approaching South American partners to make links between Council; and
- Continue to oversee the “Advancing Range-Wide Waterbird Conservation Throughout the Western Hemisphere,” which funds foundational work for areas south of Mexico, but transition the tasks of producing regional plans (regional=Mexico, Caribbean, Central American and South America) to the Regional Committee.

### CONSERVATION ACTION COMMITTEE

Role: To foster awareness and actions to assure the conservation of waterbird species. Emphasis will be given to those species listed as Highly Imperiled or of High Concern.

Pressing conservation issues will be addressed in a pro-active manner.

Highest priority tasks for 2005

- Continue to promote the importance of the waterbird conservation plan and its implementation and work to obtain increased funding to foster waterbird conservation as outlined in the NAWCP through such measures as Congressional appropriations through the NMBCA, NAWCA, and other sources and co-ordinate actions with the Resources Committee;
- Ensure that conservation strategies facilitate the involvement of international partners across the entire NAWCP area;
- Work to support efforts to prioritize islands in the Americas for eradication of introduced species causing problems for seabirds breeding on these islands; and
- Identify significant threats to 11 imperiled seabird species within the NAWCP plan area, obtain professional peer review of these threats, and foster plans for solutions.

### MEMBERSHIP COMMITTEE

Role: To ensure the on-going vigor of the Council, by identifying and recruiting new members to Council to provide broad and appropriate representation of the many conservation interests (geographical, taxonomic, thematic) of the Waterbird Conservation for the Americas Initiative. In addition, facilitate active participation of members and promote the benefits accruing to members from Council membership.

Resolve issues of Mexican federal-agency representation on Council, as well as the Council’s relationship to the North American Bird Conservation Initiative Mexico.

Priority Tasks for 2005 are:

- Revise and release operating guidelines (primarily principles of membership document and Terms of Reference);
- Develop and implement a strategy for populating council based on principles; and
- Promote benefits of membership to existing and prospective members.

Stewart, D.L., Weseloh, D.V.C., Collins, B., Timmermans, S. & McCracken, J. 2006. Canada's Waterbird Conservation Plan – building on 30 years experience on the North American Great Lakes. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 206.

Bird conservation in Canada is increasingly being planned and implemented with international cooperation, using integrated approaches under the North American Bird Conservation Initiative (NABCI). Bird species are grouped under the four pillars of NABCI: waterfowl, shorebirds, waterbirds, and landbirds. The vision of waterbird conservation planning in North America is that the distribution, diversity and abundance of populations and the habitats of breeding, migratory, and non-breeding waterbirds are sustained or restored throughout the lands of North America, Central America, and the Caribbean.

To date, this has produced a Canadian Plan (Wings Over Water – WOW) (Milko *et al.* 2003), a North American Plan (Waterbird Conservation for the Americas) (Kushlan *et al.* 2002), and several smaller plans based on multi-jurisdictional regions, provinces or states, and Bird Conservation Regions (BCRs); many more are in preparation.

For the lower Great Lakes, a resource shared between Canada and the United States (U.S.), the Upper Mississippi Valley and Great Lakes Waterbird Conservation Plan will describe the current knowledge, biology, and conservation efforts for the 48 waterbird species which occur in that region. Data compiled in this plan will help fill knowledge gaps, identify information needs and key conservation issues, and promote habitat and site-based conservation actions throughout the region.

In WOW, waterbird species are assessed according to six factor scores: one to two - their North American breeding and non-breeding distributions; three to four - their population size and trend; and five to six - the threats to breeding and non-breeding populations. Canada's "responsibility" for each species is also assessed by the percent of their North American and global populations in Canada. Species are then assigned to Priority Tiers: 1 (high), 2 (medium) and 3 (low). Tier 1 species in Canada are as follows: Common Loon *Gavia immer*, Western Grebe *Aechmophorus occidentalis*, Black-footed Albatross *Diomedea nigripes*, Pink-footed Shearwater *Puffinus creatopus*, Leach's Storm-Petrel *Oceanodroma leucorhoa*, American White Pelican *Pelecanus erythrorhynchos*, American Bittern *Botaurus lentiginosus*, Whooping Crane *Grus americana*, Yellow Rail *Coturnicops noveboracensis*, Heermann's Gull *Larus heermanni*, Bonaparte's Gull *L. philadelphia*, Thayer's Gull *L. thayeri*, Ivory Gull *Pagophila eburnea*, Forster's Tern *Sterna forsteri*, Black Tern *Chlidonias niger*, Marbled Murrelet *Brachyramphus marmoratus*, Ancient Murrelet *Synthliboramphus antiquus* and Cassin's Auklet *Ptychoramphus aleuticus*.

All colonial waterbird populations in the Canadian and U.S. Great Lakes have been censused three times since the late 1970s,

on a roughly 10-year rotation. Protocols and methods have been standardized between the two countries. Biologists visit all islands in the Great Lakes over a three year period. Nests and eggs of the major species are easily identified and all nests at each site are counted. For example, a large colony of Ring-billed Gulls *Larus delawarensis*, over 50 000 nests, will take a crew of six biologists up to three days to count (Blokpoel & Tessier 1996). Results show, for example, that Double-crested Cormorants *Phalacrocorax auritus* have increased tremendously while Herring Gulls *L. argentatus* have fluctuated. The methods developed on the Great Lakes are being considered for nationwide surveys.

A volunteer-based Binational Marsh Monitoring Program (MMP) was implemented in 1995. The MMP surveys both birds and calling amphibians; we only provide information for birds here. Volunteers make two evening surveys during the last three hours of daylight between 25 May and 5 July along a route of three to eight previously identified marsh locations. Using passive listening and taped call-backs of selected species, they record all birds seen and heard on field sheets. Some of those results, indicate for example increasing numbers of Common Yellowthroat *Geothlypis trichas* but declining numbers of Black Terns *Chlidonias niger*. Originally, the MMP was implemented in Ontario but recently it has expanded into the Atlantic Provinces and Quebec. Future plans may include Canada-wide implementation.

## Population declines in North American shorebirds: ecology, life-history and sexual selection

Thomas, G.H., Lanctot, R.B., & Székely, T. 2006. Population declines in North American shorebirds: ecology, life-history and sexual selection. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 207-208.

Shorebird populations worldwide are in a perilous state, with 48% of the 200 populations with known trends in decline (International Wader Study Group 2003). Only 16% of the world's shorebird populations with known trends are increasing. These declines are troubling because shorebirds are likely to be important indicators of wetland health on a global scale.

Of North America's 51 breeding species of shorebirds, 22 are in population decline and only three are increasing. To address why these declines are occurring, this study investigated the biological factors (migratory behaviour, biogeography, life-history, sexual selection) that may make some shorebirds more prone to decline than others. Preliminary examination suggests that both the migratory route of a species and their mating system relate to population trends. These initial findings require corroboration using formal statistical analyses to account for the phylogenetic relationships amongst shorebirds.

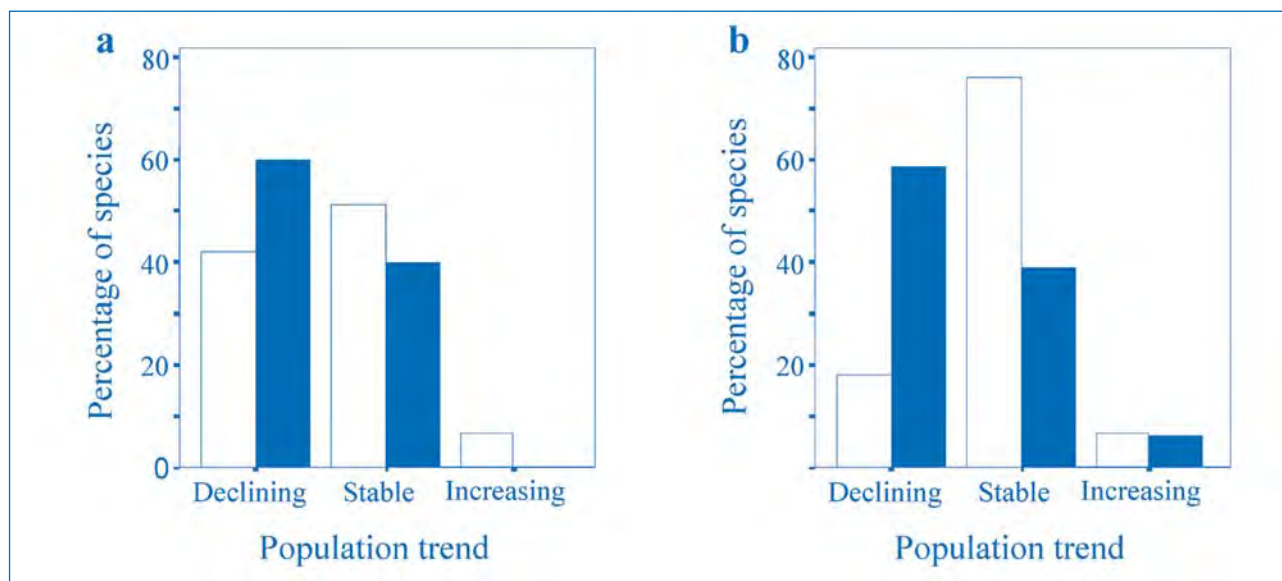

Typically, extrinsic threats such as habitat loss, predation, climate change, and hunting are cited as the major probable causes of population decline or elevated extinction risk across many taxa. Recent studies indicate that this is only part of the story, and the intrinsic biology of a species influences whether a population is predisposed to decline and extinction (Fisher & Owens 2004). Shorebirds exhibit an unusual diversity in various ecological and behavioural traits among birds, so they are an excellent group to investigate biological correlates of population trends (Székely & Reynolds 1995, Thomas 2004). The focus of

this study was to investigate the factors that predispose certain shorebird species to decline, using North American shorebirds as a model group.

Data on population trends of 51 North American breeding shorebirds were taken from the United States, Canadian, and Alaskan shorebird conservation plans (Brown *et al.* 2001, Donaldson *et al.* 2000, Alaska Shorebird Group 2004). In addition, data was collated from the literature on a suite of characters, including: migratory behaviour (distance and route), biogeography (population size, breeding and non-breeding range), life-history (body size, clutch size, adult mortality), and sexual selection (social mating system, testis size).

There are more species with declining populations than stable, or increasing, populations amongst socially polygamous shorebirds, but the reverse is true of socially monogamous shorebirds (Fig. 1a). In addition, shorebirds that migrate across continental North America tend to be declining, rather than stable or increasing, whereas the majority of coastal and oceanic migrants have stable populations (Fig. 1b).

This preliminary examination indicates important biological traits that may predispose some shorebird taxa to decline more than others. However, since closely related species tend to share similar life-histories, ecology, and behaviours (Harvey & Pagel 1991), statistical analyses that incorporate shorebird phylogeny would need to be conducted to separate the effects of common ancestry from biological predisposition (Fisher & Owens 2004).

**Fig. 1.** Population trends of North American shorebirds depending on: a) social mating system (open bars indicate social monogamy, filled bars indicate social polygamy); and b) migration route (open bars indicate coastal or oceanic migration route, filled bars indicate continental migration route).

Furthermore, there is an urgent need to examine the interactions between intrinsic biological traits and extrinsic threats in driving population trends (Fisher & Owens 2004). For instance, Eskimo Curlew *Numenius borealis*, a continental migrant highly dependent on upland grasslands (Gill *et al.* 1998), has declined to near extinction, partially due to the conversion of upland areas into agriculture. Thus, the species dependence on uplands and the concurrent demise of their upland natural habitat interacted to drive the species decline. Since many migratory shorebirds are reliant on small, ephemeral wetlands that are rarely protected adequately (Brown *et al.* 2001), the links between migration routes and habitat change appears to be particularly important in shorebird conservation.

Effective conservation management to halt and reverse recent population declines therefore requires detailed studies of both intrinsic and extrinsic factors that predispose some species to decline more than others on both a regional and global scale.

## Coordinated waterbird monitoring in the Pacific flyway of the western U.S.: the Idaho Bird Inventory and Survey (IBIS)

Rex Sallabanks & Colleen E. Moulton

Non-game and Endangered Wildlife Program, Idaho Department of Fish and Game,  
600 S. Walnut, PO Box 25, Boise, Idaho 83707, USA. (email: rsallaba@IDFG.STATE.ID.US)

Sallabanks, R. & Moulton, C.E. 2006. Coordinated waterbird monitoring in the Pacific flyway of the western U.S.: the Idaho Bird Inventory and Survey (IBIS). *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 209-210.

With the exception of waterfowl surveys for setting harvest limits, waterbird monitoring in the Pacific flyway has generally lacked regional coordination and agreement on standardized protocols. To remedy this situation in Idaho, we launched an all-bird monitoring program called the Idaho Bird Inventory and Survey.

Phase I of the Idaho Bird Inventory and Survey (IBIS) launched in 2004 emphasizes aquatic species and habitats, and focuses on determining the distribution and abundance of waterbirds at Idaho's wetland Important Bird Areas (IBAs) and Idaho Department of Fish and Game Wildlife Management Areas (WMAs). Ultimately, IBIS will generate much-needed inventories of WMAs, initiate permanent surveys at globally-recognized IBAs, yield baseline data for statewide population trend monitoring, and address high priority management issues using short-term species assessments. IBIS is designed to fit within the framework of larger-scale national and international Coordinated Bird Monitoring programs and can easily be adapted for use in other states, especially those within the Pacific flyway of the western U.S.

IBIS is a plan to monitor all birds in Idaho that most wildlife and land-management agencies would contribute to and benefit from. Importantly, IBIS is designed to be part of a relatively new program called "Coordinated Bird Monitoring" (CBM) that is currently being developed at the national level. CBM is a joint effort by managers and bird monitoring specialists to improve the success of bird monitoring programs, and make the information available to all partners. This all-bird coordination effort is modeled after a long-standing program,

implemented by the Flyway Councils, of continent-wide tracking of waterfowl to set management and harvest strategies for game species. As with the waterfowl model, coordinated all-bird monitoring is intended as a feedback system that can provide a scientific basis for management and conservation planning for birds of management concern. This paper focuses on Phase I of IBIS and addresses only waterbirds (terrestrial species are added in Phase II).

Waterbird monitoring will take place at all aquatic IBAs in Idaho, Idaho Department of Fish and Game (IDFG) WMAs and other significant wetlands. Under the framework of CBM, these sites either fall within the Idaho portion of the Northern Rockies Bird Conservation Region (BCR) or the Idaho portion of the Great Basin BCR; these regions correspond to Bird Monitoring Region 50 (BMR-50) in northern Idaho and BMR-51 in southern Idaho, respectively (Fig. 1).

Wetlands in Idaho are used regularly by 119 bird species, 68 of which are considered focal species and potentially of management concern. Providing migration stop-over habitat is probably the most important function of Great Basin wetlands (i.e. those in BMR-51; Fig. 1) for many species of waterfowl, waterbirds and shorebirds. Lake Lowell of Deer Flat National Wildlife Refuge (NWR), for example, is a site of regional importance for shorebirds. American Falls Reservoir is a major stop-over site for most aquatic species, and especially for shorebirds. Major breeding colonies of Western Grebes *Aechmophorus occidentalis* and Franklin's Gulls *Larus pipixcan* also depend on these

**Fig. 1.** Bird monitoring regions in Idaho (shaded state) in which the Idaho Bird Inventory and Survey (IBIS) statewide coordinated all-bird monitoring plan is being implemented. Bird Monitoring Region 50 (BMR-50) corresponds to the Idaho portion of the Northern Rockies Bird Conservation Region (BCR) and BMR-51 corresponds to the Idaho portion of the Great Basin BCR.

American Avocets *Recurvirostra americana* at Bear River Migratory Bird Refuge. Photo: US Fish & Wildlife Service.

habitats, and Grays Lake NWR supports the largest breeding concentration of Sandhill Cranes *Grus canadensis* in the world. Many permanent wetlands serve as wintering habitat for waterfowl, such as Harriman State Park and Bear River NWR for Trumpeter Swans *Cygnus buccinator*.

Abundance of waterbirds is usually determined using area searches by foot, boat, or plane across all of a site or in a series of randomly selected plots. Because vegetation may change between years, which could result in substantial changes in numbers recorded even if the number of birds present does not change, careful attention must be paid to estimating detection rates where birds are obscured by vegetation. Site descriptions, including survey protocols, are provided for all major aquatic sites in Idaho in the full IBIS plan.

As IBIS is a new program, monitoring data have yet to be generated. Results are therefore pending the collection of data in the initial 2004–2006 period. Management issues to be addressed with these data include: (1) identifying species at risk and causes

of declines; (2) inventory of WMAs for birds in all seasons; (3) effects of wetland loss and degradation; and (4) conflicts between piscivorous birds and fish populations. Additional issues will be addressed in v2.0 of IBIS when terrestrial habitats and species are added to the monitoring plan.

#### ACKNOWLEDGMENTS

Financial support for the initial development and implementation of IBIS (v1.0) was provided by the U.S. Geological Survey – Snake River Field Station (USGS), the Nongame and Endangered Wildlife Program of IDFG, the Bureau of Land Management, and through a State Wildlife Grant administered by the U.S. Fish and Wildlife Service. We are especially grateful to Elisabeth Ammon (Great Basin Bird Observatory) and Jonathan Bart (USGS) for technical assistance with writing v1.0; Rita Dixon, Steve Rust, Jeff Gould, John Augsburger, and Greg Kaltenecker also helped with developing management issues and/or describing monitoring strategies.

Pearce J.M. 2006. Individual behaviour, population genetics, and phylogeography of North American mergansers. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 211-212.

Our understanding of population status and trends of the three species of merganser that inhabit North America is limited. This project is investigating factors involved in population dynamics of common and red-breasted mergansers using mark-recapture and DNA data collected from across North America.

As with eider and scoter populations 10 years ago, little is known about the habits and ecology of the three species of merganser that inhabit North America: the Common *Mergus merganser*, Red-breasted *M. serrator* and Hooded Merganser *Lophodytes cucullatus*. While trend data suggest that in North America all species are stable, if not increasing, our understanding of population status and trends of these species is limited (Dugger *et al.* 1994, Titman 1999, Mallory & Metz 1999). Aerial surveys flown throughout North America are not designed to sample large sections of river and coastal areas commonly used by mergansers. When encountered, mergansers are not differentiated to species, but lumped into a single “merganser” category. As a result, surveys detect variable numbers of birds each year, poorly describe the distribution of mergansers, and leave large portions of the distribution of these species unsurveyed (e.g., Hodges *et al.* 1996). All mergansers occupy portions of the boreal forest in Alaska and Canada and this ecozone is experiencing rapid conversion to agriculture in Canada, declining by as much as 0.89% per year since 1974 (Hobson *et al.* 2002). The lack of basic biological information for mergansers has prompted the North American Sea Duck Joint Venture (SDJV) Management Board (2001) to list “Population Dynamics” as the highest priority and most urgent information need for the management of Common and Red-breasted Mergansers, and “Population Delineation” as the highest priority for Hooded Mergansers.

The distributions of all three species of merganser differ markedly across North America, and populations may differ demographically and genetically (Hewitt 2000). This project therefore proposes to investigate factors involved in population dynamics of common and red-breasted mergansers, such as nesting ecology and annual fidelity to breeding areas. Since field-based estimates of fidelity may not be representative of larger regions, DNA samples will be collected from across North America. This linkage of multiple markers such as banding and genetic data is important because both historical and contemporary factors influence the distribution and genetic differentiation of populations (Pearce & Talbot 2006). The combination of these different markers should allow more confident conclusions about the location of population mixing and a possible mechanism for genetic similarity across the arctic. Since many arctic dwelling species have only recently colonized deglaciated areas, genetic similarity could mean that fidelity takes place, but is not manifested in genetic data. Therefore, direct estimates from banding

and telemetry data are crucial to fully understand population movements in relation to genetic patterns (Pearce & Talbot 2005).

On field sites in south central Alaska, I am using standard mark-recapture techniques (leg bands and radio transmitters) for marking individuals. Pre-nesting females and brood-rearing females will be marked with radio transmitters to find nests and to quantify brood survival respectively. Sub-adult birds will also be implanted with 2-year radio transmitters prior to fledging to provide information on general movements and dispersal. Mark-recapture data will be analyzed using Program MARK (White & Burnham 1999) as has been done recently with historic data on Common Mergansers (Pearce *et al.* 2005a).

Standard genetic methods discussed elsewhere (Pearce *et al.* 2005b) will be used to amplify nuclear and mitochondrial (mt) DNA and assess population patterns at variable loci. Samples are being acquired throughout Alaska, across North America and in Europe and Russia. Ultimately, our goal is to combine inferences from demographic and genetic data for a better understanding of population patterns at both local and continental scales.

Initial analysis of historical banding data for Common Mergansers suggests that coastal and interior breeding areas may differ in their migratory tendency and survival rates (Pearce *et al.* 2005a). Similar patterns are also being investigated using historical banding data for Hooded Mergansers (Pearce *et al.*, unpublished data). In a preliminary analysis of 437 base pairs of mtDNA control region (domain I), I observed little differentiation between Pacific and Atlantic migratory flyways. Nucleotide and haplotypic diversities of these two flyways suggest a colonization event from the east or contemporary female-mediated gene flow between continental populations.

Further work is needed to adequately quantify levels of contemporary movement and gene flow among populations of all mergansers species. Additional quantification of population patterns using markers with both historic (genetic) and more contemporary (banding, stable isotopes) perspectives are being pursued and will allow more robust inferences regarding levels of gene flow and population dynamics of these species.

### Request for assistance

I am seeking additional DNA samples from both breeding and wintering birds of all merganser species. DNA can come from blood, tissue, developing eggs, or nest feathers and egg shell membranes (Pearce *et al.* 1997). Please contact John Pearce at the address above for details.

### ACKNOWLEDGEMENTS

Thanks to D. Derksen, P. Flint, M. Lindberg, K. McCracken, J. Morton, M. Olson, J. Reed, J. Schamber, K. Winker. P. Padding assisted with DNA sampling of Hooded Mergansers. Funding

was provided by the North American Sea Duck Joint Venture and the Alaska Science Center, U.S. Geological Survey.

<sup>4</sup>Manomet Center for Conservation Sciences, Manomet, Massachusetts, USA.

Donaldson, G., Andres, B., Estrada, A. & Brown, S. 2006. Using national plans in North America to conserve shorebirds at an international scale. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 213.

A recent report on the status of shorebirds breeding in Canada and the United States indicated that there were 35 species with enough information to determine population trends and 18 species with insufficient information (Morrison *et al.* 2001a). Of those species with trend indicators, 28 showed negative trends (19 were statistically significant) and seven showed positive trends (one was statistically significant). This information illustrates the need for immediate management action to reverse the large number of negative population trends. However, effective conservation efforts will be challenging given a dearth of information on some of the most basic biological parameters for shorebirds in North America. The most recent report on shorebird population numbers indicated the following accuracy ratings: high (accurate and precise), two species; good (estimates on which confidence limits can be placed), five species; moderate (within 50% of true number) 13 species; low (estimate within correct order of magnitude) 21 species; and poor (based on educated guess) 12 species (Morrison *et al.* 2001b).

Recognizing that implementing conservation actions is best done using national or regional instruments, in Canada and the United States it was decided that planning for shorebird conservation at the national level was most appropriate. The Canadian (Donaldson *et al.* 2000) and US (Brown *et al.* 2001) shorebird conservation plans were developed in parallel and contain the framework necessary for regional implementation while recognizing the importance of international collaboration. Given the mobility of shorebirds among nations, it was also noted that a high level of communication was needed to ensure that the two plans were compatible and would support a high level of collaboration. Subsequently, when Mexico began development of their national shorebird conservation plan, the two established plans were used as tools and it is expected that the final version of the Mexican plan will also describe a framework for regional implementation and international collaboration.

Just as the national plans allow for stepping down to regional actions or up to international efforts, shorebird-specific implementation of habitat monitoring and research occurs at the various levels through three different programs. The Western Hemisphere Shorebird Reserve Network (WHSRN) was established in 1985 and is working in a growing number of countries in the Americas to address shorebird habitat issues. The Program for Regional and International Shorebird Monitoring (PRISM) is designed to tackle monitoring for shorebird species during breeding, migration and non-breeding periods of the year using a variety of methods in a coordinated manner at all scales. The Shorebird Research Group of the Americas (SRGA) facilitates communication among

researchers by promoting the establishment of species specialist working groups that tackle information gaps for species and those that relate to determination of conservation needs and direction for conservation actions. It is important to note that all of these initiatives have been designed to be inclusive of shorebird conservation needs in all parts of the Americas, so while they may have had their initiation in the north, all aim to be inclusive of all countries of the Western Hemisphere. All recognize that incorporation of additional conservation needs may be warranted as more countries become involved.

### ABSTRACT

Many species of North American birds continue to experience population declines of a magnitude and duration that warrant concern. Although relatively few species are in immediate danger of being lost from the most northern areas, a large number require conservation efforts to ensure sustainability and reverse declines before expensive recovery actions are needed. The purpose of this paper is to examine, in general terms, the major conservation issues facing these bird species, and challenges that complicate the delivery of solutions. National wildlife agencies in Canada and the United States have recently developed national strategies for the conservation of migratory birds. These planning efforts help us to propose the general framework for a national bird conservation program that incorporates the following components: science (knowing the status of birds, what is affecting their populations, and how to mitigate adverse effects), legislation and policy (government tools for promoting and compelling protective actions for birds and their habitats), habitat (ensuring natural spaces are available where birds can carry out their lives), and international considerations (coordinate conservation efforts so that population sustainability is not threatened by failure in non-participating nations).

### INTRODUCTION

The purpose of this paper is to examine the major issues facing migratory bird conservation programs in North America and the challenges that complicate the delivery of conservation solutions. For definition purposes, North America includes Mexico, the United States and Canada only because these countries have recently developed mechanisms for cooperation on bird conservation; we recognize that the North American continent includes many other nations of importance to migratory birds whose bird conservation perspectives are not reported here.

Migratory bird programs have many important characteristics among nature programs that tend to keep them at the forefront of conservation:—

- Bird conservation is reflected in national or higher level legislation and jurisdiction. This is partly because birds are highly migratory, and so cannot be dealt with effectively by more local levels of government.
- Many international conservation fora have been established for birds because cooperation among the nations that share species through the annual migratory cycle is needed.
- Biological information on birds is relatively good. This fact owes much to the flying ability of birds which gives them some freedom from attack by mammals (such as people). As a consequence, birds can afford to advertise their presence through attractive plumages and vocalizations that not only

provide for ease of study but also create fondness for the species by people.

- Birds attract strong public interest for their beauty and cultural value, and also for their ecology and as food.

Birds have high vagility, and therefore high value as ecological indicators – in effect, birds reflect the current state of habitats better than most other organisms because they have freedom of movement.

Bird conservation faces powerful challenges. Before the sixteenth century, natural forces, combined with sometimes very significant land-use factors wielded by the indigenous people of North America, had operated on birds with positive and negative population effects that resulted in a particular distribution of birds across the continent. This situation is tempting to consider as a target for conservation because modern anthropogenic factors were absent.

Although birds face many new population pressures, it is not always easy to determine which are significant. Birds occur in every North American ecological region, and so they can be affected by almost every kind of economic activity. As favoured species for conservation, birds can be used in arguments against many societal undertakings, sometimes with little regard for evidence of effects on bird populations. Scientific studies of birds along with solid monitoring programs are needed to determine which factors must most urgently be addressed by bird conservation programs. However, what should conservation programs do in the absence of scientific certainty?

Factors that could be used to model population change in birds include natural processes, land use, water use, climate change, invasive species, environmental contaminants, and harvest (from Mac *et al.* 1998). An effective science-based program should attempt to quantify such factors in the context of their impact on birds. Without complete information, progress can still be made by assessing the potential scale of impact and developing habitat oriented approaches that have promise in softening anthropogenic effects for incompletely predicted benefit of birds and other natural resources. If very general habitat approaches are not at the outset sufficiently tied to research on birds, or, as is more often the case, if some scientific understanding is in place but it develops more slowly than habitat project work, bird conservation managers should be looking for improved scientific validation of work underway on an ongoing basis: the underlying philosophy of adaptive management.

North Americans are developing a framework for bird conservation, the North American Bird Conservation Initiative. More recently, both the U.S. Fish and Wildlife Service (2004) and the Canadian Wildlife Service (in prep.) have drafted strategic plans for migratory birds. These planning efforts help us

to propose the general framework for a national bird conservation program that incorporates the following: science (knowing the status of birds, what is affecting their populations, and how to mitigate adverse effects), legislation and policy (government tools for promoting and compelling protective actions for birds and their habitats), habitat (ensuring natural spaces are available where birds can carry out their lives), and international considerations (coordinate conservation efforts so that population sustainability is not threatened by failure in non-participating nations).

## SCIENCE ISSUES

To understand the issues that arise in science, it is useful to begin with a simple version of a bird conservation program designed to make appropriate use of science. Assuming a system that begins with the designation of conservation categories for species, there should be bird population monitoring sufficient to assign all species to the correct conservation categories, and make sure that category changes are detected within a reasonable timeframe. Research should be sufficient for understanding the requirements of priority species, and to allow development of conservation actions oriented to those species and their habitats. Although this is simply put, the research supporting conservation actions may require significant socio-economic components. Science is also required for evaluation, development of new models, structured learning, and revision of plans.

It is difficult to predict all the issues that will arise in bird conservation science. This is partly because of the wide range of scientific disciplines that may be applied to problems about birds, and partly because the natural environment poses such a wide range of questions. Nevertheless, a number can be described.

Population monitoring provides a basis for bird conservation. We know that there are currently monitoring failures, and this is an issue that reduces the quality of program delivery. For example, we have poor knowledge of the status of rails (Rallidae) and other, similar marsh species. The issue becomes the need to establish adequate monitoring systems. Nocturnal species, boreal species, and some tundra-nesting shorebirds are also outside the coverage of current bird monitoring programs.

Many issues arise in knowing what factors are reducing populations, and in getting knowledge to drive conservation. For example, what is limiting populations of the Loggerhead Shrike *Lanius ludovicianus* in Canada, and what can be done about it? What has been the population effect of West Nile virus on North American birds? What design factors are important to reduce bird collisions with buildings, wind turbines, and stationary towers? Are there important sub-lethal effects from a wide range of contaminants present in the environment of birds?

Among the science issues, it is important to know that there is currently a general lack of habitat monitoring in North America, and often only rudimentary knowledge of how habitat variables that we can measure relate to bird populations.

There is growing recognition of ongoing failures in communication of results and loss of scientific knowledge. Working against this are advances in technology and use of the Internet for sharing information. Sometimes it is possible to recover long-lost data from archives and bring them back into use, as the Arctic Goose Joint Venture intends to do with a number of century-old surveys of waterfowl that U.S. scientists carried out in Mexico.

As important as any other science issue is the need to use science to evaluate and improve conservation programs. This lies

at the heart of adaptive management. A current example is the planned biological evaluation of the conservation initiatives through the North American Waterfowl Management Plan.

## LEGISLATIVE AND POLICY ISSUES

When migratory bird legislation was introduced in North American countries, the immediate conservation issues were excessive hunting, especially market hunting, and collection of birds, feathers, nests, or eggs for personal use. Such practices had already led to the extinction of some species. Therefore, although habitat requirements for birds were recognized, the main thrust of regulatory tools dealt with hunting and prohibitions against possession of birds. The migratory bird treaties date from the first half of the twentieth century, but their overall intention, the preservation of migratory birds, remains valid.

Things have changed since the original treaties were developed. Additional legislative tools are available such as those that deal with endangered species and requirements for environmental assessments of new development and activities on the landscape. Governments are also increasingly committing themselves to conservation approaches through various international agreements for wildlife and habitat. An example of the latter is the Ramsar Convention on Wetlands. Unfortunately, human impacts on birds have accelerated, so that the indirect take of birds, as described below, now numbers in the many millions and is becoming an issue of high priority for North American governments.

Among the legislative issues facing us, we feel that three should be highlighted from the current perspective: forestry management systems need to support sustained populations of forest birds; agricultural programs need to encourage preservation of threatened bird habitats such as wetlands and native grasslands; and governments need effective tools to manage the incidental take of birds caused by economic or industrial activity. Examples of the latter include the occurrence of birds oiled at sea and the damage to bird populations as a result of fishing and forestry practices.

## HABITAT AND CONSERVATION ISSUES

When assessing conservation from a risk or assessment point of view, it is almost impossible to remove the role of habitat. Among the conservation issues affecting birds, there is such a wealth of possible risks, combined with a lack of information about how the risks could affect the sustainability of bird populations, that it is not possible to provide rankings. Wetlands continue to disappear, old growth forests and native prairies are shrinking. Habitat quality is under threat from overuse, pollution, and disturbance by exotic species. Increased contaminants including airborne global pollutants are finding their way into even those ecosystems quite recently thought to be pristine. At the risk of being unspecific, we note the following list of issues that are active concerns because of their potential impact on birds:

- Habitat loss and nest destruction
  - Expansion of farms, urban development; transportation and other linear development
  - Wetland drainage and modification
  - Unplanned consequences of fire management, livestock management, shrimp farming, tourism development, salt extraction, energy development, mining, aquaculture and many other human activities

- Contaminants
  - Oil at sea and oil tailings and production spills
  - Pesticides
  - Lead from fishing and hunting
  - Hazardous industrial wastes
- Introduced predators, competitors or diseases
- Environmentally triggered diseases (botulism)
- Physical threats - entanglement in fishing gear, collisions
- Hunting taking place outside conservation frameworks

Wetlands in all parts of the continent are of importance to a variety of species. Because the diversity of activities that occur near wetlands and wetland types are richer in Mexico, we have chosen to summarize the wetland issues in that country as an example of the diverse challenges for conservation in these habitats. The following issues were extracted from Inventory of Mexican Wetlands (Carrera & de la Fuente 2003): stream flow reduction by reservoirs, sedimentation, salt extraction industries, shrimp farming, tourism development, agricultural expansion, contamination, extraction of water for other uses, and drainage for reclamation.

One of the more quantitative recent works on conservation issues for birds was the review of the extent that birds may be affected by collisions and electrocutions associated with man-made objects in the United States (Manville 2005). Estimates were reported for vehicles strikes ( $10^7$  birds), building and window collisions ( $10^7$  -  $10^8$  birds), smoke stack casualties ( $10^4$  -  $10^5$  birds), power line electrocutions ( $10^4$  -  $10^5$  birds), power line impacts ( $10^5$  -  $10^7$  birds), communication tower accidents ( $10^6$  -  $10^7$  birds), and wind turbine impacts ( $10^5$  birds). This would amount to a total mortality of  $10^8$  to  $10^9$  birds annually. This information was adapted from the U.S. report; however, we state the results rounded to powers of 10, in recognition of the difficulty in coming up with precise estimates of these problems. The take-home message is that the cumulative impact of collisions is probably very significant.

The impact of climate change on birds is mostly predicted by models, rather than having much evidence from direct results. That is why we can hypothesize major impacts on the distribution and abundance of birds from climate model predictions, while, at a species level, climate change is not often identified as a current threat. Gross predictions of changes in moisture distribution can be applied to landscapes and the birds that occur there. That is not to say that the authors do not recognize the future threat of climate change on bird habitats, but that there is generally a lack of sufficient information to characterize it for particular bird species.

### INTERNATIONAL COORDINATION ISSUES

The creation of national boundaries across landscapes used by wildlife can impose considerable challenges to wildlife that may encounter widely ranging differences in land use depending on the country they are in. Economic status, government structures and priorities, and differing cultural practices and values among other factors will vary among countries and influence the availability and quality of habitats for wildlife. Considerations for North American migratory birds include the countries of the Western Hemisphere as well as countries across the Atlantic and Pacific oceans that birds may access if originating at northern latitudes.

Communication and coordination are key elements of successful international conservation efforts. For example,

effective internationally coordinated monitoring efforts for migratory birds will ensure that all countries in a species' range have access to information on distribution, abundance and trends. In addition, international collaboration on monitoring will allow for discussion on how best to monitor species so that efforts are directed to the best locations and times of year. Other key elements include:

- Consistency among legal protection mechanisms
- Access to international conservation resources for birds
- Meeting the obligations for wetlands, and expansion of international focus beyond wetlands.

Conservation at a national level is often challenging in terms of capacity to coordinate a variety of interests and participants (e.g. government and non-governmental organizations); these challenges are multiplied when efforts move into the international arena. There is a need in the Americas to bring together governments and citizens to develop a framework for the conservation of migratory wildlife among nations. Environment Ministers at the 2001 Summit of the Americas in Quebec City recognized this and called for just such an effort.

### CONCLUDING REMARKS

Considering the challenges presented by issues of science, habitat, legislation and international cooperation, the task at hand is not to be taken lightly. An increasing trend is towards the development of partnerships among governments, non-governmental organizations, academia and industries to come together to work towards common goals. By working together to identify conservation priorities and develop action plans that take advantage of each partner's strengths and capacities, the seemingly complicated task of effecting positive change becomes more tangible. To this end, the North American Bird Conservation Initiative (NABCI) is bringing people and organizations together on local, regional, national and international scales to meet common conservation goals in Mexico, the United States and Canada. NABCI's principles and achievements to date offer an example to other regions of a model that can be adopted or modified in other countries to address conservation using a partner-driven approach.

Many of Africa's migratory and resident waterbirds have poor conservation status and largely unknown population trends. Whilst there has been some research and conservation of migratory birds in Africa, this has focussed largely on African-Eurasian migrants, and the status and needs of most intra-African migrants are much less clear.

The workshop aimed to identify actions that would be important to promote development of research and conservation of intra-African migrants and resident waterbirds, including through the implementation of the African-Eurasian Waterbird Agreement. It reached the following recommendations:

#### Identifying actions needed for the conservation of intra-African migratory waterbirds

A key issue that hampers the conservation of African waterbirds is a limited knowledge of their conservation needs, particularly related to their movements, which are often unpredictable. It is also difficult to identify key site networks in some areas, due to the irregular but important role of temporary wetlands. In order to promote development of research and conservation of African waterbirds, the following recommendations are proposed. These are drawn largely from the issues affecting intra-African migration presented in the workshop and subsequent discussions. Dodman & Diagana provide further information about intra-African migration:–

- 1 Improve our knowledge of the status of African waterbirds and their migratory patterns through:
    - Applied research of weather patterns, site conditions and waterbird seasonality;
    - Extending the African Waterbird Census to other seasons and other areas;
  - 2 Identify key sites and site networks for intra-African migrants, especially threatened species (Mlingwa & Baker highlight the key importance of networks of sites for Lesser Flamingo *Phoenicopterus minor* in the soda lakes of Tanzania).
  - 3 Develop Species Action Plans for African waterbirds.
  - 4 Promote increased focus on intra-African migrants in the implementation of the African-Eurasian Waterbird Agreement.
  - 5 Adopt a precautionary principle; it is often necessary to implement conservation action before knowing the full picture.
  - 6 Enhance awareness of African waterbirds, especially their values and ecological roles.
  - 7 Highlight the plight and lack of knowledge of threatened African waterbirds.
  - 8 Mobilise resources for conservation and monitoring of intra-African migrants, especially through development and subsequent implementation of a Conservation Strategy for African Waterbirds.
- Use/analysis of existing African Waterbird Census and other data to identify site linkages and migratory patterns;
  - Increased adoption of satellite telemetry (Childress *et al.* gives an example as to the value of this technology in elucidating sites networks for Lesser Flamingo *Phoenicopterus minor*);
  - Initial conservation focus on a series of 'high profile species';
  - Monitoring, research and conservation of threatened species (Young's description of research on the ecology of Madagascar Teal *Anas bernieri* is a good example of what is needed); and
  - Development of AFRING.

## Conservation dilemmas for intra-African migratory waterbirds

### ABSTRACT

Africa is a vast and diverse continent, rich in coastal and inland wetlands, permanent and temporary, tropical and temperate. Waterbirds in Africa have developed diverse strategies to exploit this wetland diversity. Some species are largely sedentary, especially those in relatively static tropical climates. However, most demonstrate movements in response to changing seasons and environmental conditions. The onset of rain is an important trigger for migration within Africa. Some waterbirds are harbingers of the rainy season, whilst others follow in the wake of rain. However, levels and timing of rain can be unpredictable, and rain may not fall at all in some years. When rain falls in arid and semi-arid areas, productive temporary wetlands can appear overnight, and attract large numbers of waterbirds, many of which display some nomadic tendencies. This unpredictability presents difficult management scenarios. Overall, waterbird movements within Africa are poorly understood, and there are few clearly identifiable “named” flyways. This directly limits our abilities to conserve waterbirds in Africa, and to implement the African-Eurasian Migratory Waterbird Agreement. It will take major resources and many years before we have clear pictures of waterbird movements within Africa. Yet conservation measures are needed now, especially for those species in decline.

### INTRODUCTION

This paper constitutes a desk-study review of the movements of waterbirds within Africa, drawing on published references, analyses of African Waterbird Census (AfWC) data and observations. As these movements are poorly understood, we aim to illustrate some intra-African migratory strategies and behaviours, and use these to draw up recommendations for conservation purposes and, in particular, improved implementation of the African-Eurasian Migratory Waterbird Agreement (AEWA) in Africa.

### METHODS

The methodological process of the review was to identify potential conservation dilemmas for migratory waterbirds in Africa and, as far as possible, to illustrate in the “results” the migratory strategies adopted by waterbirds in relation to these dilemmas and to Africa’s geography and climate, whilst the focus of the discussion is on drawing up recommendations. However, the first dilemma concerns definitions, and is best considered under the methodology.

#### Dilemma 1: Definition disorders

**Waterbird:** The Convention on Wetlands (Ramsar, 1971) defines “waterfowl” as species of birds that are ecologically dependent upon wetlands, and “waterbird” as being synonymous with “waterfowl” (Wetlands International 2002). Rose & Scott (1994) define “waterfowl” more precisely as all species of 32 families,

essentially comprising the main waterbird groups falling between the Gaviidae (divers) and the Rhynchopidae (skimmers) following the traditional sequence of bird families (Morony *et al.* 1975). This group of families is noted, non-exclusively, by the Convention on Wetlands for application of waterbird criteria, although not all their members are wetland-dependent, such as the Crowned Plover *Vanellus coronatus* and coursers. Conversely, there are wetland-dependent birds in other families, such as the Osprey *Pandion haliaetus*, and some kingfishers, coucals and warblers.

#### Migration, nomadism and “wintering”:

Using the definition of the Convention on the Conservation of Migratory Species of Wild Animals, “migratory species” refers to “the entire population or any geographically separate part of the population of any species or lower taxon of wild animals, a significant proportion of whose members cyclically and predictably cross one or more national jurisdictional boundaries”. In terms of migratory waterbirds, the northwards and southwards movements of birds breeding in the Northern Hemisphere during the northern summer and spending the northern winter further south are arguably the most clearly understood and fit within this definition very well. Intra-African movements are often less clear, as they are sometimes neither cyclical nor predictable. Several species usually referred to as “migrants” in Africa are essentially “nomads” or “dispersers”, whilst many often described as “residents” do perform regular migrations within Africa. Waterbirds have developed a range of strategies to survive Africa’s changing seasons and to exploit temporary habitats, most usually linked to rainfall.

The term “migratory species” can also be misleading, as some species have both discrete migratory and sedentary populations. An example is the Eurasian Spoonbill *Platalea leucorodia*, which has four populations occurring in Africa. Two are migratory populations breeding in Europe and spending the northern winter in Africa, whilst there are also two (largely) resident populations, *balsaci* in coastal Mauritania and *archeri* in the Red Sea and Somalia.

**Intra-African migration** is generally accepted to refer to movements within Africa. In this paper, intra-African migration is considered as “the movement of birds within Africa and around its coastline according to local triggers and continental weather patterns, especially rainfall”. Movements between the African continent and its outlying islands are also considered here.

**Nomadism** is displayed by animals that move irregularly; nomads are wanderers, though their movements away from and to particular areas may be predictable, usually relating to climatic conditions.

**“Wintering”** is a term that is widely used to describe birds temporarily residing in areas during winter, usually the northern

winter. It is often more widely applied, such that “wintering areas” are taken to be the main places of residence when not breeding. As there are two winters in Africa (north and south of the equator) and no winter at all in the tropics, the term is very misleading in an African context, where most movements of birds bear no relation to winter as such. “Non-breeding” is proposed here as an alternative term for “wintering”.

## RESULTS

### Dilemma 2: Complicated arrows (diverse migratory behaviour)

Familiar flyway maps depict migratory routes, mostly in north-south directions and often reasonably well-defined and characterized by bottlenecks, such as the Straits of Gibraltar, coastlines, such as the East Atlantic Flyway, and major rivers, such as the Nile. By comparison, intra-African movements are more complex, with “arrows” in all directions. Some movements occur across a broad front, some are “one-way tickets”, some are of greatly varying lengths, whilst some species disperse widely in a wide range of directions. Recoveries of the Red-billed Teal *Anas erythrorhynchos* ringed in southern Zambia, for instance, are from further north in Zambia, west in Namibia, south in South Africa and Botswana, and east in Zimbabwe (Dowsett & Leonard 2001). Complex movements like these present difficult challenges for waterbird conservation, such as the identification of key sites for different stages in the life cycle.

The main causal factor for waterbird movements within Africa is the availability of food and water, which is principally affected by the climate, notably rainfall. Marine productivity also affects food availability for coastal species. Other factors, such as breeding, altitude, moulting and fire, are all important parts of “the migration equation”, but mostly relate to the underlying importance of food availability. There are several different “migratory behavioural types”:

- **Local movers / short-distance migrants.** Some waterbirds move relatively short distances between a network of key sites. Their migrations are fairly regular and predictable. An example is the sub-population of the Black Crowned Crane *Balearica pavonina* breeding in marshy floodplains of the Casamance of southern Senegal between August and November, then migrating to wetlands of Guinea-Bissau, where numbers peak in January (Diagana *et al.* in prep.).
- **Rains migrants / arid migrants.** This group includes a large number of species for which rainfall or, conversely, dwindling water resources are the principal triggers for movement, as discussed below (Dilemma 3).
- **Nutrition migrants / post-roost dispersers.** Some waterbirds share common night roosts and disperse widely by day in search of food. White Pelicans *Pelecanus onocrotalus* can cover large distances during a single day: in some areas, their roosts may be far from any water source. They are essentially day migrants, flying to distant wetlands daily from secure roosts or breeding colonies. Some large White Pelican roosts or breeding sites, however, are found very close to their main feeding areas, such as those in the lower Senegal Valley, so the need for undisturbed roosts may be the principal factor behind their migratory behaviour.
- **Post-breeding dispersers.** Many birds disperse after breeding and also fall into other “migration categories”, such

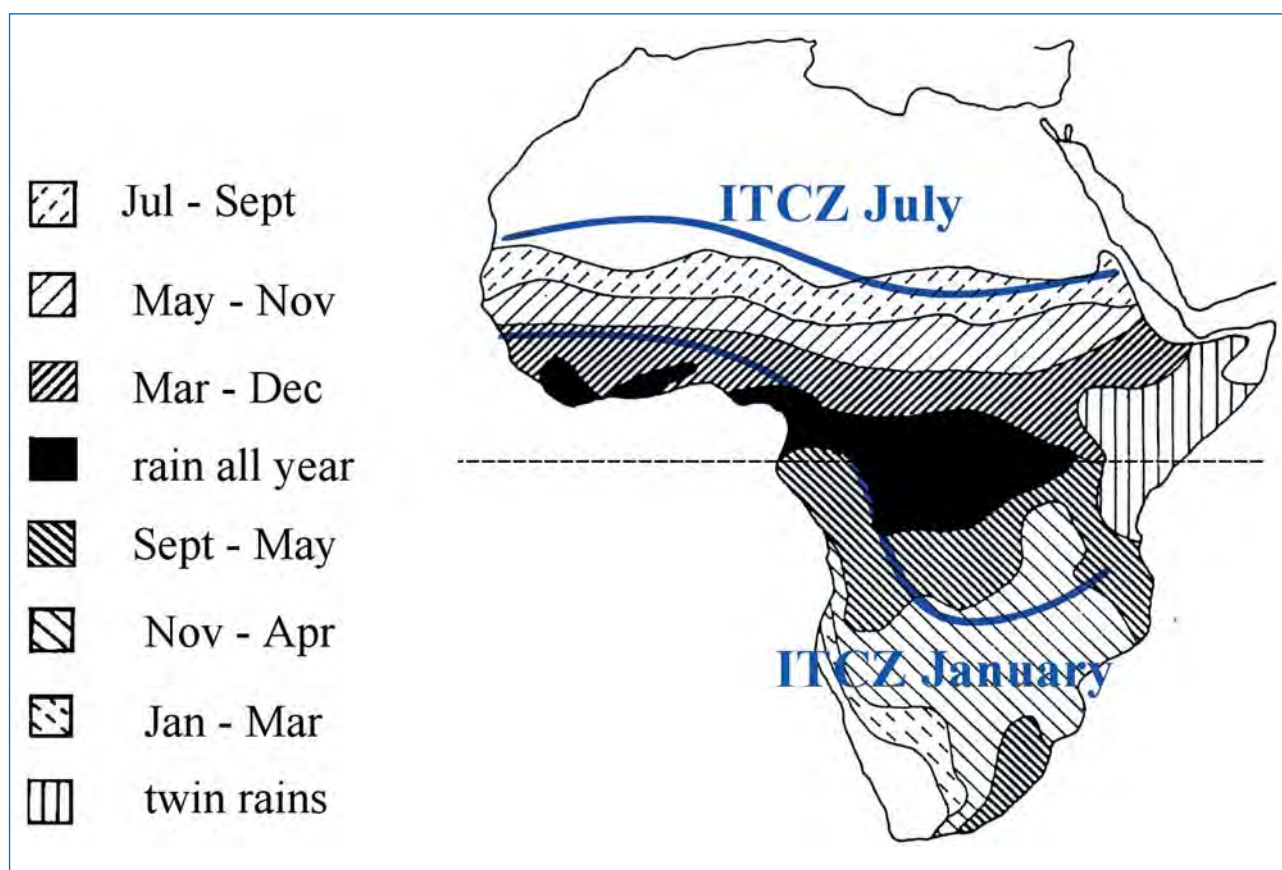

as rains migrants. Some, however, disperse widely away from breeding sites in different directions, an example being the Grey-headed Gull *Larus cirrocephalus*. Ringing recoveries from birds ringed at colonies in South Africa (on the eastern Witwatersrand) show striking dispersal, with movements to Mozambique, Zimbabwe, Zambia, Botswana, Namibia and Angola, and within South Africa to the south-west and east coasts (Underhill *et al.* 1999). It is hard to determine if these constitute migratory movements, as it is not clear if the same birds are returning to breed in the area or colony where they were themselves born.

- **Nomads.** True nomads are not migrants, as they do not move in a cyclical or predictable manner. However, some nomadic movements are predictable to a certain extent, in that they are usually in response to, often irregular, climatic or environmental conditions, for instance in semi-arid areas with irregular rainfall. In such areas, temporary wetlands may attract large numbers of waterbirds, even when they only appear every few years. The Lesser Flamingo *Phoenicopterus minor* can be considered as a nomad, with birds in eastern Africa moving frequently and unpredictably between a series of known key sites in the Rift Valley, as demonstrated by Childress *et al.* (2006).
- **Altitudinal migrants.** Some waterbirds, particularly in eastern Africa, are at least partial altitudinal migrants. One example is the (Eastern) African Snipe *Gallinago nigripennis aequatorialis*, which breeds in highland bogs up to 4 000 m above sea level, from where altitudinal migration takes place to lower-lying and warmer areas during the non-breeding season (Gichuki *et al.* 2000).
- **Environmental response migrants.** Some waterbirds move opportunistically as a result of, sometimes irregular, environmental conditions and local habitat changes. Apart from rainfall, other environmental conditions such as fire and locust eruptions can precipitate movement. Movements of the Lesser Black-winged Lapwing *Vanellus lugubris*, for instance, may in part be dictated by brush fires in some areas, which cause new grass growth suitable for nesting (Urban *et al.* 1986).

### Dilemma 3: Complex rain patterns

The main trigger for intra-African migration of waterbirds is food availability in relation to rainfall. In Africa, rainfall derives primarily from the Inter-Tropical Convergence Zone (ITCZ), where moist maritime air meets dry continental air, along which rain then falls on a broad front (Jones 1995). The movement of the ITCZ north and south across the equator gives rise to the annual pattern of rainy seasons. In general, the broad rainy season north of the equator, including the Sahel zone, is between May and November, and in southern Africa between November and April, with rain in equatorial regions occurring all year round and with a pattern of variable twin rains in eastern Africa (Fig. 1). However, rainfall is not always regular, nor is it reliable in its duration and amount. Sometimes there is no rain at all in semi-arid and arid areas, such as south-western Africa. Rainfall is the major trigger for migration, and some species are trans-equatorial migrants, such as Abdim's Stork *Ciconia abdimi*, which leaves the Sahel after rains and visits eastern and southern Africa as rains begin.

Direct effects of local rainfall are particularly apparent in semi-arid areas, for instance the filling of ephemeral wetlands in

**Fig. 1.** The timing and duration of rainfall in sub-Saharan Africa (Jones 1995). The thick lines show the July (northern midsummer) and January (northern midwinter) positions of the Inter-Tropical Convergence Zone (ITCZ).

semi-arid Namibia and Niger. In Namibia, widespread rains reduce bird numbers at permanent wetlands, when birds disperse widely to newly flooded parts, whilst some breed opportunistically as wetlands fill up. This occurred in 1996/97, when the Common Coot *Fulica atra*, Lesser Moorhen *Gallinula angulata*, Whiskered Tern *Chlidonias hybridus* and Black-necked Grebe *Podiceps nigricollis* bred *en masse* at Nyae Nyae Pan in central north-east Namibia (R. Simmons in Dodman *et al.* 1997). Several species of wetland birds in Namibia directly follow rain fronts, descending onto pans as they fill (Simmons *et al.* 1999). In Niger, isolated temporary wetlands provide an important resource for waterbirds, with the smaller lakes usually having a higher nutrient load and supporting high densities of waterbirds as they gradually dry out (Mullié *et al.* 1999).

Another feature of rainfall that drives the movements of waterbirds is the cycle of flooding and changing water levels of riverine wetlands. This is particularly important in floodplain areas, such as those found on the Niger, Nile and Zambezi rivers. The flooding patterns do not relate so much to local rainfall as rainfall in the headwaters and wider catchments of the rivers. The effect is particularly strong on the middle stretches of the Nile and Niger rivers, where rainfall in the Sahel zone is limited, whilst rainfall in the upper reaches of these rivers is much more significant. This effect of “indirect rain” is important in understanding the movements of birds into and out of extensive wetlands such as the Inner Niger Delta. Here, peak floods occur between November and January (Zwarts & Diallo 2002), several months after the period of peak rainfall from June to August in the upper reaches of the Niger River in Guinea.

#### Diverse rain triggers waterbird movements

Within this dynamic picture of rainfall in Africa, there are different triggers for the movements of waterbirds. These include:

- **Sudden availability of productive wetlands.** This is usually caused by direct rainfall, and is particularly apparent in semi-arid areas, with filling of ephemeral wetlands. Many prey items for waterbirds are prolific at the onset of rains, and ephemeral wetlands can support high biomass densities. In Niger, for example, small lakes tend to have the highest fish production and highest densities of waterbirds (Mullié *et al.* 1999).
- **Rising water levels / flooding.** Rising water levels are attractive for some floodplain waterbirds, especially those that feed on wetland plants and on prey items in swamps. The inundated wetlands and rice-fields of Guinea-Bissau are attractive for some Palearctic migrants such as the Black-tailed Godwit *Limosa limosa*, but they also support good numbers of intra-African migrants, notably herons, egrets, rails and Black Crowned Cranes (Dodman *et al.* 2004). The Wattled Crane *Grus carunculatus* also favours floodplains; its diet includes the tubers of floodplain plants (Meine & Archibald 1996). Conversely, rising water levels drive some waterbirds out of wetlands, especially shorebirds, which lose the habitat of exposed mud or lake edge. Almost the entire Zambian population of Kittlitz’s Plover *Charadrius pecuarius* leaves during high floods (Urban *et al.* 1986), when its preferred semi-arid floodplain habitat becomes inundated.

- **Falling water levels / edge effects.** As dry seasons set in or as floods of major rivers recede, many wetlands start to shrink. This provides rich new food sources for many waterbirds, as previously unobtainable mud-dwelling invertebrates become exposed and as nutrient loads in smaller wetlands increase. As waters gradually recede, feeding conditions are optimal for birds which forage at the water's edge, and wader densities in particular can increase. Predatory species such as the Great Cormorant *Phalacrocorax carbo* and Marabou Stork *Leptoptilos crumeniferus* are attracted to shrinking pools, where concentrations of prey, such as catfish, can become very high. Water levels fall in the Inner Niger Delta mainly between January and April (Zwarts & Diallo 2002), providing optimum feeding conditions for several species of Palearctic-breeding waders. Some intra-African migrants also start to increase in number in the delta from February/March as floods recede, as detailed in van der Kamp & Diallo (1999): Kittlitz's Plover colonizes the dried flats, where it breeds, whilst the Spur-winged Plover *Vanellus spinosus* appears almost as soon as floods start to recede.
- **Lack of rain / increasing aridity.** In semi-arid areas where there are limited permanent water sources such as larger rivers, wetlands are only available for a relatively short period. When these ephemeral wetlands finally dry up, there can be a sudden exodus of waterbirds. In such cases, it is the prevailing arid conditions that act as the trigger for migration, not the onset of rains elsewhere. Some birds exploit the last shrinking wetlands until they dry up completely. There are several ephemeral pools in Botswana's Makgadikgadi System, including Rysana Pan. In January 2001, this pan was dry except for ten remnant pools; some of the last birds to leave here were Kittlitz's Plover, Chestnut-banded Plover *Charadrius pallidus*, Caspian Plover *Charadrius asiaticus* and Little Stint *Calidris minuta*, whilst a pair of South African Shelducks *Tadorna cana* still remained at one dwindling pool (Tyler 2001).

Most of the main rains/water-related triggers for migration, such as flooding, falling water levels and direct rainfall, can thus serve as instigators of arrival or departure. This may be illustrated by comparing the movements of two storks: Abdim's Stork and the African Openbill *Anastomus lamelligerus*. Both are trans-equatorial migrants. Abdim's Stork breeds in the Sahel belt of west-central Africa between May and August and migrates after breeding to eastern and southern Africa, stopping en route in productive feeding areas. Popular migration routes and key non-breeding sites have recently been described by Peterson *et al.* (in press), who tracked storks moving from breeding areas in Niger across to north-west Tanzania and further south, eventually moving back, following the rains north, to the same area to breed. Conversely, the African Openbill breeds mainly in southern and eastern Africa, usually late in the rainy season and into the dry season, with some thence migrating north of the equator, where it is mainly a dry season visitor, arriving after the rains and staying for a good part of the dry season. It also has some irregular mass migrations. The preferred food of Abdim's Stork is grasshoppers, whilst the African Openbill feeds almost exclusively on snails and freshwater mussels. Optimal feeding conditions for Abdim's Stork

are during wet periods, when there is plenty of food available in grasslands and floodplains. It pays for this stork to leave its breeding area as food resources become scarcer during the dry season, and to move into areas just as rains begin. However, for the African Openbill, molluscs are more readily available well into the rainy season and as wetlands start to recede.

One species that is often quick to exploit productive wetlands is the Fulvous Whistling Duck *Dendrocygna bicolor*, which can appear periodically in very large numbers, suggesting that it is highly mobile (Scott & Rose 1996). Whistling-ducks display semi-nomadic tendencies, exploiting diverse wetland habitats such as floodplains, coastal lagoons and ephemeral wetlands, congregating at large wetlands for moulting and feeding. The White-faced Whistling Duck *D. viduata* is also regular within the forest block. The importance of the forest block of Central Africa as a refuge and stopover zone for intra-African migrants is poorly understood.

#### Dilemma 4: Divergent coastal movements Madagascar-Africa migration

A handful of birds migrate between continental Africa and Madagascar. Two are of particularly unfavourable conservation status. The Madagascar Squacco Heron *Ardeola idae* leaves Madagascar around April after breeding and heads for southern and central-southern Africa, where it is mainly present during the dry season. It has declined dramatically, possibly due to competition with the Squacco Heron *A. ralloides*, which appears to be spreading in Madagascar and is more adaptable to man-made habitats (Morris & Hawkins 1998). The Madagascar Pratincole *Glareola ocularis* migrates to coastal eastern Africa, where it is mainly present from April to September. It breeds mostly in eastern Madagascar and migrates to Madagascar's west coast, before uplifting for coastal Tanzania, thence moving along the coastal belt of Kenya to southern Somalia. As the only pratincole to occur in Madagascar, its migratory behaviour may have originated in Africa, in pursuit of suitable breeding localities. Whatever the reason, it is a species in decline (Dodman 2002) and in need of conservation action at key non-breeding sites and in breeding areas.

The Madagascar Teal *Anas bernieri*, however, is a short-distance migrant within Madagascar. After breeding in the mangroves of western Madagascar, this globally threatened duck moves to secluded areas for the moult, and then to wetland refugia during the dry season (Young 2004, 2006); conservation measures must take account of the networks of sites essential to the teal during the different stages of this annual cycle.

#### Coastal migration

There are divergent movements of waterbirds all around Africa's coastline, with varying patterns in West Africa, the Red Sea, the Mediterranean and the Mozambique Channel; but what are the main triggers for movement? A key factor affecting the distribution of many species is the availability of suitable breeding areas. Movement is mainly governed by marine productivity and the life cycles of pelagic fish, with breeding occurring when feeding conditions are optimal near breeding islands, and with subsequent dispersal afterwards in pursuit of profitable feeding areas. The Royal Tern *Sterna maxima* depends on a range of breeding sites in West Africa, mostly low-lying sandy islands, where it breeds in May. Yet estuarine systems and off-shore

sandy archipelagos are fairly dynamic, and some breeding islands may disappear completely in strong seas, as happened recently in Guinea (N. Keita pers. comm.). However, as the terns depend on a network of sites, they can breed elsewhere within a similar area. Indeed, there are regular fluctuations in breeding numbers at several sites monitored in Senegal, The Gambia and Mauritania (Veen *et al.* 2003). After breeding, the terns disperse along the coast. The Caspian Tern *S. caspia* also breeds on similar islands off West Africa, although it differs in having an extended breeding season, enabling birds to be much more flexible in their annual life cycle. Annual variations in timing of breeding of the Roseate Tern *S. dougallii* and Lesser Noddy *Anous tenuirostris* on Aride Island, Seychelles, reflect the unpredictability of food supplies at the start of the breeding season (Ramos & Monticelli in press).

## DISCUSSION

### Conservation management dilemmas

There are a number of difficulties in attempting to manage migratory species and to maintain populations in a healthy conservation status. Such challenges have been widely discussed in the past, and indeed formed the bedrock of international co-operation that led to the creation of the Ramsar Convention on Wetlands. More recently, the AEWA was launched as another vehicle for international co-operation. However conservation of intra-African migrants presents additional difficulties, in particular:

- Many African flyways are diffuse, and not easy to specify.
- Some sites are only important irregularly, e.g. once every few years, especially temporary wetlands.
- Site networks are not always obvious, and may include large numbers of small wetlands or sites that are not used regularly.
- Several species exploit wetlands at different periods and for different reasons, such that sites cannot be maintained in a constant state; rather it is important to permit natural flooding and other cycles.
- Many waterbirds are nomadic and are not faithful to specific routes or annual seasons.
- It is difficult to monitor intra-African migrants: current procedures under the AfWC focused on co-ordinated bi-annual censuses are not effective enough in identifying migratory strategies.
- On a practical level, there are low resources and capacity for conserving intra-African migrants, whilst other issues also influence monitoring, such as inaccessibility and security.

### Recommendations for the conservation of intra-African migrants

The high diversity of “movement strategies” of African waterbirds and the often limited ability to predict movements render their management and conservation quite difficult. The life cycles and movements of most African waterbirds are not precisely known, and the networks of key sites not well determined. In light of this, and taking account the issues summarized above, the following recommendations are proposed:

- 1 Improve our knowledge of the status of African waterbirds and their migratory patterns through:
  - Applied research of weather patterns, site conditions and waterbird seasonality;
  - Extending the AfWC to other seasons and other areas;
  - Use/analysis of existing AfWC and other data to identify site linkages and migratory patterns;
  - Increased adoption of satellite telemetry;
  - Initial conservation focus on a series of “high profile species”;
  - Monitoring, research and conservation of threatened species;
  - Development of AFRING (African bird ringing scheme).
- 2 Identify key sites and site networks for intra-African migrants, especially threatened species.
- 3 Develop Species Action Plans for African waterbirds.
- 4 Promote increased focus on intra-African migrants in the implementation of the AEWA.
- 5 Adopt a precautionary principle; it is often necessary to implement conservation action before knowing the full picture.
- 6 Enhance awareness of African waterbirds, especially their values and ecological roles.
- 7 Highlight the plight and lack of knowledge of threatened African waterbirds.
- 8 Mobilize resources for conservation and monitoring of intra-African migrants, especially through development and subsequent implementation of a Conservation Strategy for African Waterbirds.

## ACKNOWLEDGEMENTS

We acknowledge the support of Wetlands International and the Government of The Netherlands in enabling us to participate in the Waterbirds Around the World Conference. We thank all participants and supporters of the African Waterbird Census. Special thanks to Dr Peter Jones for permission to reproduce the map. Thanks also to Dr Gerard Boere for accepting our rather late submission and to an anonymous referee for constructive comments.

Whittington, P.A., Griffin, J., Bartlett, P., Crawford, R.J.M., Klages, N.T.W., Randall, R.M. & Wolfaardt, A.C. 2006. An investigation into inter-colony movements of African Penguins *Spheniscus demersus*. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 224-225.

The African Penguin *Spheniscus demersus* is endemic to southern Africa, breeding mainly on offshore islands from the coast of central Namibia to Algoa Bay in the Eastern Cape Province of South Africa. The population of this species declined by 90% during the 20th century and it is considered Vulnerable under the IUCN Red Data List criteria. African Penguins visit breeding colonies other than those at which they are known to breed or at which they were born, and are occasionally recorded outside their breeding range (Randall *et al.* 1987, Randall 1989, Whittington *et al.* 2005a).

Breeding colonies of the African Penguin fall geographically into three main groups: the Algoa Bay islands in the Eastern Cape of South Africa, colonies in the Western Cape of South Africa and those in Namibia. These three groups are each about 600 km apart and were used as the three regions in the analysis. A total of 52 260 African Penguins was flipper-banded between 1970 and June 1999 (Whittington *et al.* 2005a). Searches were made for flipper-banded penguins at breeding colonies and the band numbers were read in the field using binoculars or a tele-

scope. Most re-sightings were made between August 1994 and October 1999.

Movements were analysed for birds banded as chicks and for those banded when in adult plumage, attained at 12–22 months of age (Randall 1989). Those banded as chicks were further separated into birds re-sighted when two years old or younger and those re-sighted when over two years of age. A movement was defined as the outward journey away from the breeding or natal colony; most birds later returned to their colony. Movements to the west and/or north were termed as “clockwise” while those to the south and/or east as “anticlockwise”. The proportions of birds moving in each direction from each region were calculated, along with the numbers moving between regions.

Between 1970 and 1999, 42 267 re-sightings were made of 10 470 banded birds and a further 1 217 birds were recovered dead. Of the birds banded as chicks that were re-sighted, 35% were recorded away from their natal colony and 9% of adults re-sighted had also visited colonies other than the one at which they were known to breed.

**Table 1.** Directions of movements of chicks re-sighted away from the natal colony when two years old or less and when greater than two years old. Z-values are positive for clockwise movement or negative for anticlockwise movement. Values greater than 1.96, or less than –1.96, shown in bold type, are significant at the 5% level.

	Clockwise		Anticlockwise		Z-value	
	≤ 2 years	> 2 years	≤ 2 years	> 2 years	≤ 2 years	> 2 years
Eastern Cape	102	22	1	18	<b>9.95</b>	0.63
Western Cape	96	209	86	155	0.74	<b>2.83</b>
Namibia	85	118	111	113	-1.86	0.33

**Table 2.** Movements of chicks between breeding regions; re-sightings made when two years old or less and when over two years old.

	To					
	Eastern Cape		Western Cape		Namibia	
	≤ 2 years	> 2 years	≤ 2 years	> 2 years	≤ 2 years	> 2 years
Eastern Cape	11	25	89	13	2	2
From Western Cape	2	4	160	328	19	32
Namibia	0	2	12	54	184	175

African Penguins banded in the Eastern Cape Province showed a marked clockwise movement around the coast during their first two years of life. This was less pronounced in birds re-sighted when over two years of age, although birds of this age group banded in the Western Cape did show a significant clockwise pattern of movements (Table 1). Birds banded as adults in the Eastern Cape also showed a significant clockwise movement ( $Z = 4.09$ ,  $P = < 0.05$ ). Adults banded in the Western Cape and in Namibia exhibited mainly anticlockwise movements but these were not statistically significant.

Most movements were made to other colonies within the natal region (Table 2) or, in the case of adult birds, to other colonies within the region of their breeding colony. However, 87% of the birds banded as chicks within the Eastern Cape and recorded at other colonies when aged two years or younger were recorded at colonies in the Western Cape and two were found in Namibia.

Of 598 birds that were banded as chicks and subsequently recorded breeding, 514 (86%) were breeding at their natal colony (Whittington *et al.* 2005b). Most of the remaining 84 birds settled to breed at non-natal colonies within their natal region. Most emigrants from Namibian colonies were found breeding in the Western Cape.

Nine birds, eight of which were banded in adult plumage, were reliably recorded breeding at more than one locality. The ninth bird, banded as a chick, was first recorded breeding at its natal colony (Robben Island) before apparently emigrating to nearby Dassen Island two years later (Whittington *et al.* 2005b).

This study confirms that in their first two years of life African Penguins disperse away from their natal colonies and may travel considerable distances. Birds from the Eastern Cape moved west towards nutrient rich areas around Agulhas Bank and in the Benguela upwelling system off the West Coast. Pelagic shoaling fish such as Sardine *Sardinops sagax* and Anchovy *Engraulis encrasicolus*, which form the major part of the African Penguin's prey, are abundant in these areas (Randall *et al.* 1987, Randall 1989). Most African Penguin colonies in the Western Cape lie within the Benguela upwelling system or on Agulhas Bank, while those in Namibia are situated within the Benguela upwelling system, giving birds in these regions the possibility of finding adequate food resources in either direction. Adult birds were less likely to be seen at other colonies than young birds, and the distances travelled tended to be shorter. It is likely that most of the journeys made by adults were foraging trips.

Most African Penguins banded as chicks returned to their natal colony to breed, which is the normal pattern for this species (Randall *et al.* 1987). Those that emigrated were thought to have done so in response to a change in distribution and abundance of prey species (Crawford 1998, Whittington *et al.* 2005b). This study provides the first documented evidence of African Penguins breeding at more than one locality. The eight birds banded as adults that did so were all survivors of the *Apollo Sea* oil spill and had been cleaned and subsequently released by the Southern African Foundation for Conservation of Coastal Birds (SANCCOB). Five of them made their first breeding attempt within a year of being cleaned. It is possible that the trauma of oiling, petro-chemical poisoning and stress undergone during the rehabilitation procedure, caused the birds to be disorientated, resulting in them attempting to breed at a colony other than the one at which they finally chose to settle.

Support from British Petroleum, Chicago Zoological Society, the Darwin Initiative, Earthwatch Institute, International Fund for Animal Welfare, Marine Living Resources Fund, National Research Foundation, WWF South Africa and a Jagger scholarship from the University of Cape Town is gratefully acknowledged. Western Cape Nature Conservation Board, South African National Parks, Robben Island Museum, The Department of Correctional Services and Eastern Cape Nature Conservation gave permission and arranged accommodation for work at penguin colonies under their administration. The Marine and Coastal Management section of the Department of Environmental Affairs and Tourism, the South African Defence Force, Robben Island Museum, The Department of Correctional Services, Wilfred Chivell, Port Elizabeth Museum and Portnet provided transport to offshore islands. We thank all those who contributed re-sightings to the penguin database.

## Anatidae numbers and distribution in West Africa in winter

Bertrand Trolliet & Olivier Girard

Office National de la Chasse et de la Faune Sauvage, F-85340 L'Île d'Olonne, France. (email: bertrand.trolliet@oncfs.gouv.fr)

Trolliet, B. & Girard, O. 2006. Anatidae numbers and distribution in West Africa in winter. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 226-227.

In West Africa, the largest wetland areas are associated with large hydrographic basins. This paper summarises recent information on wintering Anatidae numbers in three large wetland systems in West Africa, from west to east, the Senegal Delta, the Inner Niger Delta and the Lake Chad Basin.

The Senegal Delta (Senegal and Mauritania), is very artificial with dams, canalisation of the river, and rice field developments; the estimates of Anatidae numbers are based on annual counts made between 1990 and 2001. The Inner Niger Delta (Mali), is a large area seasonally flooded by the overflow of the Niger river; aerial counts were made in this area in January 1999, 2000 and 2001. The Lake Chad basin (Chad, Cameroon, Nigeria, Niger), consists of Lake Chad itself, the Logone floodplain and numerous seasonal wetlands situated close to the Chari river, and Lake Fitri. Aerial counts were made in this area in the winters of 1999-2000 and 2003-2004.

Overall, the numbers of Palearctic ducks counted in these three major wetlands averaged 240 000 for the Senegal Delta, 610 000 for the Inner Niger Delta, and 500 000 for the Lake Chad Basin. During the winter of 1999-2000, the total number of Palearctic ducks counted simultaneously in the three areas was 1.7 million birds. Taking into account censuses made elsewhere in West Africa, and those areas not censused, it is estimated the regional Anatidae population numbers are 2 - 2.5 million birds.

In all areas, the Garganey *Anas querquedula* was the most abundant Palearctic duck, forming on average nearly 80% of the total population. The average number counted in the three main areas amounted to a little over one million birds, and the total regional population number is probably over 1.5 million. The Northern Pintail *Anas acuta* represents c. 20% of Palearctic ducks and its regional number is now probably less than 500 000. The Northern Shoveler *Anas clypeata* is abundant only in the Senegal Delta, with 19 000 birds. Among the other Palearctic ducks, Common Teal *Anas crecca*, Eurasian Wigeon *Anas penelope*, Common Pochard *Aythya ferina* and Tufted Duck *Aythya fuligula* and, in rarer cases, Common Shelduck *Tadorna tadorna*, are only present in small numbers. However, the recent counts made in Mali and Chad, found unexpectedly high numbers of Ferruginous Ducks *Aythya nyroca*, with up to 14 000 in Mali and 8 500 in Chad.

The total numbers of Afrotropical Anatidae counted in these three areas amounted to 31 400 for the Senegal Delta, 55 000 for the Inner Niger Delta, and 180 000 for the Lake Chad Basin. During the winter of 1999-2000, a total of 480 000 Afrotropical Anatidae were counted in the region, including other wetlands. On the basis of what is known of the distribution of these birds, and of the areas covered by these counts, it is estimated that the total regional Afrotropical Anatidae population is approximately 700 000 birds.

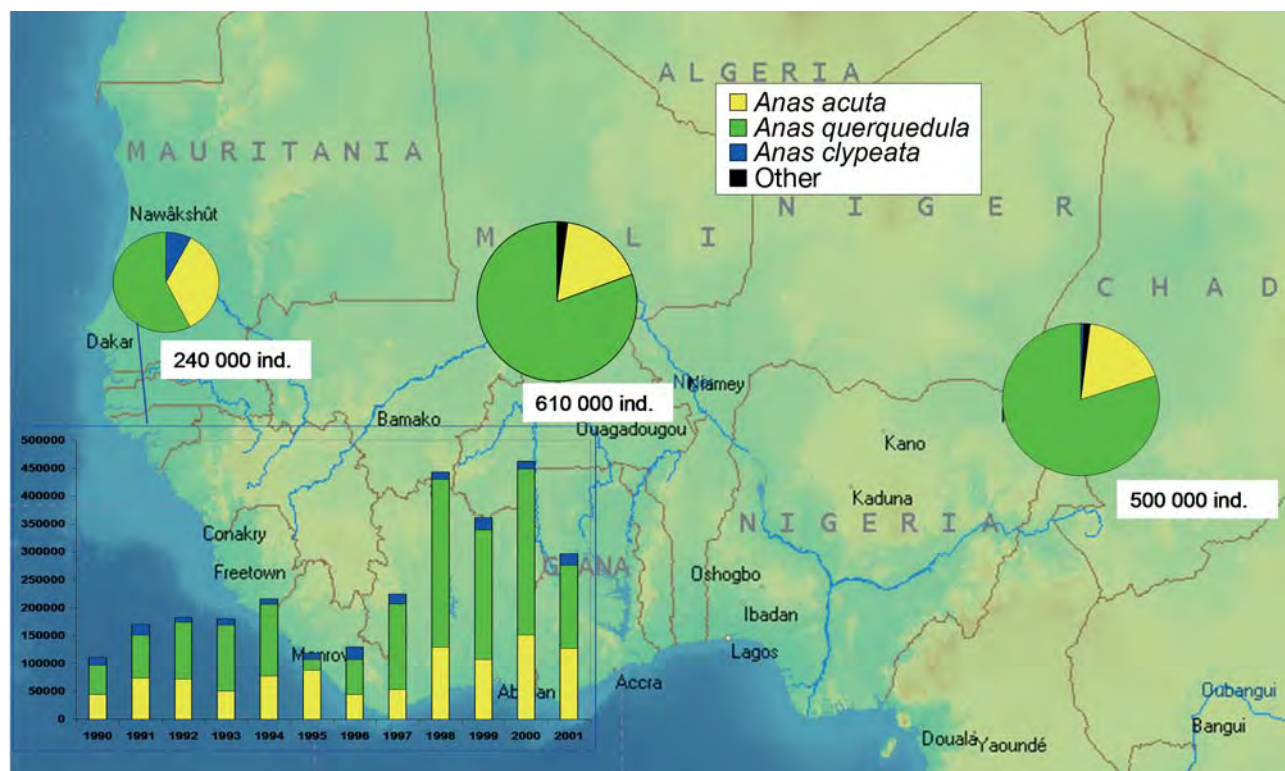

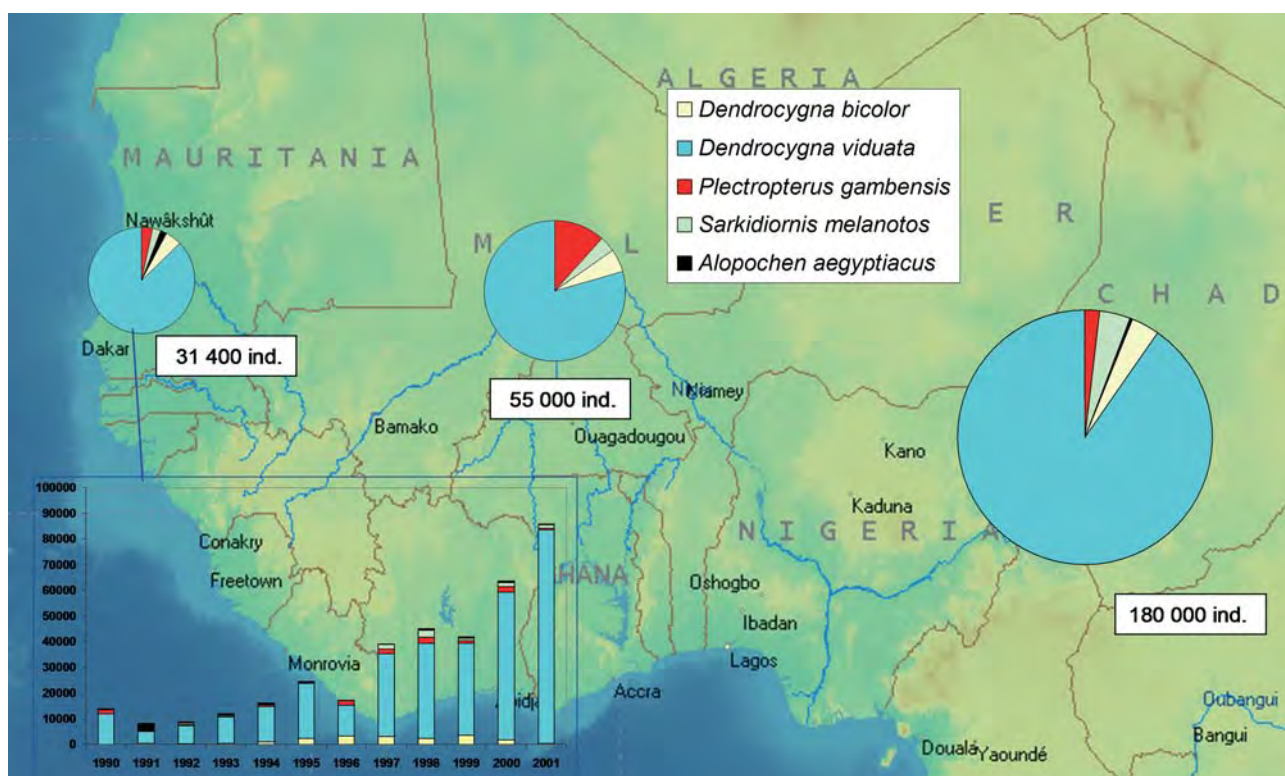

Fig. 1. Average numbers of Palearctic Anatidae counted in recent years in three main wetland areas of the Senegal Delta, the Inner Niger Delta and the Lake Chad Basin.

**Fig. 2.** Average numbers of Afrotropical Anatidae counted in recent years in three main wetland areas of the Senegal Delta, the Inner Niger Delta and the Lake Chad Basin

The White-faced Whistling Duck *Dendrocygna viduata* is the most abundant species in all three major areas, representing c. 85% of the total. Other Afrotropical Anatidae present are Fulvous Whistling Duck *Dendrocygna bicolor* (5%), Comb Duck *Sarkidiornis melanotos* (5%), and Spur-winged Goose *Plectropterus gambensis* (4%). The Egyptian Goose *Alopochen aegyptiacus* and African Pygmy-goose *Nettapus auritus* also occur but are uncommon (Fig. 2). Further information on numbers of Anatidae and other waterbirds in West Africa is provided by Dodman & Diagana (2003) and Trollet *et al.* (2003).

## Anatidae wintering in the Inner Niger Delta, Mali

Olivier Girard

Office National de la Chasse et de la Faune Sauvage, F-85340 L'Île d'Olonne, France. (email: o.girard@oncfs.gouv.fr)

Girard, O. 2006. Anatidae wintering in the Inner Niger Delta, Mali. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 228-229.

In January 1999, 2000 and 2001, aerial counts were made in the Inner Niger Delta in Mali. Aerial counts are the only method for surveying such a vast (c. 35 000 km<sup>2</sup>) and inaccessible area as the Inner Niger Delta in a relatively short time span. The surveys required 40 to 50 flight-hours to count 85% to 90% of the flooded areas containing Anatidae.

Ten species of Anatidae were observed. Six were Afrotropical species: Fulvous Whistling Duck *Dendrocygna bicolor*, White-faced Whistling Duck *Dendrocygna viduata*, Egyptian Goose *Alopochen aegyptiaca*, Spur-winged Goose *Plectropterus gambensis*, Knob-billed Duck *Sarkidiornis melanotos* and African Pygmy-goose *Nettion auritus*, and four were Palearctic: Garganey *Anas querquedula*, Pintail *Anas acuta*, Northern Shoveler *Anas clypeata* and Ferruginous Duck *Aythya nyroca*. Numbers varied from 10 600 to 77 600 for Afrotropical species and from 258 000 to 922 600 for Palearctic species (Table 1).

The most numerous Afrotropical Anatidae were White-faced Whistling Duck (more than 70 000 in 2001), Fulvous Whistling Duck (almost 8 000 in 2000) and Spur-winged Goose (almost 6 000 in 2000). The most numerous Palearctic species were Garganey (almost 745 000 in 2001) and Pintail (almost 165 000 in 2001).

The majority of the birds were north of latitude 14°30'N, in the largest area of inundation in the Inner Niger Delta; an area with the largest lakes, a very large number of inundated depres-

sions, many backwaters and rivers, and extensive floodplains. Among the 1 380 flocks of ducks that were counted, 605 were single-species flocks. Spur-winged Goose and Garganey were the two species most often encountered in monospecific flocks, whilst Knob-billed Ducks were almost always associated with at least one other species.

Comparison between the numbers counted during the three years of this study and those from counts made at the beginning of the 1970s shows very great fluctuations in population numbers for all species (Table 2). However, with the exception of the Northern Shoveler, a species that seems to be declining considerably in numbers, there is no trend for any of the other species. Between 10% to 50% of wintering Anatidae estimated to be present in West Africa are found in the Inner Niger Delta (Table 3). This region is of major importance for the globally Near Threatened Ferruginous Duck, with 8 000 to 15 000 birds wintering on just a few lakes situated in the northwestern part of the delta.

There was no relationship between the degree of inundation of the Delta and total population numbers ( $r = -0.10$ ), the numbers of Afrotropical Anatidae ( $r = -0.02$ ) or Palearctic Anatidae ( $r = -0.11$ ) (Fig. 1). The best year, 1978, and the worst, 1974, were observed with similarly low water levels. The difference between the maximum and minimum numbers counted between 1999 and 2001, under quite similar flooding conditions, was a factor of four.

Mlingwa, C. & Baker, N. 2006. Lesser Flamingo *Phoenicopterus minor* counts in Tanzanian soda lakes: implications for conservation. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 230-233.

### ABSTRACT

Counts of the Lesser Flamingo *Phoenicopterus minor* in Tanzanian soda lakes have been carried out since the 1960s. We present here data on population estimates for this species in Tanzania. Despite the sporadic nature of the counts, the available data indicate the nomadic nature of this species within the soda lakes in northern Tanzania. The lowest number of birds recorded was 68 163 in 1969, and the highest, 2 759 026 in 1995. The total population of the Lesser Flamingo in East Africa may be at least four million birds, if data from Kenya are included. It is evident from the data currently available that a full set of soda

lakes, regardless of size, is necessary in order to secure the conservation of the Lesser Flamingo in East Africa.

### INTRODUCTION

The Lesser Flamingo *Phoenicopterus minor* occurs in eastern, southern and western Africa, as well as in Pakistan and north-western India. In East Africa, the Lesser Flamingo is a characteristic bird of soda lakes in the Rift Valley where it is highly gregarious and nomadic (Britton 1980, Zimmerman *et al.* 1996). The East African Rift Valley lakes may host about 95 percent of the total world population of this species, which is estimated at

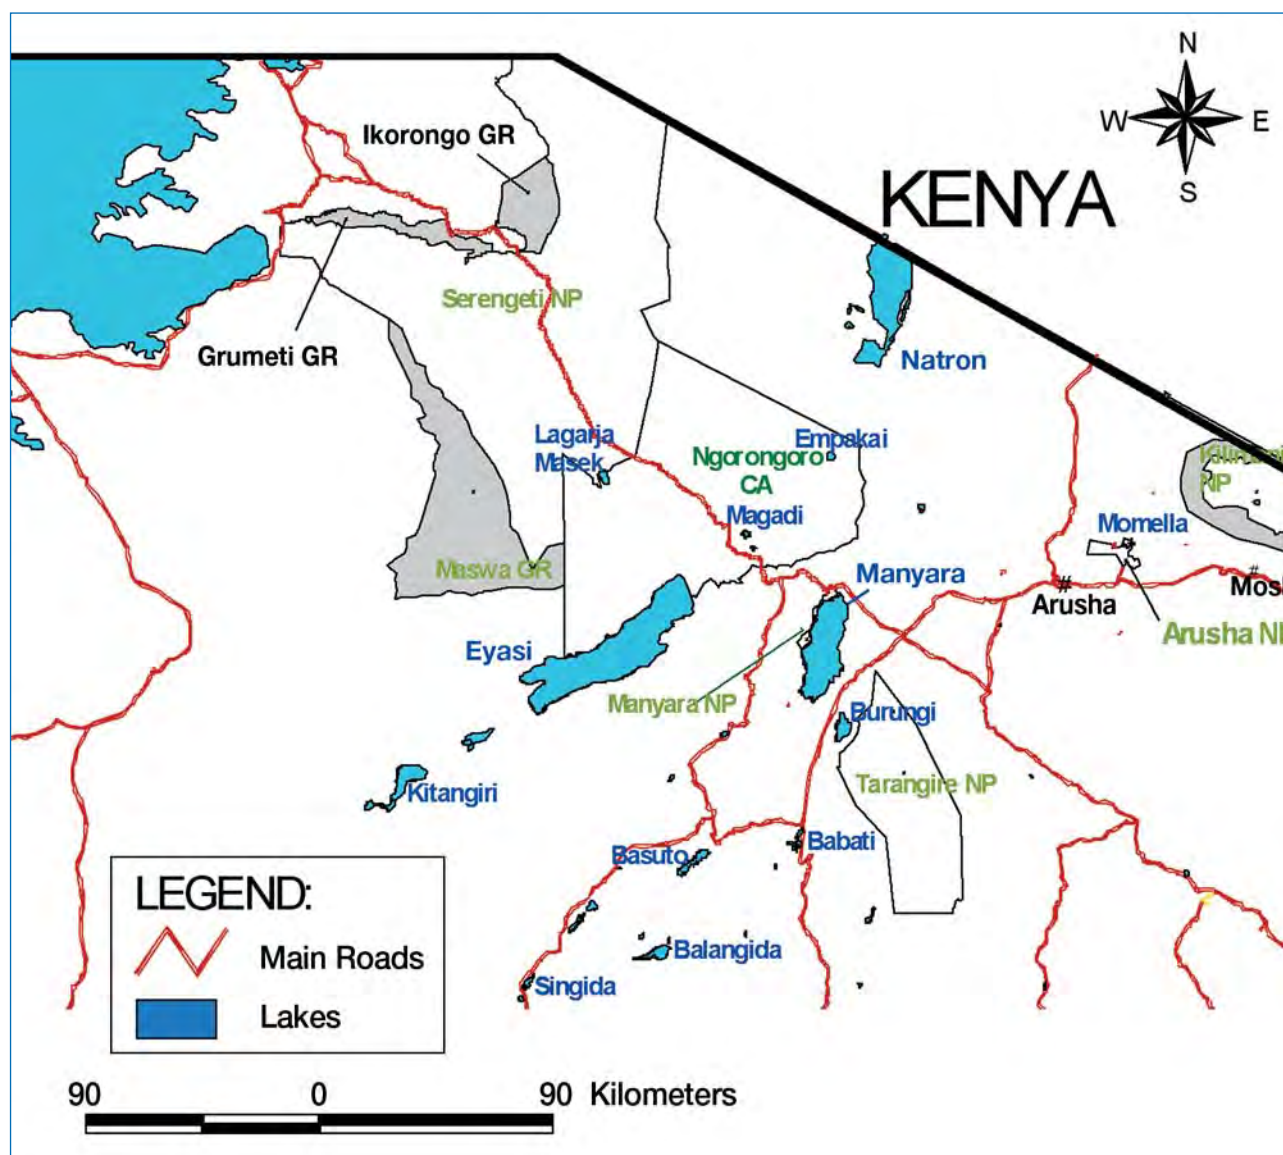

Fig. 1. Soda lakes in northern Tanzania.

**Table 1.** Counts of the Lesser Flamingo *Phoenicopterus minor* at soda lakes in Tanzania during the period 1969-2004. The numbers preceding the year indicate the months in which the censuses were carried out.

about 3-4 million birds (Baker 1996, Njaga & Githaiga 1999). Lake Natron is the main and only regular breeding site in East Africa for this species, with nesting recorded most frequently during the dry period from August to November (Brown & Root 1971, Brown & Britton 1980). The Lesser Flamingo is considered to be Near Threatened globally because of its restricted distribution and the loss of habitat as a result of siltation in some of the soda lakes (Collar *et al.* 1994). It has been the subject of a number of censuses dating back to the 1960s (Bartholomew & Pennycuik 1973), but these censuses have been sporadic, even at individual sites. The aim of this paper is to present an overview of the census data collected in Tanzania during the period from 1969 to the present. We use these data to assess the importance of each of the soda lakes and the implications for the conservation of this species.

## METHODS

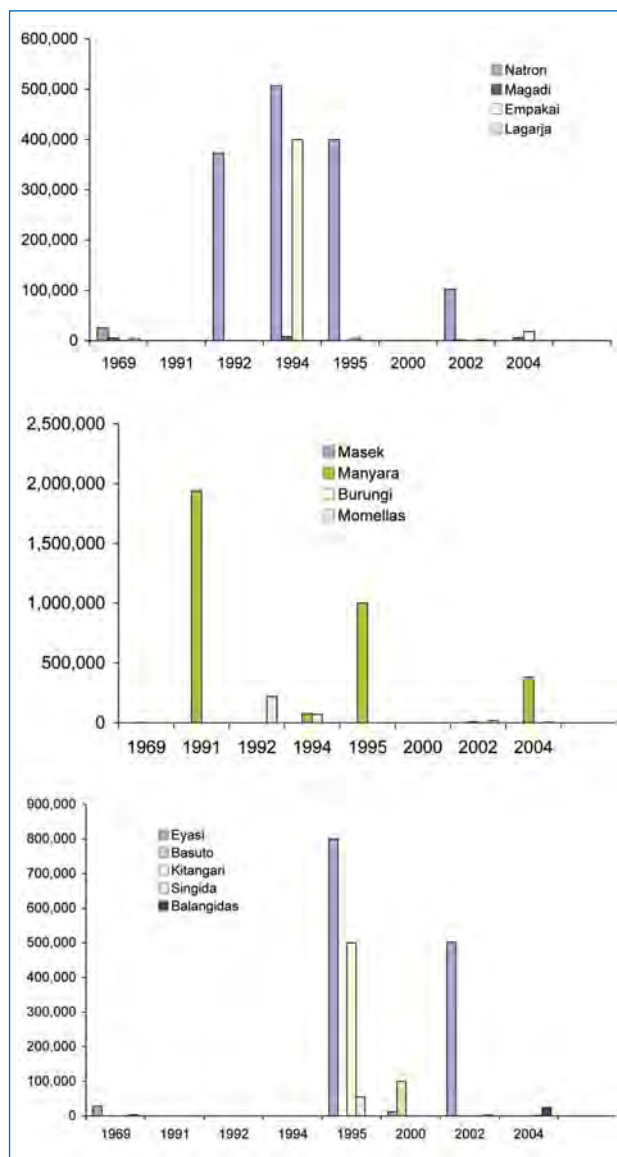

Data on the numbers of Lesser Flamingos at various soda lakes (Fig. 1) are derived from aerial censuses carried out in 1969, 1991, 1992, 1994, 1995, 2000 and 2002 using the Aerial Point Survey technique (Northon-Griffiths 1978), and total ground counts (Bibby *et al.* 1998) in 2000 at Basuto lake only, in 2002 at the Momella lakes only, and in 2004 at all lakes counted in this year. Each site was counted in a single day. The census data are scattered in the published literature (e.g. Bartholomew & Pennycuik 1973, Baker 1996, Baker & Baker 2002), as well as in unpublished reports at the Conservation Information and Monitoring Unit of the Tanzania Wildlife Research Institute in Arusha, Tanzania. In all cases, total counts were obtained either by counting birds on the spot during ground surveys, or by counting birds in photographs taken during aerial surveys (Norton-Griffiths 1978). At no time of year, however, did the censuses cover all of the soda lakes indicated in Fig. 1, even in those years when extensive surveys were carried out (1969, 1994, 1995, 2002 and 2004).

## RESULTS

Table 1 lists the 13 soda lakes in northern Tanzania where flamingo counts were carried out during the period 1969-2004. However, in none of the years was there a complete survey of all the lakes. Furthermore, the counts in any one year were not carried out on the same day. Thus it has never been possible to gain a complete picture of the occurrence of Lesser Flamingos at the study lakes at any one time. Despite these limitations, it is evident that high numbers of Lesser Flamingos were present in Tanzania in 1991 and 1995, with populations of nearly two million (at a single lake, Manyara) in 1991 and three million in 1995 (Fig. 2). The lowest numbers were recorded in 1969, although eight lakes were surveyed, and 2000, when only three lakes were surveyed. The occurrence of Lesser Flamingos at each of the 13 soda lakes surveyed during the period 1969 to 2004 is indicated in Fig. 3. Numbers ranged from none at many lakes to nearly two million at a single lake (Lake Manyara). In all five surveys at Lake Natron, Lesser Flamingos were present, albeit in widely varying numbers (Fig. 3). Seven of the 13 soda lakes held 100 000 or more Lesser Flamingos on at least one occasion (Table 1 & Fig. 3). These seven included two of the

**Fig. 2.** Population estimates of Lesser Flamingo *Phoenicopterus minor* in Tanzania during the period 1969 to 2004. The figure with each bar indicates the total number of soda lakes surveyed.

**Fig. 3.** Counts of the Lesser Flamingo *Phoenicopeterus minor* at various soda lakes in Tanzania. Only those years in which surveys were conducted are included. Lake Lagarja includes Lake Masek.

smaller lakes, the Momella Lakes and Lake Empakai, which held as many as 220 000 and 500 000 birds, respectively. No similar concentrations were recorded at the other small lakes.

## DISCUSSION

According to the census data currently available, the distribution of the Lesser Flamingo in Tanzania is restricted to soda lakes within the Rift Valley and Volcanic Highlands in the northern part of the country. It is possible, however, that other saline lakes, such as Lake Rukwa in south-western Tanzania, may also hold populations of this species (Baker 1996). Due to their highly nomadic movements, populations of the Lesser Flamingo are hard to estimate within a given region in any one year unless surveys are conducted at all suitable lakes within the space of a few days. Previous rough estimates for Kenya and Tanzania, the stronghold for this species, have been about five million birds (Brown 1959), and more recently, around four million birds (Baker 1996). Assuming that during any given period in January 1995, Tanzania held close to three million birds (see Table 1 & Fig. 2), while there were nearly one million birds in Kenya

(Nasirwa & Bennun 1995), the total population of the Lesser Flamingo in East Africa at that time may have been close to four million birds, particularly if Ethiopia were included. However, the total count of Lesser Flamingos in Kenya and Tanzania on the same day in January 2002 amounted to only about 1.5 million birds (TAWIRI 2002), although no surveys were carried out in Ethiopia at that time. The nomadic behaviour of the Lesser Flamingo is demonstrated by annual fluctuations in the total number of birds counted countrywide, ranging from less than 100 000 birds in March 1969 to nearly three million in January 1995. This situation is further demonstrated by annual changes in numbers at individual lakes. It has been noted that the distribution and abundance of flamingos are related to food supply (Tuite 1981, Burgis & Symoens 1987). Thus, changes in the numbers of flamingos at a particular soda lake during the year and between years may reflect fluctuations in the availability of the food supply. The Lesser Flamingo is specialized for feeding on *Spirulina*, a species of blue-green algae that is found in alkaline water. The abundance of these algae at a particular site may attract large numbers of birds irrespective of the size of the lake, as demonstrated at Momellas and Empakai. Any other factors accounting for the differing abundance of the flamingos among the lakes may be indirect by affecting the food supply. For example, Lagarja and Masek lakes, which are only two kilometres apart, are sometimes diluted to fresh water during years with high rainfall, and become joined together to form a single lake (Baker 1996). Under such conditions, no *Spirulina* can grow and the lakes are avoided by the flamingos.

## Conservation implications

The Lesser Flamingo is a highly nomadic species that is dependent on a range of soda lakes to complete its annual cycle. Changes in the annual counts for the entire country give an indication of the numbers of birds that may be occurring outside Tanzania at certain times. Furthermore, annual changes in flamingo counts at individual sites may indicate changes in the importance of each of the soda lakes both within years and between years. This situation may be caused by changes in the food supply of *Spirulina* at each lake. The soda lakes in Kenya and Tanzania are the most important habitat for the Lesser Flamingo in Africa. However, most of the important lakes in Tanzania are outside the network of highly protected national parks and game reserves. For example, only a portion of Lake Manyara is within the Lake Manyara National Park. Empakai, Lagarja, Masek and the Momella lakes are the only lakes located within highly protected areas. Increased siltation and chemical pollution from agricultural activities pose a major threat to most of the lakes which are not well protected (pers. obs). A similar situation is also found for the soda lakes in Kenya (Nyaga & Githaiga 1999). The two countries should therefore take responsibility for preserving all of the existing soda lakes, regardless of size, in order to ensure the continued survival of this near-threatened species as well as other waterbird species. Any human activities that can be detrimental to the Rift Valley drainage system should be discouraged (Nyaga & Githaiga 1999). No simultaneous counts of Lesser Flamingos have been made in all African countries where soda lakes could be important for this species. Thus estimates of the Lesser Flamingo population for Africa as a whole remain incomplete. We therefore suggest that there be a continent-wide, co-ordinated count of Lesser Flamingos in order to improve our understanding of the

temporal and spatial distribution and abundance of these birds, and hence to assist in the planning of effective conservation action for the species.

An unusually high number of Lesser Flamingos *Phoenicopterus minor* were found dead at Lake Nakuru in 2006. Such, and more serious mortality events, have occurred in the Rift Valley lakes with increasing frequency. The root causes of this mortality remain unknown although it is likely to involve the interaction of environmental factors as well as impacts on the lake ecosystem which combine to influence the susceptibility of flamingos to both toxic and infectious disease. Integrated studies are urgently required better to understand the long-term implications of such die-offs. Photo: Ruth Cromie.

### ABSTRACT

The itinerant Lesser Flamingo *Phoenicopterus minor* is dependent on a network of specialized sites for its survival. To study the movements of individual birds and define this network in East Africa, four adult male Lesser Flamingos were tagged with satellite transmitters (PTTs) at Lake Bogoria, Kenya, in October 2002. During the first 15 months, there was no significant difference in the length of their inter-lake flights. However, there were significant differences in the number of flights and the number of days spent at each stopover. One bird flew 2 964 km, making 20 visits to eight different lakes (mean stay 21.8 days), while another made 18 visits to six different lakes (mean stay 24.1 days), flying 3 012 km. A third bird moved among lakes 70 times, visiting 11 different lakes (mean stay 6.4 days) and flew 7 870 km. The fourth bird's PTT stopped transmitting after 38 days. There were no flights outside East Africa. The flyway for the Lesser Flamingo in East Africa consisted of a 940 km north-south range between Lake Logipi, Kenya, and Lake Bahi, Tanzania. The network of sites used by the study birds consisted of nine alkaline lakes in Kenya and Tanzania. The conservation status of these nine sites varies from well-protected to completely unprotected.

### INTRODUCTION

The Lesser Flamingo *Phoenicopterus minor* is the smallest and most numerous of the world's six flamingo species, and is estimated to number between 2 220 000 and 4 230 000 individuals (Wetlands International 2002). It occurs in four regional populations in Africa and central Asia, the largest of which (2.0-4.0 million birds) occurs on the alkaline lakes of East Africa (Wetlands International 2002). Hundreds of thousands of birds frequently gather on these lakes in Kenya and Tanzania (Brown 1975, Vareschi 1978, Howard 1994), a spectacle that is vital to eco-tourism in this region.

The species is classified by IUCN as Near Threatened, due to its dependence on a limited number of unprotected breeding sites and a narrow range of required breeding conditions that occur irregularly and infrequently (BirdLife International 2000). The East African population is known to have bred successfully at only one location during the past 40 years, Lake Natron in Tanzania, and this lake, on the border with Kenya, is unprotected. Schemes such as the recently proposed soda-ash extraction business and hydroelectric power generation at Lake Natron could result in rapid population declines (BirdLife International 2000).

The Lesser Flamingo is an itinerant species (Evans 1985), moving frequently and unpredictably from lake to lake within the Rift Valley (Brown 1975, Vareschi 1978, Tuite 1979, Brown *et al.* 1982, Tuite 2000), and between salt pans and other wetlands in southern Africa (Borello *et al.* 1998, McCulloch *et al.* 2003), but returning to the same breeding sites. The frequent inter-lake movements have traditionally been thought to be associated with fluctuation in food abundance (Vareschi 1978, Tuite 1979). However, it is not clear that this alone is responsible. At Lake Bogoria, the Lesser Flamingo population can double or halve during periods as short as two weeks, despite a constant density of *Arthrospira fusiformis*, the Lesser Flamingo's primary food in East Africa (Brown 1975, Vareschi 1978, BC unpubl. data). Other hypotheses have included changes in the availability of fresh water, changes in the conductivity of the lake water, movement to breeding sites, and disturbance by predators (Vareschi 1978). However, with the exception of movement to breeding sites, none of these hypotheses seemed viable to Vareschi (1978).

Historically, it was thought that the three African populations of the Lesser Flamingo were separate and that no regular interchange took place (Brown 1973). However, circumstantial evidence has been assembled to show that East African Lesser Flamingos may fly to Botswana and Namibia to breed during periods when the Etosha and Makgadikgadi salt pans are flooded (Tuite 1979, Borello *et al.* 1998, Simmons 2000, McCulloch & Borello 2000), and that there may be interchange between the West African and other African populations (Trolliet & Fouquet 2001). However, very little is known about the movements of individual Lesser Flamingos. The only previous study to use satellite tracking was by McCulloch *et al.* (2003), who followed three Lesser Flamingos in southern Africa.

The primary aim of the present multi-year study was to use satellite tracking to document the flyway and network of key sites used by this Near Threatened species in East Africa during different periods of the year to support the development of an effective international site conservation plan. Secondary aims were to improve understanding of the movements of individual Lesser Flamingos and document whether there was any regular interchange between the East African population and the smaller populations elsewhere in Africa and India.

### STUDY SITE

This study was based at Lake Bogoria in Kenya (0°11'-0°20'N, 36°06'E), located within the Lake Bogoria National Reserve, a

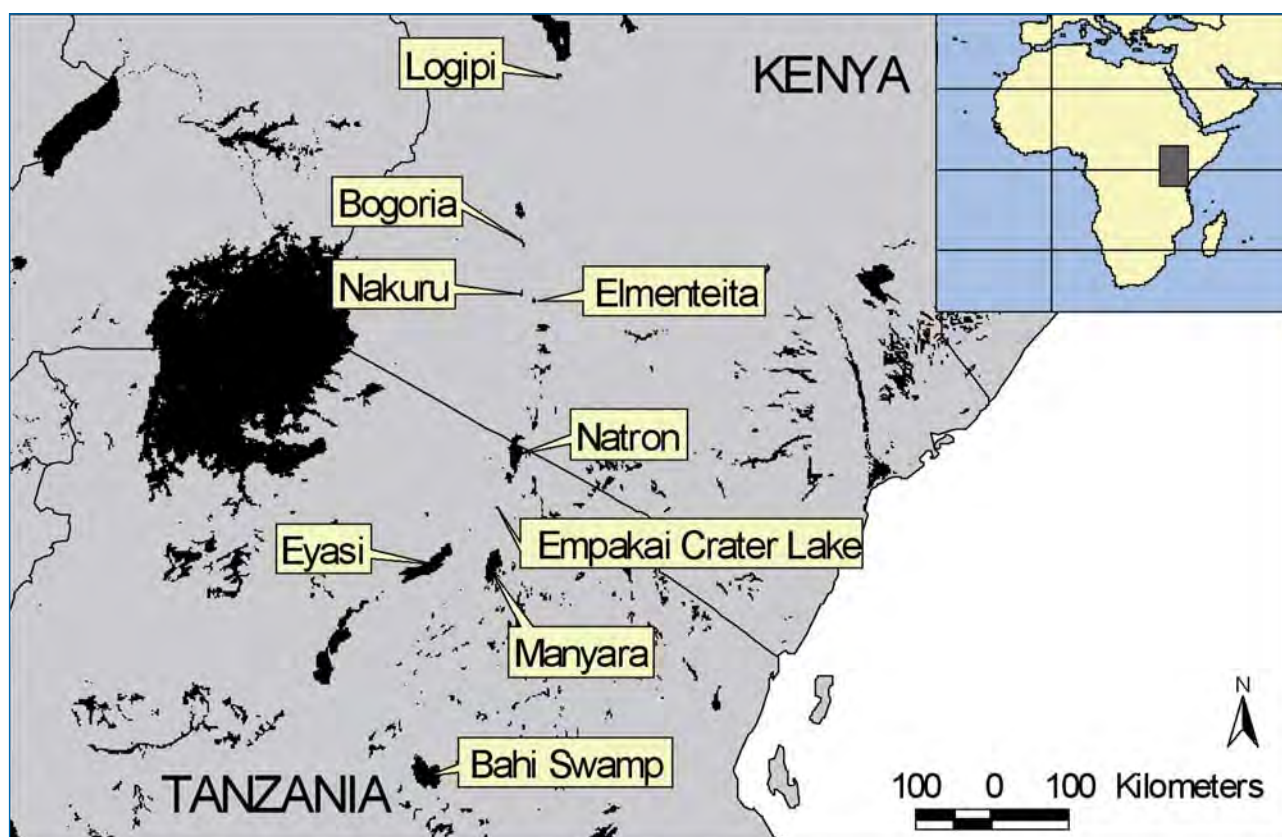

Fig. 1. Key sites for Lesser Flamingos *Phoenicopterus minor* in East Africa: November 2002 – January 2004.

protected area of 10 700 ha (Bennun & Njoroge 1999), 64 km north of Nakuru town in the eastern Rift Valley (Fig. 1). A recently-designated Ramsar site, Lake Bogoria is one of the two main feeding lakes for the Lesser Flamingo in Kenya, and regularly holds several hundred thousand birds. It is a long (16 km), narrow (3 km), shallow (max. depth 10.2 m), alkaline ( $1\,160 \pm 14.2 \text{ meq l}^{-1}$ ) lake with a pH of 10.2–10.3, situated at 975 m above sea level (Harper *et al.* 2003, Vareschi 1978).

## METHODS

In October 2002, four adult male Lesser Flamingos were captured and tagged with satellite transmitters (PTTs): two with solar-powered PTTs and two with battery-powered PTTs. The birds were captured using loops of 50 lb test polyethylene fishing line attached to a 120 x 245 cm grid of 3 mm wire mesh squares (7.5 x 7.5 cm) (Childress *et al.* 2004). Approximately 50 loops were tied to the grid. The grid was placed in the water perpendicular to the shoreline in a shallow, flat area where flamingos gathered and walked back and forth. The birds were captured when their feet became entangled in the loops.

Microwave Telemetry, Inc. supplied the two battery-powered PTTs. They were PTT-100 45 g units with estimated transmission lifetimes of 1 200 hours. The pre-set duty cycle specified for both was eight hours on and 60 hours off, which was estimated to result in operational periods of approximately 15 months. These units represented 2.2% and 2.3% of the body mass of the birds to which they were affixed. The two solar-powered PTTs had been reconditioned by their manufacturers, North Star Science and Technology, LLC, and Microwave Telemetry, Inc., respectively. The duty cycle of the North Star PTT (weight 40 g) was pre-set to be on for eight hours and off for 18 hours. As a test, the Microwave Telemetry PTT (weight 35 g) had no pre-set duty cycle. With no pre-set duty cycle, the PTT shuts itself off when its battery power is low, and then restarts automatically every six hours. If its battery has recharged sufficiently, it continues to transmit; if not, it shuts down for another six hours. These PTTs represented 1.6% and 1.9% respectively of the body mass of the birds to which they were affixed, and were expected to have operational lifetimes of three to five years.

We used a “backpack” harness specially designed for multi-year studies of large birds such as storks and flamingos (Van den

**Table 1.** Summary of number of inter-lake flights, number of different lakes visited, mean number of days spent at each stop, and approximate total distance moved by three satellite-tagged adult male Lesser Flamingos *Phoenicopterus minor* in the Rift Valley, East Africa, November 2002 – January 2004.

Bird	No. inter-lake flights	No. different wetlands visited	Mean days spent at each stop $\pm$ SD (range)	Approx. inter-lake distance flown
Safari	18	6	$24.1 \pm 28.4$ (1–87)	3 012 km
Bahati	20	8	$21.8 \pm 34.1$ (2–137)	2 964 km
Imara	70	11	$6.4 \pm 15.1$ (0–110)*	7 870 km

\* 0 = less than one day

Bossche 2002), consisting of 3 mm braided nylon cord inside a Teflon sleeve (Childress *et al.* 2004). The PTTs were positioned as high as possible on the birds' backs (Fig. 2). We fitted the harness to allow all four fingers of a flat hand to pass easily between the transmitter and the bird.

Argos CLS (Collecte Localisation Satellites) in Ramonville Cedex, France, calculated and reported the locations of the study birds utilizing the National Oceanic and Atmospheric Administration (NOAA) satellite system to receive transmissions from the PTTs. Argos's multi-satellite service was used to enable location calculations from all six satellites that passed over the Rift Valley regularly during the study.

We used locations in Argos's classes 0-3 (0: >1 000 m with no upper limit; 1: 1 000 m; 2: <350 m; 3: <150 m; Taillade 1992), as our purpose was only to identify the lake or wetland being used by the study birds during each transmission period. The length of each stopover visit was determined by subtracting the first date a location calculation was received from that lake (assumed date of arrival) from the first date a location calculation was received from a succeeding lake. We assumed that the date of departure from one lake and date of arrival at a new lake were the same, although this may not have been the case in all instances, as we were unable to tell when a movement was made if it was made when the PTT was in its "off" phase (60 hours out of every 68 hours). In most cases, the distance between the lakes and the quality of the location calculations were sufficient to determine that the bird had indeed moved from one lake to another. However, in some cases, the quality of the location calculations received was too poor to enable us to distinguish between two locations that were fairly close to each other. In these cases, we assumed that the bird had not moved.

Statistical analyses of inter-lake flight distances and lengths of stopovers were conducted with Kruskal-Wallis and Mann-Whitney tests in Minitab Statistical Software, Release 13 (Minitab Inc. 2000), as these data were either counts (length of stopovers) and/or not randomly distributed (both). We named the four birds "Bahati", "Safari", "Imara" and "Bendera" for discussion purposes.

## RESULTS

### Inter-lake movements

Between November 2002 and January 2004, Safari made 18 inter-lake flights, visited six different lakes, spent 24.1 days (SD  $\pm$ 28.4) at each stop (range 1-87 days) and travelled approximately 3 012 km; Bahati made 20 inter-lake flights, visited eight different lakes, spent 21.8 days (SD  $\pm$ 34.1) at each stop (range 2-137 days), and travelled approximately 2 964 km; Imara made 70 inter-lake flights and visited 11 different lakes and wetlands, spent 6.4 days (SD  $\pm$ 15.1) at each stop (range <1-110 days), and travelled

**Fig. 3.** Mean and median lengths of inter-lake flights by three Lesser Flamingos *Phoenicopeterus minor*, with 95% confidence intervals for the means; cross-hair symbols are medians: November 2002 – January 2004.

**Fig. 4.** Mean and median lengths of stopovers by three Lesser Flamingos *Phoenicopeterus minor*, with 95% confidence intervals for the means; cross-hair symbols are medians: November 2002 – January 2004.

7 870 km (Table 1). Bendera's PTT stopped transmitting after 38 days at Lake Bogoria. The movement sensor on the PTT indicated no movement throughout the final day of transmission.

There were no significant differences among the three birds in terms of the length of their inter-lake flights ( $H = 4.76$ ,  $DF = 2$ ,  $P > 0.05$  adj. for ties,  $N_1 = 18$ ,  $N_2 = 20$ ,  $N_3 = 70$ ; Kruskal-Wallis Test), although there was a significant difference between Imara and Safari on this dimension ( $W = 1\ 018.5$ ,  $P < 0.05$  adj. for ties,  $N_1 = 18$ ,  $N_2 = 70$ ; Mann-Whitney Test) (Fig. 3). There were significant differences among the three birds in terms of the number of days spent at each stopover ( $H = 23.5$ ,  $DF = 2$ ,  $P < 0.001$  adj. for ties,  $N_1 = 19$ ,  $N_2 = 21$ ,  $N_3 = 71$ ; Kruskal-Wallis Test), and these differences were between Imara and the other two birds (Fig. 4), as there was no significant difference between Bahati and Safari on this dimension ( $W = 370.5$ ,  $P > 0.05$  adj. for ties,  $N_1 = 19$ ,  $N_2 = 21$ ; Mann-Whitney Test).

### The East Africa flyway and key site network

Ninety-nine percent of all flights by the three study birds were within the Rift Valley along a 940 km range between Lake Logipi in northern Kenya and Lake Bahi in central Tanzania (Fig. 1). There were no flights outside these two countries.

The three birds spent 99.9% of their combined stop over days at nine alkaline lakes in Kenya and Tanzania (Logipi, Bogoria, Nakuru, Elmenteita, Natron, Empakai Crater, Eyasi Manyara and Bahi), and 73.1% on just four lakes (Bogoria, Logipi, Manyara and Nakuru).

## DISCUSSION

### Movements

During the first fifteen months of this multi-year study, the three tagged birds remained within the Rift Valley, travelling north and south along a 940 km range between Lake Logipi in northern Kenya and Lake Bahi in central Tanzania. They spent 99.9% of their combined time on alkaline lakes, Bahati moved between lakes 20 times, Safari moved 18 times, and Imara moved 70 times.

The reasons for these movements are still unclear. The birds moved independently of one another, and it was often the case that one of the tagged birds would depart from a lake within days of another arriving at the same lake, or that another remained on the lake for several days/weeks after the first bird had departed. This phenomenon has become more apparent with the addition of a further four tagged birds to the study in June-July 2003, and indicates that the movements are probably not related to major fluctuations in food availability. There are occasions, such as those reported by Tuite (2000) and Vareschi (1978), where substantial changes in food availability result in large-scale population shifts away from or towards one particular lake. However, these large-scale changes in food availability do not occur overnight (Vareschi 1978), and do not seem to be directly related to the daily arrivals and departures of Lesser Flamingos at a given lake. There may be seasonal patterns in the movements, related either to the rains or the annual breeding season (October-December) at Lake Natron, or both. However, too few data are available to form any conclusions at this stage. Although Lesser Flamingos breed in large numbers at Lake Natron during both the 2002 and 2003 breeding seasons, none of the tagged birds appeared to have made an effort to breed. During October-December 2002, two of the three tagged birds did not visit Lake Natron at all, while the third made seven visits to that lake, all of between one and three days in length.

During October-December 2003, two of the three tagged birds did not visit Lake Natron, while the other visited the lake for 12 days in October and three days in November, but not at all in December. All four tagged birds added to the study in 2003 made one three-day visit to Lake Natron in November, but no visits in October or December. It appears that all of the study birds were non-breeders during these two years.

Although the number and frequency of movements by the three birds differed substantially between Bahati and Safari, and Imara, there was no significant difference in the length of their inter-lake flights. On the other hand, there was a significant difference between Bahati and Safari, and Imara, in the length of their stopovers, even though all three birds spent long periods of time (e.g. 45-137 days) at several different lakes.

The reasons for these differences in movement patterns are as unclear as the reasons for the inter-lake movements themselves. Since Lesser Flamingos rarely fly alone, all of the recorded movements are believed to have been made within flocks of other Lesser Flamingos. This confirms the general view that the Lesser Flamingo is a truly itinerant species. During the 15-month period reported here (and the subsequent period to March 2004), there were no flights outside Kenya and Tanzania, either by the initial three birds tagged or the four tagged birds added to the study in July 2003. Thus the study has provided no direct evidence as yet of any interchange between the East African population and any of the other smaller populations.

Conditions at the Makgadikgadi salt pans in Botswana and at Etosha Pan in Namibia during the 2002-03 breeding season were not conducive to Lesser Flamingo breeding, as it was a drought year and both locations were too dry for nest-building (G. McCulloch & R. Simmons *in litt.*). The 2003-04 breeding season was wetter, and Lesser Flamingo breeding occurred at both locations (G. McCulloch & R. Simmons *in litt.*). However, because there was breeding at Lake Natron during both 2002 and 2003, the finding that the tagged birds showed no interest in breeding at Lake Natron probably indicates that conditions in southern Africa had no effect on the movements of the tagged birds during these periods.

### Key site network: implications for protection and conservation

On a combined basis, the initial three tagged birds spent 99.9% of their time at nine alkaline lakes in Kenya and Tanzania (Logipi, Bogoria, Nakuru, Elmenteita, Natron, Empakai Crater, Eyasi, Manyara and Bahi), and these nine lakes, appear to comprise the key site network for Lesser Flamingos in East Africa. It has been known for many years that these nine alkaline wetlands are important for this species in East Africa (e.g. Bartholomew & Pennycuik 1973). This study documents their relative importance.

The conservation status of the nine lakes varies considerably. In Kenya, Lakes Bogoria and Nakuru are well protected, both being Ramsar sites and Lake Bogoria being entirely within a national reserve, while Lake Nakuru is within a national park. Lake Elmenteita is partly within a private wildlife sanctuary and partly unprotected (Bennun & Njoroge 1999). It is a small lake (1 800 ha) with several tourist facilities around its perimeter. Lake Logipi is completely unprotected and suffers from high levels of insecurity and overgrazing (W. Kimosop pers. comm.).

In Tanzania, the Empakai Crater Lake is well protected, being within the Ngorongoro Conservation Area. However, only

the north-western quadrant of Lake Manyara is within the Lake Manyara National Park. The remainder of the lake, where the Lesser Flamingos congregate most frequently, is outside the park and thus unprotected. Incredibly, Lake Natron, the only successful breeding location for the East African population of Lesser Flamingos during the past 40 years, is also unprotected. This lake has been threatened in recent years by proposals for a major dam and hydroelectric power generation project on one of the major inflows from Kenya and a new soda ash extraction scheme (BirdLife International 2000), and there is currently a proposal for a new tourist lodge and facilities along its shore (N. Baker *in litt.*). Lake Eyasi and Lake Bahi are not protected in any way, and their surrounding areas are under heavy pressure from deforestation, overgrazing and agriculture (Baker & Baker 2002, N. Baker *in litt.*).

In view of the critical importance of these nine sites to the survival of the Lesser Flamingo in East Africa, it seems clear that there is an urgent need to protect those sites that remain unprotected. Proposals for such protection will be included in the forthcoming AENA/CMS Flamingo Conservation Action Plan currently being prepared by the Wetlands International/IUCN-SSC Flamingo Specialist Group, and supported by the findings from this study.

## ACKNOWLEDGEMENTS

This study was conducted under the auspices of the Department of Ornithology, National Museums of Kenya, the Baringo and Koibatek County Councils, and William Kimosop, Senior Warden, Lake Bogoria National Reserve. DH thanks the Ministry for Science and Technology for permission to conduct research in Kenya. In addition to their own organizations, the authors thank the following organizations and individuals for their financial and logistical support: International Flamingo Foundation, Darwin Initiative, Earthwatch Institute, Vodafone Group Foundation, Peter Scott Trust for Education and Research in Conservation, Ms Cicely Port, Mr Anthony Van Nice and Mr Errett Van Nice. We also thank the volunteers in Earthwatch Institute's Lakes of the Rift Valley research programme for their assistance with the fieldwork.

### ABSTRACT

In April 2002, backpack PTTs were fitted to three Greater Flamingos *Phoenicopterus ruber roseus* at two sites in northern Tanzania. To maximise battery life, the transmitters were programmed to send signals for 12 hours at intervals of 192 hours. All three batteries lasted into 2004, having provided more than 24 months of data. This paper maps the recorded movements of the three birds, comments on each individual and raises issues related to the conservation of the species within Tanzania and Kenya.

### BACKGROUND

Satellite transmitters have revolutionised our understanding of large animal movements at the level of the individual (Meyburg & Lobkov 1994, Hughes *et al.* 1998, Stuwe *et al.* 1998). Advances in technology have enabled lighter transmitters to be fitted to an increasing range of species but weight constraints are still a significant issue. However, the most significant drawback remains that of cost. The transmitters alone are far from cheap and the added download and computer time means the technology still remains beyond everyday use. Movements of a few of the larger wetland birds between the Western Palearctic and the Afrotropics have featured in most studies undertaken to date in Africa (Berthold *et al.* 2001). Movements of waterbirds within the Afrotropical Region are still largely conjectural but advances have been made in recent years with long-term studies of Lesser Flamingo *Phoeniconaias minor* in southern Africa (McCulloch *et al.* 2003) and East Africa (Childress *et al.* in press). More recent studies have focussed on Abdim's Stork *Ciconia abdimii* between the breeding grounds in the northern Tropics and wintering grounds south of the equator, mainly in Tanzania (Flemming Pagh Jensen, pers. comm.).

During discussions about knowledge gaps with colleagues at the Max-Planck-Institut für Ornithologie Vogelwarte Radolfzell the possibility arose of redirecting three transmitters from their White Stork project and fitting these to Greater Flamingos. MPI Radolfzell duly provided the transmitters and the download costs while the Tanzanian Bird Atlas Project provided logistical support and capture of the birds. The birds were tagged with

battery powered satellite backpack transmitters. These were PTT-100 platform transmitter terminals (PTTs) from Microwave Telemetry (USA) weighing 45 g. Each unit was programmed to emit a signal for 12 hours duration at intervals of 192 hours. The transmitter was attached to the bird's back as a backpack by a continuous strip of a 3.5 mm nylon rope with the 250 mm antenna angled backwards and free.

The PTTs transmitted with an impulse of 53 seconds, the length of one impulse was about 300 millisecond. Each impulse contained information in code regarding identification number, battery level, temperature and activity. The signals were received 850 km above the earth by NASA-satellites of the TIROS-series and forwarded to the ARGOS ground-station in Toulouse, France. ARGOS then calculated the PTT location using doppler shift analysis and their own algorithms, and the processed data were received at Radolfzell by email.

The Argos computer system assigns a 'location class' (LC) to each data record. Poor weather and low battery conditions can adversely affect signal reception by the satellites and therefore birds can not always be located with the same degree of accuracy. There are seven LCs of which only the four most accurate (from 150 m to 1 km) were used.

### TRAPPING METHODS

Slipknots made from 0.5 mm clear fishing line were attached at intervals of 30 cm to 50 m lengths of nylon rope. These lines were sunk in shallow water in a 'V' formation and held in place by locally occurring stones. The trap lines were under constant surveillance throughout and birds were removed within minutes of being caught. The two females were fitted with metal numbered rings from the East African Ringing Scheme (available rings were not large enough for the male bird) and red plastic rings. Standard measurements including weight were taken from all birds and are given in Table 1.

The transmitter + harness weight of 48 gm represented 1.75%, 2.06% and 2.34% of body weight, well within the recommended limit of 5%.

**Table 1.** Biometric data from the three birds.

Date	Site	Ring	Species	Age	Sex	Weight (g)	Wing (mm)	Tarsus (mm)	Remarks
30/3/02	Manyara	-	<i>Phoenicopterus ruber</i>	AD	M	2750.0	424.0	340.0	27187 - Leo
7/4/02	Magadini	W0902	<i>Phoenicopterus ruber</i>	AD	F	2330.0	380.0	264.0	27188 - Jane
18/4/02	Magadini	W0903	<i>Phoenicopterus ruber</i>	imm	F	2050.0	397.0	275.0	27186 - Paola

The first location of choice was Lake Manyara which is well known to hold significant numbers of flamingos. Much of the northern shallows where the flamingos feed occur outside Lake Manyara National Park and are subject to considerable disturbance from fishermen, tourists and bird catchers (Baker & Baker 2002). During the visit in March 2002 the latter were particularly active, trapping Yellow-billed Storks *Mycteria ibis* from the adjacent active breeding colony and even Blacksmith Plovers *Vanellus armatus* and Chestnut-banded Sandplovers *Charadrius pallidus* for the apparently insatiable export market. Levels of disturbance were such that flamingo flocks were severely agitated and it proved difficult to herd them in the direction of the trap lines. During discussions with one of the bird trappers it was established that several Greater Flamingos had been caught in recent weeks and were being held in a house in Mto wa Mbuu, the nearest village. The Park Ecologist from Lake Manyara National Park, who had accompanied us in the field, quickly located the house and we negotiated to purchase (for only \$10) the largest and healthiest bird from the dozen or so walking around an empty room in a recently constructed house. It is not appropriate to go into detail here concerning the bird trade, but suffice it to say that the smear lines on the walls clearly

We chose not to trap birds within protected areas and it was decided to limit our search to those lakes known to regularly harbour smaller numbers of birds. Magadini is a small, seasonal rainfed alkaline lake between Mounts Meru and Kilimanjaro and barely 10 km from the Momella Lakes within Arusha National Park. This lake is known to hold numbers of both flamingo species on a regular basis. It was also only a few kilometres from our home base at the time on the south-west slopes of Mt. Kilimanjaro.

As this was the first bird caught and tagged and he had been held in captivity for an undetermined number of days, there were obvious concerns about his well-being. However, within minutes

of being released he appeared to be walking and feeding normally within a small flock of some 80 birds. During subsequent observations he was seen to preen the antenna and did not appear to be disturbed by it, the backpack transmitter or the harness. Worthy of note is that he may have spent some 418 days at Bogoria, was the only bird to visit Logipi in the far north near Lake Turkana, and that he did not visit the coast.

The movements of the adult female bird tagged at Magadini are shown in Fig. 2.

This bird was the only one of the three to visit Lake Burungi and may have stayed on this small lake for nearly two months. She was also the only bird to visit Empakai Crater lake within the Ngorongoro Conservation Area, although this was only a single fix so her visit was a short one. Perhaps the most interesting of her movements was the visit to Rasini Bay in coastal Kenya. This single fix indicates a stay of no more than 15 days and it could have been far less than this. Lake Manyara was obviously important to this bird during the two years with a potential long single stay and many return visits.

The movements of the immature female bird tagged at Magadini are shown in Fig. 3.

The long stay of this bird on Lake Manyara seems at first to be quite remarkable. Fixes were so close together for so many weeks that it was feared she had died and we were seeing simple errors in accuracy. Equally, her long stay on the Kenyan coast was also surprising but due to the long intervals between fixes it is not possible to draw firm conclusions from these two long stays as single sites. There is no significant wetland within several kilometres of the fix on the 8 May 2004 and at a time of 13:12 GMT this would not suggest a bird on a long overland flight. Lake Chala, a small steep sided crater lake (unsuitable for flamingos) is some 15 km to the north-east of this fix and Lake Jipe (which would be suitable as a stopover site) is 20 km to the south-east. The shortest distance between Elmenteita and Mida Creek on the Kenyan coast is 520 km but it cannot be stated from these results that this distance was covered in a single flight.

#### Habitat usage on Lake Manyara

Many of the flamingo lakes within the Rift Valley are quite small and little can be inferred from satellite tracking movement of individual birds due to inaccuracies inherent in the methodology and the lack of choice when birds are disturbed for any reason. However, the results mapped here for Lake Manyara show quite remarkable individual choice of habitat selection within the lake.

Fig. 4. details the 81 fixes from all three birds during their visits to Lake Manyara.

Of the 45 fixes for Jane, 40 (88%) were from the southern half of the lake with two clear concentrations in the south-east. Yet only one fix from 16 and one fix from 20 were recorded for Leo and Paola respectively from this part of the lake. The latter is actually well to the southeast of the lake and she may well

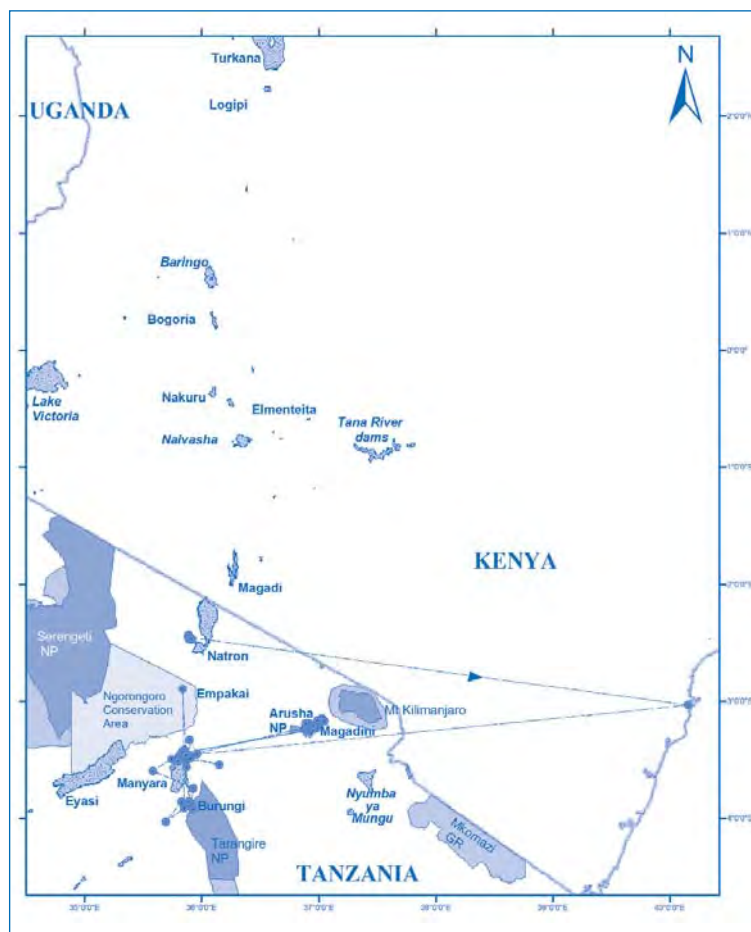

Fig. 2. Satellite tracking of three Greater Flamingos April 2002 to June 2004: Paola.

have been on her way to Lake Burungi. Ten of the 16 fixes for Leo are in the far north-east section of the lake, close to where he was caught and released and although 17 of the 20 fixes for Paola are in the same general area they are clearly well to the south of the habitat preferred by Leo.

Long intervals between fixes make it difficult to be more dogmatic about these results but these three birds clearly showed individual choice in their usage of this lake.

### CONSERVATION IMPLICATIONS

These comments relate only to the lakes visited by these three birds and not to all the lakes in East Africa utilised by the Greater Flamingo.

The importance of **Lake Manyara** to this species cannot be over emphasised. Of special note here is that these birds spend the majority of their time in the eastern and southern portions of the lake that are not included within the National Park. The entire lake area should be protected as suggested in the national Important Bird Areas inventory (Baker & Baker 2002).

Although only one of the three birds utilised **Lake Burungi** this lake is known to be seasonally important to both flamingo species (Baker 1997, Baker & Baker 2002) and it is surely an oversight that this lake has not yet been incorporated into Tarangire National Park lying as it does just outside the current protected area boundary.

That **Lake Natron** is critical for the entire Rift Valley population of Lesser Flamingos is well understood (Mlingwa & Baker 2006) but it is less clear how significant this lake is to the

much smaller population of Greater Flamingos although it does appear to be a regular breeding site for this species too. All three tagged birds used the lake to varying degrees and its status as a Ramsar site should prevent undue damage to this unique ecosystem. However, renewed calls to exploit the soda ash and the threat of a tarmac road through the valley certainly give cause for concern.

**Lake Bogoria** is protected as a National Reserve managed by the local county councils and as such is free from undue disturbance (Bennun & Njoroge 1999).

**Lake Elmenteita** is largely protected by private ownership (Bennun & Njoroge 1999) but requires some formal protection, perhaps best served for now by bringing it within the Ramsar Convention.

**Rasini Bay** is used here to denote two small bays along the southern shoreline of Ungwana (Formosa) Bay in coastal Kenya. Rasini is the southern most bay and Fundisa a few kilometers to the north. Within the context of this study and accepting the limitations imposed by the 192 day signal interval, Jane spent 211 consecutive days here between August 2003 and March 2004. In contrast Paola visited this part of the Kenyan coast for less than two weeks giving a single fix on 14 January 2004. Little is known about this site and only the northern shoreline was included in the Kenya Important Bird Areas (Bennun & Njoroge 1999). It would seem worthwhile to include the whole of this area in future waterbird counts and in particular to conduct regular counts of Great Flamingo here to ascertain the importance of this site to this species.

## ACKNOWLEDGEMENTS

The generosity of Peter Berthold and Ulrich Querner of the Max-Planck-Institut für Ornithologie Radolfzell in providing transmitters, download costs and computer time is fully acknowledged and very much appreciated. NEB acknowledges the research clearance afforded by the Tanzania Commission for Science and Technology. We thank Emilion Kihwele, the Park Ecologist at Lake Manyara National Park for accompanying us in the field while working on the shores of Lake Manyara.

## Waterbirds in Tanzania: what we know and what we do not; where are the knowledge gaps?

N.E. Baker & E.M. Baker

Tanzania Bird Atlas Project, PO Box 1605, Iringa, Tanzania. (email: tzbirdatlas@yahoo.co.uk)

Baker, N.E. & Baker, E.M. 2006. Waterbirds in Tanzania: what we know and what we do not; where are the knowledge gaps? *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 245-249.

This paper presents a summary of current knowledge of waterbird numbers in Tanzania. Reports from earlier surveys contained in the literature have been supplemented by recent survey work. Recommendations are made for monitoring.

Prior to 1995 only four sites had been "counted" in Tanzania for the African Waterbird Census (Table 1). Counting waterbirds on some of the larger lakes and swamps is extremely difficult. At 945 000 km<sup>2</sup> Tanzania is the size of Germany, The Netherlands and France combined (941 965 km<sup>2</sup>) (Times Atlas 1985). It is estimated that 5.8% (5 439 000 ha) of Tanzania is covered by lakes and swamps but this does not include the many seasonal wetlands (Hughes & Hughes 1992).

With close to 15 million waterbirds frequenting Tanzania and 42 sites known to hold internationally important numbers (1% of populations) it is clear that coverage remains poor and must be improved upon.

The larger lakes, swamps and dams are listed in Table 2. Many of the swamps have boundaries that are difficult to define and only now are they beginning to be mapped with any degree of accuracy. There are many hundreds of small cattle dams and many thousands of ephemeral ponds, lakes and swamps. The lengths of coastline and shorelines of the larger lakes are also given in Table 2 but again these have yet to be delineated accurately. The major wetlands are shown on Map 1.

The preliminary Atlas map for the African Fish Eagle *Haliaeetus vocifer* gives an indication of how few dry squares there are in Tanzania (Map 2). The pale grey squares on all these maps indicate poor coverage and clearly indicate sites for future fieldwork.

In 1995 the first co-ordinated count of the major wetlands took place with significant assistance from the Royal Society for

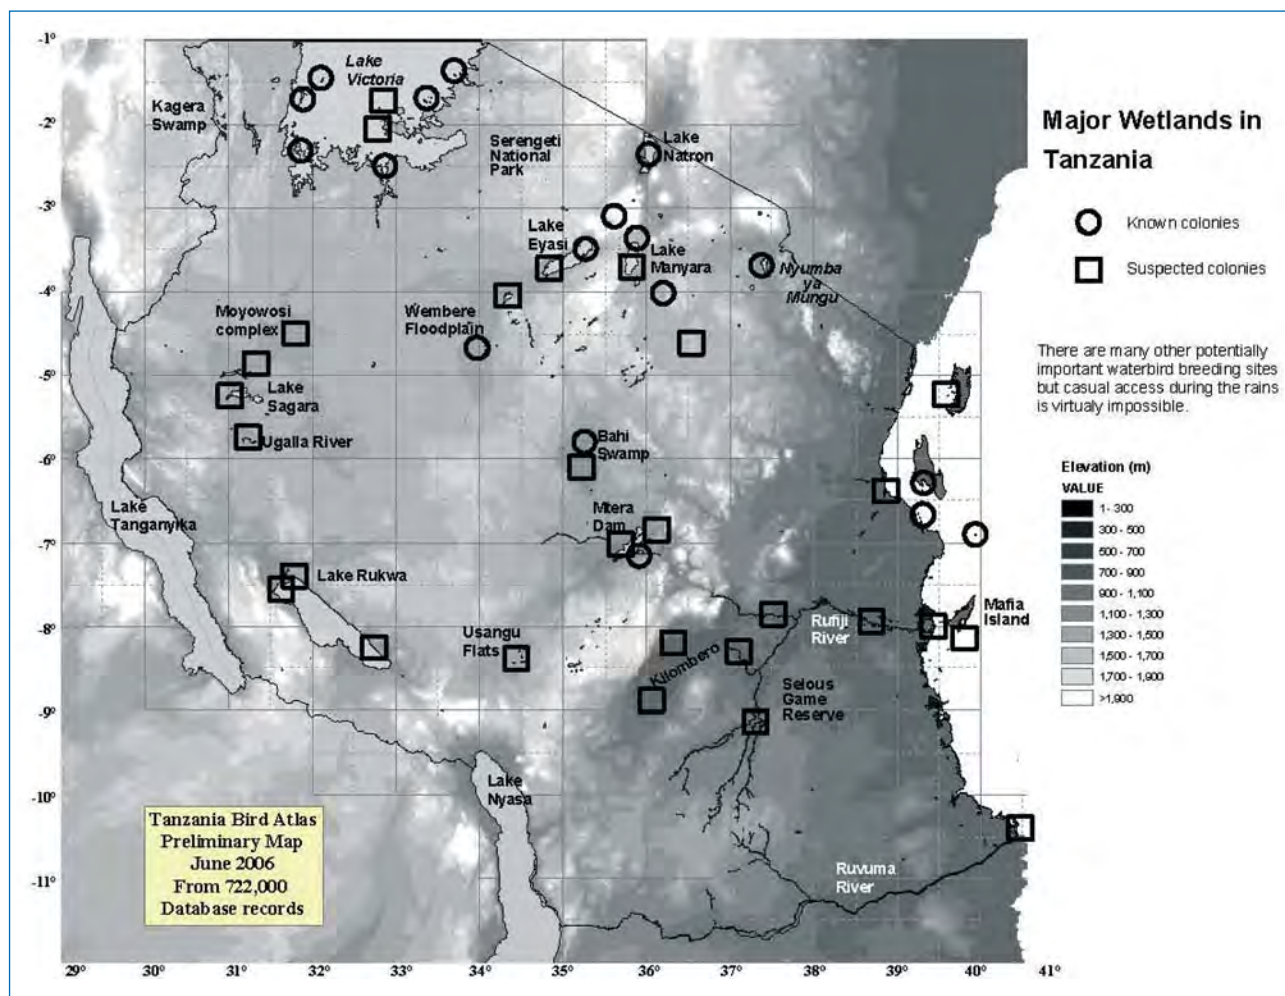

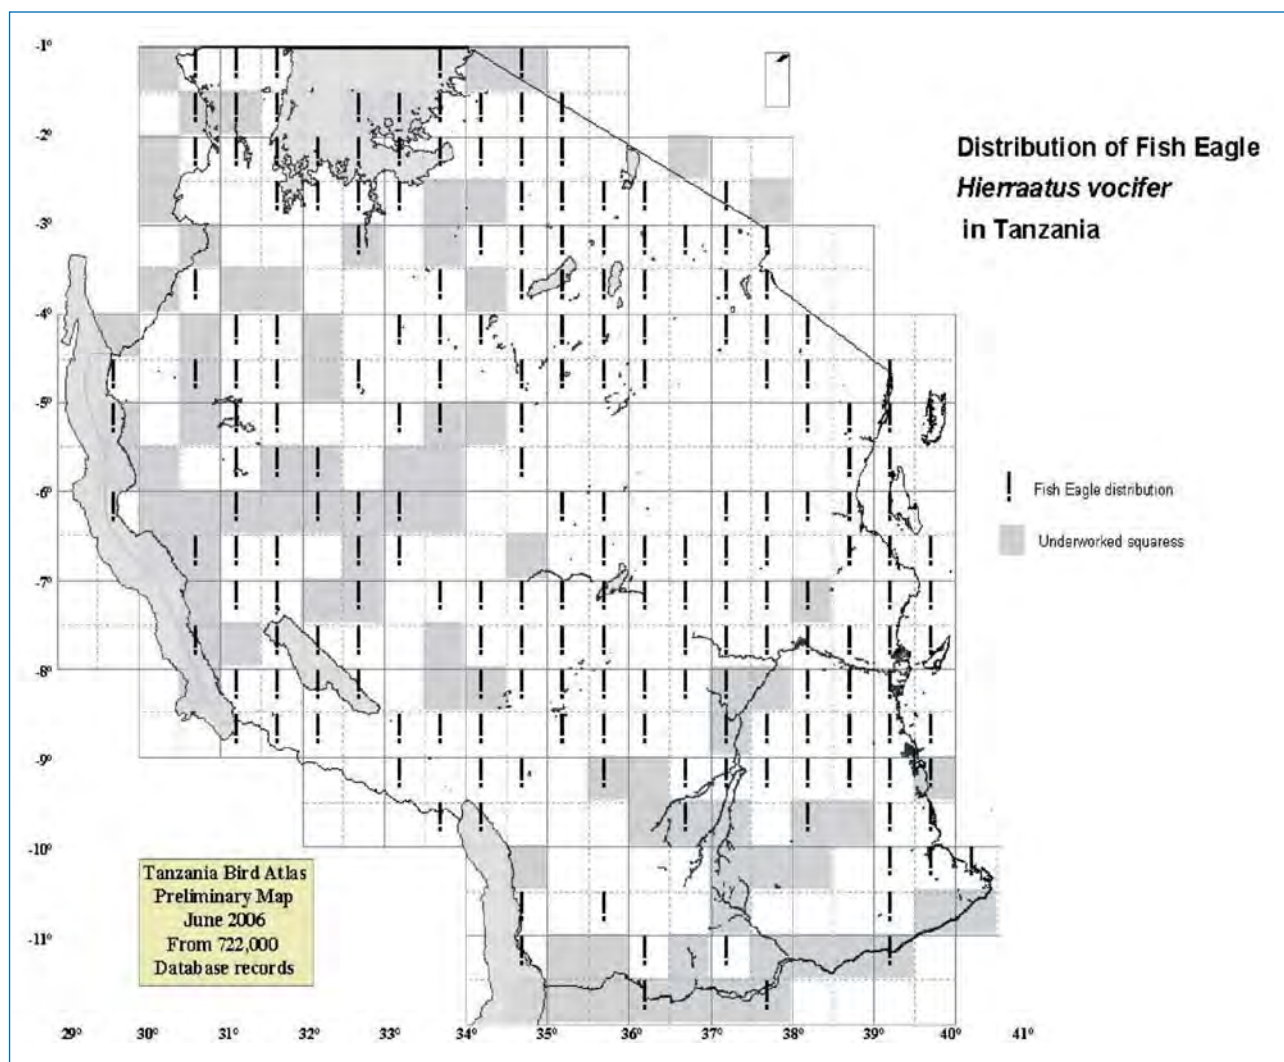

Fig. 1. Major wetlands in Tanzania.

**Fig. 2.** Distribution of the Fish Eagle *Haliaeetus vocifer* in Tanzania.

the Protection of Birds and the Global Environmental Facility. The publication of these results and the first waterbird population estimates for Tanzania provided the raw data to designate shadow Ramsar sites (Baker 1997). These data were also used to designate sites of global importance using IUCN Red List criteria and Ramsar 1% levels. Of the sites holding 1% of a population, 41 are listed in the IBA inventory (Baker & Baker 2002) and more are being added with continuing fieldwork.

The second co-ordinated count took place in January 2005 (N.E. Baker in prep.). The Tanzania Bird Atlas database held 105 000 records in 1996; by May 2006 it held 722 000 records of which 114 600 (15.8%) are for waterbirds. With records being submitted on a regular basis from a growing number of observers it is anticipated that the one million mark will be reached within three years. From this increased knowledge base it is possible to revise the population estimates for many waterbird species utilising Tanzania.

Currently 201 species from 31 families of waterbirds are known from Tanzania, 28 of these are vagrants and 14 are not actually wetland birds (Table 3). Records of the remaining 159 species have been used to plot known waterbird concentrations at the level of the Atlas square ( $\frac{1}{2}$  degree x  $\frac{1}{2}$  degree, approximately 2 500 km<sup>2</sup> at the equator) shown on Map 3.

**How many waterbirds?** Table 4 below lists crude population estimates (guesses in some cases) for the total number of waterbirds utilising Tanzania. These figures are currently being refined at the species level but the rough figure of 15 million birds appears to be credible. There are 16 million cows in

Tanzania and one rarely sees cattle without a seemingly similar number of Cattle Egrets!

**Breeding species:** Known and suspected colonies are marked on Map 1. Our knowledge of these major breeding sites the numbers involved threats and their success rates are poorly known. Access during the rainy season is the greatest problem. Aerial surveys and counts are essential if our knowledge of these sites is to be improved.

**The knowledge gaps:** From the above it is clear that far more effort is required to visit more wetlands and to count the birds on them as accurately as possible. All wetlands should be

\* waterbirds are defined here as those species counted each year under the AfWC

mapped using current GIS technology. All the known or suspected colonies require monitoring. To achieve this, dedicated teams are required within the two major conservation bodies, National Parks and Wildlife Division and the Tanzania Wildlife Research Institute. Other bodies such as International and National NGOs should be encouraged to support these efforts. WWF, IUCN, African Wildlife Foundation, Frankfurt Zoological Society, the Wildlife Conservation Society and the Wildlife Conservation Society of Tanzania are all active in Tanzania and all are in one way or another involved with wetlands. Tanzania is a signatory to both the Ramsar and the Bonn Convention and has a National Wetlands Working Group in place. Enough resources exist to support regular monitoring of known sites and surveys of new sites - it just requires supporting and organising.

**Table 4.** Waterbird population estimates for Tanzania.

## ACKNOWLEDGEMENTS

The Leverhulme Trust awarded NEB a research grant to allow fieldwork to continue in Tanzania during 2004/2005. Frankfurt Zoological Society provided funds that enabled NEB to attend the Edinburgh Conference. Both organisations are fully acknowledged and thanked for their support. The Commission for Science and Technology are thanked for granting research permits in Tanzania.

Zefania, S. & Székely, T. 2006. Conservation biology of an endemic waterbird of Madagascar, the Madagascar Plover *Charadrius thoracicus*: distribution, surveys and photographs. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 250-251.

The Madagascar Plover *Charadrius thoracicus* is an endemic shorebird classified as Near Threatened by the International Union for the Conservation of Nature (IUCN), but is close to being classified as Vulnerable, with little known of its biology. We present the results of surveys in 2002 and 2003 of the distribution and ecology of the Madagascar Plover.

Major wetlands were surveyed in the west coast of Madagascar both during the wet and dry seasons. The surveys showed that the Madagascar Plover has wider geographic distribution than previously thought, the breeding sites are scattered, and the number of plovers appears to fluctuate at most sites. The Madagascar Plover coexists with two other plover species, Kittlitz's Plover *Charadrius pecuarius* and the White-fronted Plover *Charadrius marginatus*, with which it appears to compete for nest sites. We designated areas for a population study, ringed adults and chicks and took morphological measurements. We anticipate that the surveys and population monitoring will enable us to estimate the total number of individuals of this endemic plover, and we will then be able to project its future population changes.

Madagascar Plover *Charadrius thoracicus* adult at Mahavavy delta (Andolomikopaka), August 2003.

**Fig. 1.** Wetlands (24) surveyed during dry and wet seasons 2002 and 2004 in the west cost of Madagascar; 11 are nesting areas of Madagascar Plover *Charadrius thoracicus* in which we found nests with eggs, chicks and juveniles.

The status and the distribution of the Madagascar Plover have been changing from year to year. Previous records and the new survey results from the west coast during the dry and wet seasons of 2002, 2003 and 2004 show a wider geographic distribution with a scattered breeding sites (see Fig. 1); the analysis identified some competitor species and an alarmingly small population (see Table 1). The species occupied mainly wetland in the west cost of Madagascar between Mahajanga (north) and Fort Dauphin (south). The size of the population is very low and fluctuates each year - 370 individuals in the dry season of 2003 and 262 in the wet season of 2003-2004. An accurate estimate of population numbers is urgently required.

The competition of this species with the White-fronted Plover and Kittlitz's Plover in both their nesting and feeding areas is more than previously known. The Three-banded Plover *Charadrius tricollaris* is rarely seen with the Madagascar Plover.

**Table 1.** Variation in population size of Madagascar Plover *Charadrius thoracicus* according to census season and surveyed sites.

## Madagascar Teal *Anas bernieri*: the ecology and conservation of a short distance migrant

Hywel Glyn Young

The Durrell Wildlife Conservation Trust, Les Augrès Manor, Trinity, Jersey, JE3 5BP, UK.

Young, H.G. 2006. Madagascar Teal *Anas bernieri*: the ecology and conservation of a short distance migrant. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 252-254.

This paper describes the breeding behaviour and ecology of the Madagascar Teal *Anas bernieri* based on field observations from Madagascar and Durrell Wildlife.

The Madagascar Teal is the western-most representative of the Australo-Asian grey teal (genus *Anas*) and limited data suggest that breeding occurs in Madagascar during the wet-season in seasonally flooded mangrove in tree-holes produced by decay (Young *et al.* 2001, Young 2002). Teal are, however, more widely reported from shallow saline lakes and estuaries during the dry-season, April-December, and flightless birds have been found annually at a moult site (Lake Antsamaky) in May-June (Young 2002). Field study in western Madagascar during the wet-season, December-March, has proven difficult as roads flood and mosquito numbers increase.

To understand Teal ecology, the captive population at Durrell Wildlife (Young 2000) was used to study reproductive behaviour. Results were compared with data on the related (Young *et al.* 1997) Grey Teal *A. gracilis* to predict ecology of the Madagascan endemic and integrated with known distribution and field data, resulting in a comprehensive synthesis of the species' biology interpreted in terms of implications for conservation planning (Young 2002).

Captives were studied 1998-2000 and pairs allowed to nest in conditions mimicking those in the wild (Young 2002). Behaviour (courtship, nest sites, pair-bonds, parental care, duckling development, moults) was compared with published information on Grey Teal, particularly in Queensland, Australia, (Lavery 1970, 1972a,b,c, Prawiradilaga 1985, Marchant & Higgins 1990).

Study showed that both sexes of Madagascar Teal were aggressive to congeners during group encounters and that synchronous displaying, a common feature of most dabbling ducks, was not observed. The display repertoire is smaller than that of Grey Teal, the differences most obvious in male agonistic and post-copulatory displays. Madagascar Teal has no Down-up, a display widely used by dabbling ducks in group displays (Davis 1997), or Chin-lift, another appeasement display in Grey

Teal courtship (see Prawiradilaga 1985) further suggesting that Madagascar Teal rarely indulge in social courtship and most likely live in habitats unsuited to these behaviours (Young 2002).

Madagascar Teal nesting preferences were unknown. However, related species, including Grey Teal, predominantly nest in tree-cavities (Marchant & Higgins 1990, Young *et al.* 2001) and it was predicted that Madagascar Teal would nest similarly. When supplied with boxes etc. that mimic tree-cavities this was confirmed. Nesting pairs showed that females at any stage of the reproductive cycle, particularly when foraging, were rarely unaccompanied. This concurs with observations made during the dry-season in Madagascar (Green *et al.* 1994, pers. obs 1992-1994 and 2004), when birds were principally in pairs, even within small flocks and inter-pair aggression was high (Green *et al.* 1994).

Unlike many dabbling ducks (see Johnson *et al.* 1999), Teal remained paired throughout brood-rearing and males were highly vigilant and protective of their mate and offspring. In common with the Grey Teal, Madagascar Teal exhibited a breeding strategy that involves high male input and pair-bonds that may last through consecutive seasons.

Ducklings fledged in 45-49 days (quicker than Grey Teal) and can, therefore, leave nesting areas within eight weeks of hatching. Adults moult body feathers throughout most of the year and are probably able to avoid high energy costs associated with short intense moults. Both sexes replace their wing feathers following completion of the breeding cycle, even if they have failed to rear young, and this moult and subsequent flightlessness can be delayed if environmental conditions such as rainfall delay nesting: breeding or moulting may not occur in the same month in consecutive years.

Madagascar Teal shun vegetated wetlands during the dry-season preferring open areas: this habitat choice and preferences at other times are not conducive to social encounters, and the species thus has a simplified display repertoire and marked levels of intra-specific aggression.

Madagascar Teal may have been restricted to mangrove for nesting through competition for natural cavities with other

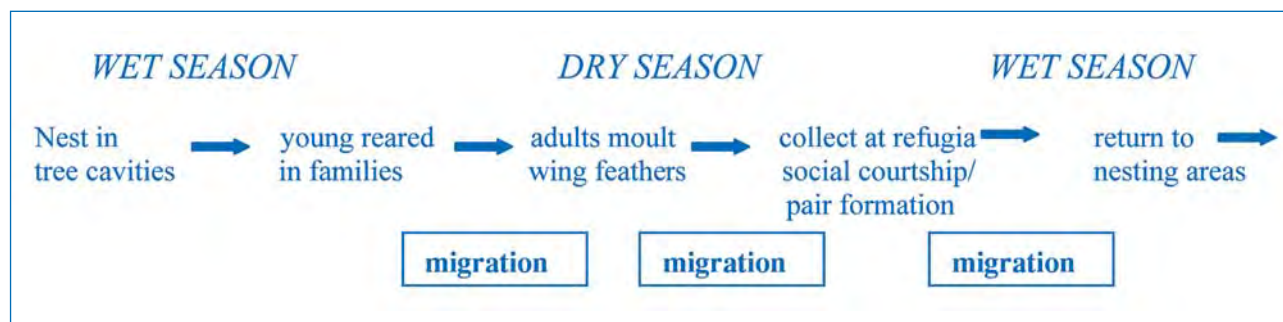

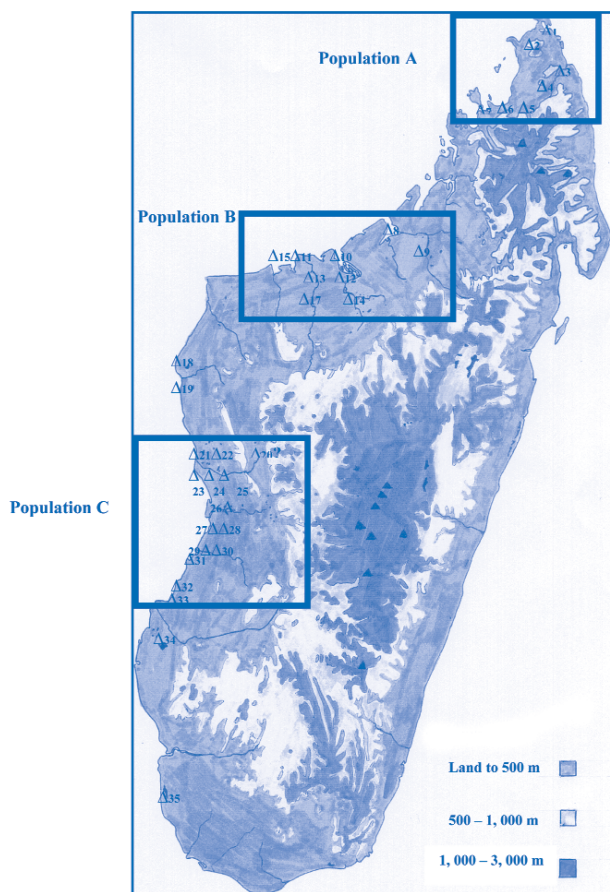

Fig. 1. Predicted annual cycle of Madagascar Teal *Anas bernieri*.

**Fig. 2.** Distribution of Madagascar Teal *Anas bernieri* showing currently known sub-populations (A).

users, notably lemurs (Young 2002, Kear 2003). All natural nests found in Madagascar (Fig. 3) have been in seasonally flooded, not tidal, areas of Black Mangrove *Avicennia marina* on the landside of littoral forest. Nesting birds must leave these sites as they dry and move short distances to nearby shallow wetlands (Figs. 1 & 4); and, as these also dry, they move further inland or to coasts and estuaries. Following brood-rearing, it is unsafe to moult wing feathers in the drying nesting-areas, and Teal move to safe sites such as Antsamaky where flightless adults have been caught and ringed annually in May-June since 1997. It is possible that in other areas, particularly in the wetter northwest, adults may moult within breeding areas before leaving for dry-season sites such as the Betsiboka Delta (Thorstrom & Rabarisoa 1997) or Ankazomborona (Razafindrajao *et al.* 2001).

Migrations between nesting, moulting and dry-season sites may include the whole Teal population in that area moving possibly only a few kilometres (Fig. 1).

Teal are threatened by subsistence hunting when nesting, clearance of mangrove for shrimp farming, trapping when in moult and the conversion of shallow coastal wetlands for rice-cultivation. Distribution of known sites (Fig. 2) suggests that three isolated sub-populations have developed as habitat conversion makes areas unsuitable. A further threat may be the potential loss of genetic diversity resulting from isolation as the species' naturally limited dispersal reduces mixing. Small numbers of Teal occur within only one protected area, at Kirindy Mitea, and future conservation strategies for this species must include adequate protection of nesting, moulting and dry-season sites from each sub-population.

## Subsistence use of waterbirds at Lake Chilwa, Malawi

Roy Bhima

Department of National Parks and Wildlife, PO Box 30131, Lilongwe, Malawi.

Bhima, R. 2006. Subsistence use of waterbirds at Lake Chilwa, Malawi. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 255-256.

### ABSTRACT

Lake Chilwa in southern Malawi is an important habitat for waterbirds. About 160 species have been recorded, including many migrants. Around 1.5 million birds occur in the wetland, including 12 species in numbers exceeding 1% of their flyway populations. The Lake Chilwa catchment area has a human density of 162 person/km<sup>2</sup>, one of the highest in Malawi. Most of the people are subsistence farmers and fishermen, but they also harvest waterbirds for local consumption and trade. At least 460 trappers use traditional traps and snares to catch waterbirds, and bird-catching takes place every year with a peak period in the rainy season. A Lake Chilwa Management Plan was developed in 2000 with the objective of enabling local communities to manage the natural resources on a sustainable basis for their own benefit. Bird Hunting Committees and a Bird Hunters Association were formed, but have not been legally established. The Danish Hunters Association began a project in 2003 to improve the Bird Hunters Association, and works with various government agencies and NGOs to regulate hunting, advise communities on sustainable management of waterbirds, and carry out research and monitoring.

### INTRODUCTION

Lake Chilwa in southern Malawi is an important wetland for waterbirds, providing breeding, resting and feeding areas for large numbers of birds in the West Asian-East African Flyway. About 160 species have been recorded at the lake, including 41 migratory species. Based on counts in 2000, it was estimated that the wetland supports around 1.5 million resident and migratory waterbirds. The numbers of 12 species exceed 1% of their flyway populations, including Glossy Ibis *Plegadis falcinellus*, Fulvous Whistling-Duck *Dendrocygna bicolor*, Black Crake *Amaurornis flavirostris*, Allen's Gallinule *Porphyrio alleni*, Lesser Moorhen *Gallinula angulata* and Grey-headed Gull *Larus cirrocephalus*.

The Lake Chilwa catchment area has a human density of about 162 persons/km<sup>2</sup>. This is one of the highest densities in the country, which has an average of 104 persons/km<sup>2</sup>. The population of the catchment is largely in rural areas and is directly dependent on natural resources such as land, water, trees, birds, fish, rodents and others for survival. Waterbirds are a major source of protein and are hunted in very large numbers at Lake Chilwa. This paper reviews information on the utilization of waterbirds at Lake Chilwa and discusses the management efforts that are being undertaken.

### STUDY AREA

Lake Chilwa is a tropical lake in southern Malawi. It is located to the north of Phalombe plain between the Zomba and Mulanje mountains at latitude 15°00'-15°30'S and longitude 35°30'-36°10'E. The water level of the lake is at an altitude of 627 m

above sea level. The lake has no outlet, and varies considerably in size depending on precipitation in the catchment, with a small increase in water level resulting in a tremendous increase in surface area. The entire wetland area is roughly 40 km across from east to east and 60 km from north to south, and has a total area of about 2 400 km<sup>2</sup>. In "normal" years, open water can cover about 1 500 km<sup>2</sup>; one-third of this is swamp and marshes, and one-third is floodplain. The entire catchment area is 8 349 km<sup>2</sup>, of which 5 669 km<sup>2</sup> are in Malawi and the rest in Mozambique. The lake and its surrounding swamps, marshes and floodplain contain water most of the time, but during the last 100 years, several recessions have occurred including three incidents of complete drying out. The maximum depth of the lake is less than 5 m, and due to this shallowness, wind action keeps the water column completely mixed throughout the year. Plant biomass production of as much as 20-30 tonnes per hectare per year has been recorded from the predominant lake habitat of *Typha* and *Phragmites* reeds.

### METHODS

Information has been obtained from various reports that were compiled in preparation for the listing of Lake Chilwa as a Ramsar site (e.g. Wilson & van Zegeren 1998). While most of the reports on the birds of the Lake Chilwa area are concerned mainly with ecology, scattered information is available on the subsistence use of waterbirds, and this information has been brought together in the present study. A management plan (Environmental Affairs Department 2000) gives detailed information on various natural resources of the wetland, and the project documents of the Danish Hunters Association (DHA) in Malawi give information on methods of bird hunting and sustainable utilization in the area.

### RESULTS AND DISCUSSION

#### Subsistence use of waterbirds

Most of the people in the Lake Chilwa catchment are small-holder subsistence farmers and fishermen. They grow maize, rice, groundnuts, cassava and tobacco. Productivity is totally dependent on adequate rainfall to recharge the lake annually and to maintain the water balance in the wetlands. The fishery is the most important natural resource in and around the lake, and yields about 25 000 tonnes per year. This is dependent on the water level in previous years. When the lake re-floods after drying out, the fishery recovers within two to three years.

Many species of birds breed during the months of January to July at various sites around the lake (Wilson 1999). Most birds favour the river mouths for breeding, as these areas are largely inaccessible to the local people and offer protection to the breeding birds because of the dense marsh vegetation.

The local people rely heavily on waterbirds as a source of protein, and usually go bird hunting when fish catches are low,

particularly during periods of drought. Bird hunting at Lake Chilwa typically involves the use of traditional methods such as birdlime, snares or string, tangling nets, fish traps and drop-nets baited with millet or rice. These are very cheap methods of catching birds, and do not require high investment.

There are at least 460 bird trappers in the Lake Chilwa catchment (Wilson 1999). An estimated 1.2 million birds are trapped every year, with an economic value of US\$ 215 000. Species trapped in large numbers include Common Moorhen *Gallinula chloropus*, Lesser Moorhen, Allen's Gallinule, Blake Crake, Fulvous Whistling-Duck, White-faced Whistling-Duck *Dendrocygna viduata* and Hottentot Teal *Anas hottentota* (Wilson & van Zegeren 1998, Wilson 1999). There are also a number of licensed hunters. Trapping and shooting of birds take place every year with a peak period in the rainy season. In unusual years when the water level in the lake is low, bird catching increases by 300-500%.

Birds are harvested for local consumption and trade. During the months of December, January and February, many households experience food shortages, and birds are a major source of protein during this period. Many roasted birds can be found on sale in recreation areas such as bars in nearby towns.

### Management of Lake Chilwa

There is no formal management of the wetland and its waterbirds. The Department of National Parks and Wildlife, which is responsible for management of wildlife in the country, has had little presence in the area as it concentrates most of its activities in national parks and wildlife reserves. However, Lake Chilwa was listed as a Ramsar site under the Ramsar Convention on Wetlands on 1 November 1997. Surveys have shown that the wetland fulfils several of the Ramsar criteria for the designation of wetlands of international importance: it regularly supports 20 000 waterbirds; it regularly supports substantial numbers of individuals from particular groups of waterbirds indicative of wetland values, productivity and diversity; and it regularly supports at least 1% of the individuals in a population of one species or subspecies of waterbirds.

The wetland was listed as a Ramsar site to ensure that there would be wise and sustainable use of all natural resources. Despite the limited presence of the Department of National Parks and Wildlife, the Ramsar listing attracted international attention to the wetland. The Danish Development Agency (DANIDA), for example, supported the development of the Lake Chilwa Wetland and Catchment Project.

A Lake Chilwa Management Plan was developed in 2001. Based on enabling policies such as the Wildlife Policy of 2000, Community Based Natural Resource Management (CBNRM) programmes were developed. The Lake Chilwa Bird Hunters Association (BHA), known locally as the "Mwayi wa Mbalame", was formed in September 2001 by eighteen bird hunters' clubs in and around the Lake Chilwa basin to promote

CBNRM activities for birds and thereby promote sustainable utilization. Twenty-nine bird sanctuaries, where trapping and shooting of birds are not allowed, have been established to provide secure breeding areas and roosting sites for birds (Wilson 2001). However, the Bird Hunters Association has yet to be legally established.

The Danish Hunters Association (DHA) has recently begun to work with the bird hunters' clubs in the Lake Chilwa area. The DHA proposes to use its experience from working at similar sites in Denmark to develop restricted use in some of the 29 bird sanctuaries and to introduce a more sustainable management of the waterbird harvest (DHA & Malawi CBNRM NGOs 2003). A DHA project entitled "Capacity Development of Bird Hunters Association of the Lake Chilwa" was initiated in 2003, and is being carried out in collaboration with various government agencies and NGOs to regulate hunting, advise communities on sustainable management of waterbirds, and carry out research and monitoring. The immediate objective of the project is "to build the capacity of the Lake Chilwa Bird Hunters Association to better organize themselves to sustainably manage the long term utilization of sedentary and migratory birds" (DHA & WESM 2003). With the listing of Lake Chilwa as a Ramsar site and the presence of the Danish Hunters Association at the lake, it is now hoped that sustainable hunting and management of waterbirds can be achieved.

## Waterbird ringing in Africa

H. Dieter Oschadleus

Avian Demography Unit, Department of Statistical Sciences, University of Cape Town, Rondebosch, 7701, South Africa.  
(email: dieter@adu.uct.ac.za)

Oschadleus, H.D. 2006. Waterbird ringing in Africa. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 257-262.

### ABSTRACT

An overview of bird ringing in Africa is presented, specifically relating to waterbirds. Summaries for West Africa and East Africa are based mainly on annual ringing reports. SAFRING's database is used for the analysis of ringing in southern Africa, the region where most waterbird ringing has occurred. Bird ringing started in southern Africa in 1948, and nearly 600 000 waterbirds have been ringed since then. There have been 15 000 recoveries of these birds (2.5%), and at least one recovery for 101 species. In addition, there have been 52 000 recaptures and re-sightings of marked birds (8.7%). There have been 1 900 recoveries and recaptures of waterbirds ringed in Europe. The annual ringing totals and recovery rates in different groups of waterbirds are investigated. More Pelecaniformes have been ringed than any other group, largely because of the large-scale ringing of Cape Gannets *Morus capensis* in southern Africa, but the highest recovery rate is found in the Gruiformes. Waterbird ringing has decreased in the last two decades, but efforts are being made to revitalize this. SAFRING is computerizing ringing data, as these provide large amounts of as yet unutilized data for analysis. Efforts are being made to expand waterbird ringing in Africa through training programmes and species projects with funding from UNEP/AEWA.

### INTRODUCTION

In 1909, the London Times announced the recovery of a European-ringed White Stork *Ciconia ciconia* found dead in South Africa. This was the first recovery of a bird migrating across the equator. The stork had been ringed in Hungary on 10 July 1908 and recovered in Himeville, KwaZulu-Natal, South Africa, in January 1909 (ring number 209). While bird ringing started in Europe in 1899, it only began in Africa some 50 years later. To date, at least 600 000 waterbirds have been ringed in Africa, and although the recovery rate is low, valuable data on migration and other movements have been collected. Ringing schemes in Africa have not operated consistently, except for two schemes, one in southern Africa and one in eastern Africa. This paper provides a general overview of waterbird ringing activities in Africa, and gives more details for waterbird ringing in southern Africa, where the vast majority of waterbirds have been ringed. Finally, the paper looks at the AFRING concept in the past, present and future.

### METHODS

To investigate the extent of waterbird ringing in Africa, the literature was searched for annual ringing reports. For southern Africa, statistics relating to waterbird ringing were extracted from the SAFRING database. As most of the waterbird ringing in Africa has been in southern Africa, more extensive analyses are presented for this region than for other parts of the continent. The

literature was searched to investigate the history of the AFRING concept, while a summary of potential future waterbird ringing projects in Africa was drawn from Underhill *et al.* (1999).

### RESULTS

#### Waterbird ringing in Africa outside southern Africa

General bird ringing has been sporadic throughout most of Africa. The first ringing scheme was started in 1948 in southern Africa; this is now known as SAFRING. Annual ringing reports have been published in the journals *Ostrich* and *Safring News* (now *Afring News*) (see Appendix I). Reports of recoveries have been published separately from ringing reports since 1993. The former are not listed in Appendix I, but are easy to trace as they always directly follow the ringing reports. More details of waterbird ringing in southern Africa are given below.

Ringing started in Zambia in the early 1960s, and initially used South African rings (address: Zoo Pretoria). Zambian rings (address: Livingstone Museum) were introduced in 1969, but by the early 1980s, it had become obvious that an independent scheme was not justified, and so Kenyan rings (address: Nairobi) and SAFRING rings (address: SAFRING UCT) replaced Zambian rings (Dowsett & Leonard 2001). Low numbers of waterbirds were ringed during the period 1985-1999; ringing totals of over 500 are listed for African Openbill *Anastomus lamelligerus* (667), Red-billed Teal *Anas erythrorhynchos* (2 121), Hottentot Teal *A. hottentota* (525), Collared Pratincole *Glareola pratincola* (518), Blacksmith Plover *Vanellus armatus* (719) and Wood Sandpiper *Tringa glareola* (852). Ringing totals for the years up to 1999 have been published by Dowsett & Leonard 2001. A total of 212 waders were ringed in Zambia between 1997 and 2003, mostly using Zambian rings but also some SAFRING rings.

#### East Africa

The East African Ringing Scheme (address: Nairobi) started in 1950, and concentrated on passerine migrants at Ngulia (from 1969 to the present), resident passerines in Nairobi, and Palearctic waders on the Kenya coast (mostly at Mwamba Bird Observatory, Watamu). The area covered by this ringing scheme includes Kenya, Tanzania, Uganda and Sudan, with small numbers of "Nairobi" rings also being used in Djibouti, Ethiopia, Rwanda, Somalia and Zambia (Backhurst 1988). Rings from other schemes have also been used in Kenya, e.g. 8 000 Lesser Flamingos *Phoenicopterus minor* were ringed with British Trust for Ornithology rings. A total of 44 927 waterbirds were ringed in East Africa between 1960 and 1987, including over 3 000 waders at Lake Magadi in the Rift Valley and Mida Creek on the coast (Backhurst 1988). Annual ringing reports were published by Backhurst and covered the years 1966-1987 (see Appendix I); in addition many reports (published or only cyclostyled) are available for bird ringing activities at Ngulia.

Liz and Neil Baker compiled separate annual ringing summaries for Tanzania. Their totals are included in the East African totals, as Nairobi rings were used. There was also a ringing scheme in operation in Ethiopia from 1969 to 1980 (Ash 1981). Annual ringing reports for this period were published by Ash; recovery reports were produced for at least two years (see Appendix I).

### West Africa

From 1958 to 1983, R. Sharland published a series of annual bird ringing reports for Nigeria in the journals *Nigerian Field*, *Bulletin of the Nigerian Ornithological Society* and *Malimbus*. Ringing in Ghana was included in these reports for the years 1960-1963. A full list of reports is provided in Appendix I; some of these were duplicated in different journals.

A ringing scheme was started again in Ghana in 1991, and there was some ringing in Senegal in 1991-1993 (Djoudj ringing project), but these schemes have not been consistent. There have been various expeditions from Europe to West Africa to ring passerine migrants, and the Dutch Working Group for International Wader and Waterfowl Research (WIWO) has undertaken expeditions to West Africa to ring migrant waders. Waders were also ringed in Mauritania by W. Dick. Brussels rings have been used in Senegal, and Jan Veen ringed gulls and terns with SAFRING rings.

### Waterbird ringing in southern Africa

Waterbird ringing began in southern Africa in 1948 with the ringing of five ducks, 15 plovers, 19 migrant sandpipers and one Caspian Tern *Sterna caspia*. Over the next 55 years, almost 600 000 waterbirds were ringed. The waterbird species reported here are the species listed in the African-Eurasian Waterbird Agreement (AEWA), as well as some seabirds and some non-AEWA waterbirds (e.g. Long-tailed Cormorant *Phalacrocorax africanus*). The annual totals of waterbirds ringed and recovered have been extracted from the SAFRING database. Many recoveries are from the Palearctic region (Fig. 1).

To understand how ringing effort has changed in southern Africa, it is practical to divide the first five decades of ringing into two periods, each of about 25 years, here referred to as the first (1948-1974) and second (1974-1999) periods. The total number of birds ringed by July 1999 was 1.8 million, of which 45% were ringed in the first period (Oschadleus & Underhill 1999). A list

of the top 10 species ringed over the 50-year period includes various non-waterbird species, two seabirds (Cape Gannet *Morus capensis* and African Penguin *Spheniscus demersus*) and two waterbirds (Yellow-billed Duck *Anas undulata* and Cattle Egret *Bubulcus ibis*).

It is striking that in the period up to 1974, the emphasis was on waterbird ringing. Thus 97% of all Cattle Egrets were ringed in this first period. Similarly 74% of the Yellow-billed Ducks were ringed in the same period. This reflects the efforts of ringers working at Barberspan, North-west Province, and Rondevlei, Western Cape, ringing egret chicks and trapping adult waterfowl in walk-in traps. Unfortunately, most of the people who were ringing during this period have either retired or passed away, and there is an acute lack of skills in using these techniques. A large amount of dam construction has taken place in southern Africa since 1974, and it is likely that the patterns of movements of waterbirds have changed since then. Some waterbirds are migratory within Africa, e.g. Comb Duck *Sarkidiornis melanotos*, while others show dispersal as far as central Africa, e.g. Cattle Egret (Underhill *et al.* 1999). These would make interesting subjects for co-operative research projects between African countries.

During the second period, the overwhelming majority of ringers focused on mist-netting. Terns, gulls and waders began to appear in the top twenty most frequently ringed species (see Oschadleus & Underhill 1999). While not many Common Terns *Sterna hirundo* have been ringed in South Africa, large numbers have been recovered in this country. This species could be studied along Africa's coastline to obtain more information on its migration, e.g. the locations of stopover sites, and the timing and rate of migration.

### Ringing and recovery totals by waterbird groups

A breakdown of waterbird ringing in southern Africa is given in Table 1. The most frequently ringed group is the Pelecaniformes due to the large number of Cape Gannet chicks that are ringed. This is followed by the Anseriformes. The highest recovery rate is for the cranes (Gruiformes), possibly because these are large birds and thus easily seen. The next highest recovery rate is for species of Anseriformes, probably because many of these are hunted and then reported, or recovered at the site of ringing. Other groups with high recovery rates include the storks (Ciconiiformes) and flamingos (Phoenicopteriformes). Very few

**Table 1.** Numbers of waterbirds ringed and recovered in southern Africa.

Order	Group	Ringed by 2000*	Recovered by Sept 2003	Percent recovered	Re-sighted or recaptured	Percent re-sighted or recaptured	Foreign recoveries
Sphenisciformes	Penguins	75 382	2 511	3.3	27 250	36.1	0
Podicipediformes	Grebes	135	0	0.0	0		0
Pelecaniformes	Pelicans etc.	162 331	3 955	2.4	21 816	13.4	0
Ciconiiformes	Storks etc.	69 766	1 027	1.5	88	0.1	809
Phoenicopteriformes	Flamingos	1 754	10	0.6	6	0.3	0
Anseriformes	Ducks	106 637	3 793	3.6	66	0.1	15
Gruiformes	Cranes	28 559	1 304	4.6	188	0.7	0
Charadriiformes, Charadrii	Waders	92 718	645	0.7	930	1.0	45
Charadriiformes, Laridae	Gulls & terns	60 617	1 780	2.9	1 959	3.2	1 036
Totals		597 899	15 025	2.5	52 303	8.7	1 905

\* Only the ringing totals up to 2000 were available at the time of writing.

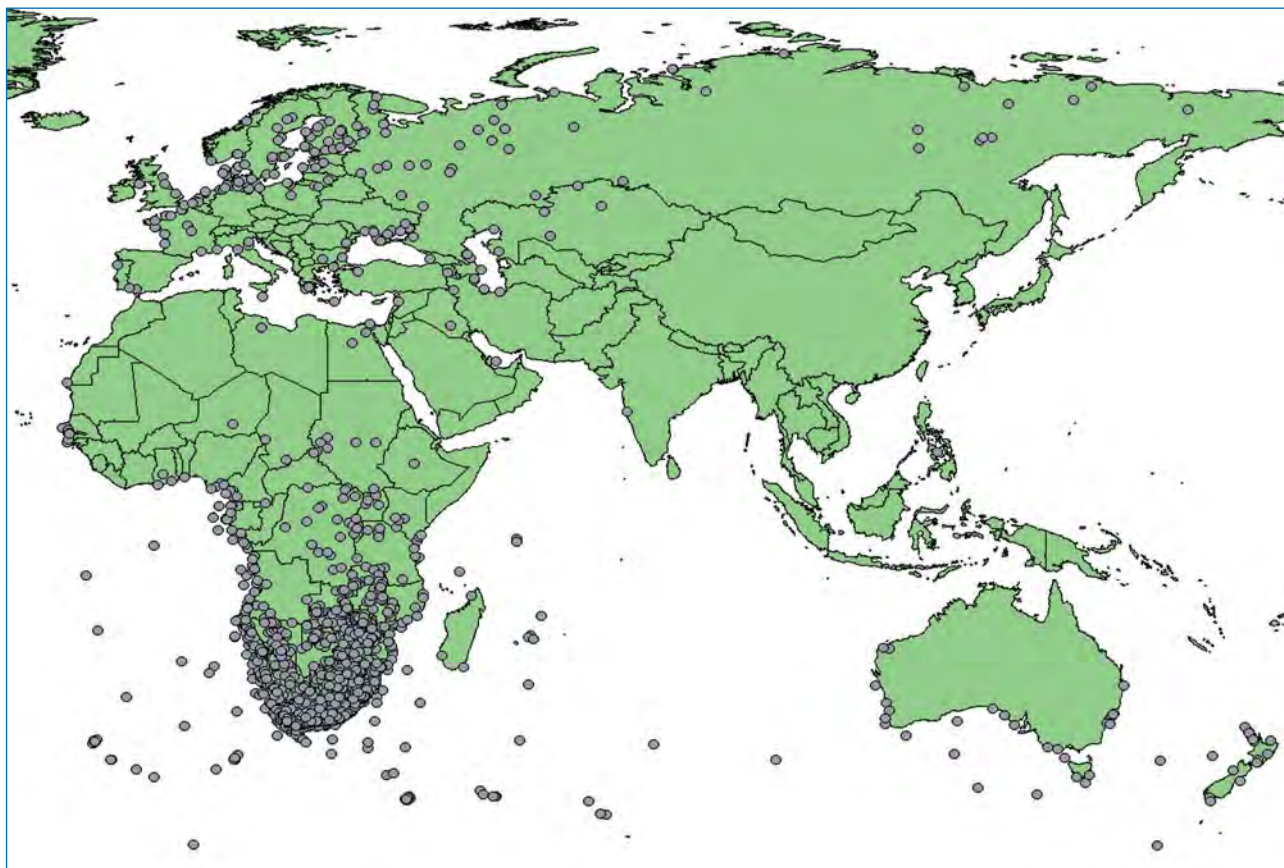

Fig. 1. Recoveries of seabirds and waterbirds ringed in southern Africa (from the SAFRING database).

grebes (Podicipediformes) have been ringed and none has been recovered. The larger birds tend to have higher recovery rates, partly because the corpses of dead birds are more visible. These rates are well over 1%, and thus mass ringing of large birds should be encouraged. Waders (Charadriiformes, Charadrii) have a lower recovery rate, and yet ringing of this group has produced spectacular information on migration routes. The highest recapture rate is in the African Penguin (36%), which has been the subject of an intensive recapture effort because of its endangered status. The next highest recapture rate is for the Great White Pelican *Pelecanus onocrotalus* (re-sightings), followed by the Cape Gannet (recaptures of birds on nests). Gulls and terns (Charadriiformes, Laridae) also have high recapture rates, while waders have a higher recapture rate than recovery rate. The highest numbers of foreign recoveries and recaptures are for the White Stork and Common Tern.

#### Marking projects – colour rings and satellite transmitters

Colour rings and flags have been used on a wide variety of seabirds, waders and other waterbirds in southern Africa, usually to identify cohorts rather than individual birds. Engraved rings are becoming popular as they can be used for re-sightings of individual birds. These are being used on African Black Oystercatchers *Haematopus moquini*, Hartlaub's Gulls *Larus hartlaubii* and other seabirds, and will be used in projects currently being planned for the Sacred Ibis *Threskiornis aethiopicus*.

Satellite tags are still little-used in southern Africa, partly because of the high costs involved. Satellite transmitters were fitted to three African Penguins after the oil spill in June 2000

from the tanker *Treasure* (Crawford *et al.* 2000), before the cleaned birds were released. These three birds, Peter, Percy and Pamela, went on to make world news headlines, e.g. on the front cover of *Time* magazine. White Storks migrate from Europe to spend the non-breeding season in South Africa, and do not normally breed there. For the last 60 years, however, a few pairs have bred regularly in the Western Cape, and many of their chicks have been fitted with satellite transmitters. Satellite transmitters have also been used by the Crane Working Group on Blue Cranes *Grus paradisea*.

#### AFRING – extending waterbird ringing throughout Africa

The concept of AFRING was first proposed in 1969, at a meeting of bird ringers during the Third Pan-African Ornithological Congress in Kruger National Park (Anon. 1971). The meeting recognized the need to establish close co-operation between ringing schemes in Africa, and between African and European schemes, and concluded that to achieve this, it was necessary to develop a code for recoveries, and to compose a numbered checklist for African species. It was agreed that another meeting should be organized within six months to develop the code for recoveries. Accordingly, an AFRING meeting was held at the 15th International Ornithological Congress in The Hague, The Netherlands, in 1970. Countries represented at this meeting included Angola, Congo, Ethiopia, Kenya, Nigeria, Senegal, South Africa, Tanzania, Uganda and Zambia. Two aims were established, namely to standardize recovery data, and to put all African recovery records on standard forms (Anon. 1970).

Ornithologists from South Africa played a leading role, but due to the political climate, these ornithologists could no longer easily be involved in African meetings. The concept of AFRING was thus not realized for nearly three more decades, although Prof. Les Underhill (at the Avian Demography Unit in the University of Cape Town) at various times applied for funding for AFRING, and made the following suggestions:

- Model AFRING on EURING;
- Standardize codes and methods;
- Facilitate bird ringing through training, the provision of rings and the establishment of a database;
- Provide leadership in all aspects of bird-marking in Africa;
- Promote collaborative projects (country/continent/flyway);
- Provide a secure backup for data;
- Curate primary data of defunct schemes; and
- Analyse data, especially with respect to conservation and management issues.

The Second International Conference on Wetlands and Development, held in Dakar, Senegal, in November 1998, recommended that the development of an intra-African ringing co-ordination scheme (AFRING) be accorded a very high priority. This opened the way for Wetlands International to apply for funding and establish the co-ordination of waterbird ringing schemes in Africa. The Avian Demography Unit received the tender for this project in January 2004. Doug Harebottle (Avian Demography Unit) was appointed to co-ordinate the project. A stakeholders' meeting was held at the Waterbirds around the world Conference in Edinburgh in April 2004, and a follow-up meeting was planned for the Eleventh Pan-African Ornithological Congress in Tunisia in November 2004.

During their review of recoveries of waterbirds in southern Africa, Underhill *et al.* (1999) identified a number of specific waterbird ringing projects in Africa, and these were presented in Israel (Oschadleus 2002). From this list of projects, a short list of species was chosen for immediate consideration: Great White Pelican, Sacred Ibis, Greater Flamingo *Phoenicopterus ruber*, Lesser Flamingo, Comb Duck, Wood Sandpiper, Sandwich Tern *Sterna sandvicensis*, Royal Tern *S. maxima* and Great Crested (Swift) Tern *S. bergii*.

An important requirement for ringing schemes is to computerize historical ringing data. These data can be used to provide information on past ringing activities and on the timing of arrival and departure of migrants (e.g. Wood Sandpiper, Oschadleus & Underhill 2002), and are required for the analysis of survival rates, moult patterns and biometrics. They can also be used to study changes in historical distribution.

## ACKNOWLEDGEMENTS

The main sponsors of SAFRING are the University of Cape Town, the South African Department of Environmental Affairs and Tourism, BirdLife South Africa and the Namibian Ministry of the Environment and Tourism. Helpful comments were provided by Marianne de Villiers and Doug Harebottle.

### 3.5 Flyway conservation in the Central Asian Flyway. Workshop Introduction

**Taej Mundkur**

*Wetlands International - South Asia, A-25, 2nd Floor, Defence Colony, New Delhi - 110 024, India.*

Mundkur, T. 2006. Flyway conservation in the Central Asian Flyway. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 263.

The permanent wetlands of the Karakum desert in Turkmenistan are of great importance for waterbird populations migrating through this region. Photo: Sergey Dereliev.

The Central Asian Flyway covers a large continental area of Eurasia between the arctic and Indian Oceans. This flyway comprises several important and overlapping migration routes for different species of waterbirds, most of which extend from Siberia to south and southwest Asia. The limited existing information that is available on waterbird populations needs to be strengthened, but existing data appears to show that many species are declining. The semi-arid condition of the Central Asian region and the effects of climatic changes observed on wetlands there have considerable impacts on the distribution and status of waterbirds, as described by Kreuzberg-Mukhina.

Most of the countries along this flyway have developing economies or economies in transition, and the focus of governments is to improve the living standards and conditions of their peoples. Accordingly, there is an inadequate allocation of resources for research and conservation, and for the involvement of local stakeholders in the sustainable management of wetlands. In addition, changes in political systems and instabilities in some countries, language and other barriers, have hindered co-operation to be developed between the agencies of the countries within the flyway. Thus there has been more limited co-operation in information sharing, research and conservation activities compared to other flyway systems or geographical regions.

The symposium made the following recommendations:

- An international framework for the development of conservation initiatives for migratory waterbirds and wetlands in the Central Asian Flyway is urgently required to promote co-operative action.
- An Action Plan for wetland and migratory waterbird conservation for the Central Asian Flyway identifying regional priorities should be finalised and endorsed by the governments of the region, in co-operation with other major stakeholders (e.g. multi-lateral environmental conventions, non-governmental organisations and others). Implementation of the plan will require active participation and resources from agencies within and outside the flyway.
- A network of internationally important sites in the Central Asian Flyway should be established to raise awareness and promote the conservation of migratory waterbirds and wetlands in the context of sustainable development.
- Trans-boundary wetland and waterbird projects should be developed with international support, involving local agencies and organisations in each participating country.
- Strong networks of people in each country within the flyway should be established for undertaking surveys and monitoring waterbirds and their habitats.
- Key threatened species which need immediate attention should be short-listed and conservation efforts for them initiated.

## Waterbirds in the valleys of the Ob river tributaries (Western Siberia) and their conservation

Blinova, T.K., Gromyshev, I.V. & Samsonova (Mukhacheva), M.M. 2006. Waterbirds in the valleys of the Ob river tributaries (Western Siberia) and their conservation. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 264.

Previous studies of the avifauna of the swamps and taiga forests in the Chulym and Vasugan river areas (Western Siberian plain) are scarce. This study describes waterbird species of the taiga zone: numbers, distribution and species assemblages of the different landscapes in the region.

Surveys were made in the eastern part of the Western Siberian plain in the Chulym-river area (Ob river right tributary) in May – July from 1996 – 2002 and in the Vasugan-river area (left tributary) in 2003 (Blinova & Samsonova 2004). Birds were counted from cutters, motorboats and hovercraft in different types of lakes and water areas of medium and small rivers. In total the surveys covered about 2 000 kilometers.

A total of 27 species of waterfowl were found during the surveys, including: Black-throated Diver *Gavia arctica*, Black-necked Grebe *Podiceps nigricollis*, Mute Swan *Cygnus olor*, Whooper Swan *Cygnus cygnus*, Bewick's Swan *Cygnus bewickii*, some species of river and diving ducks, terns and gulls and 23 other wetland associated species, including birds of prey; White-tailed Eagle *Haliaeetus albicilla*, Osprey *Pandion haliaetus*, Black Kite *Milvus migrans*, Grey Heron *Ardea cinerea*, Black Stork *Ciconia nigra*, Bittern *Botaurus stellaris*, sandpiper species, Sedge Warbler *Acrocephalus schoenobaenus*, Grey Wagtail *Motacilla cinerea*, and Sand Martin *Riparia riparia*; in total about 30 % of the region's avifauna.

Among these, 11 species (one-fifth of the total) are listed as rare (Red Data Book of the Tomsk region 2002): Great Crested Grebe *Podiceps cristatus*, Grey Heron, Black Stork, Greater Flamingo *Phoenicopterus roseus*, Whooper and Bewick's Swans, White-tailed Eagle, Osprey, Common Crane *Grus grus*, Oystercatcher *Haematopus ostralegus* and Kingfisher *Alcedo atthis*.

Other species vulnerable to the effects of human activity are those at the limits of their distribution: Bittern, Common Pochard *Aythya ferina*, Coot *Fulica atra*, Little Tern *Sterna albifrons*, Black Tern *Chlidonias niger*, White-winged Black Tern *Chlidonias leucopterus*, Great Crested Grebe and Water Rail *Rallus aquaticus*, species rare on the flyway; Ruff *Philomachus pugnax*, Greater Scaup *Aythya marila*, and passage species Herring Gull *Larus argentatus* and Mute Swan.

Species living near reservoirs and watercourses are influenced by anthropogenic factors (hunting, felling of riverside trees, spring fires, grass cutting). The most damage is from poaching, including the hunting of rare species. Spring fires affect early-nesting birds near river banks, and also destroy dead wood, which White-tailed Eagles and Ospreys use for nesting. Tree-felling also destroys White-tailed Eagle, Osprey, and Black Stork nesting sites.

In recognition of its ornithological importance, four Important Bird Areas (IBAs) of federal importance have been identified in the Chylum river basin:

- The Middle Chulym river basin IBA includes the river section between Tomsk and Krasnoyarsk oblasts and its surrounding landscapes. White-tailed and Golden Eagles *Aquila chrysaetos* nest there, and regular records of Black Stork and Osprey suggest that they also probably breed there (Blinova, et al., 2001). Corncrakes *Crex crex* are common on the flooded meadows. In winter, Gyr Falcon *Falco rusticolis* and Snowy Owl *Nyctea scandiaca* occur;
- The Bolshie Chertany Lake IBA is of great importance as a migratory bird staging area. Birds include Whooper, Bewick's and Mute Swans, Black-throated Diver, Greater Scaup, Goosander *Mergus merganser*, Osprey, Greater Spotted Eagle *Aquila marila* also use the lake, and Aquatic Warblers *Acrocephalus paludicola* occur in the riparian scrub on the banks;
- The Dikoye Lake IBA is situated between the Ob and Chulym rivers, with nesting species including White-tailed Eagle, Osprey and Whooper Swan; and
- The Lower Chulym IBA occupies a 50 km length of river from its mouth and the neighboring biotopes. Osprey and White-tailed Eagle nest here. Oystercatchers occur on the sandbanks of the Chulym, with Eagle Owl *Bubo bubo* in the forests and Horned Grebe *Podiceps auritus*, Tufted Duck *Aythya fuligula*, Whooper Swan and Little Tern in the wetlands. Black Stork also occurs as does Gyr Falcon in winter.

Measures to secure the conservation of waterbirds in the region include identification of further IBAs, the strengthening of species conservation in Nature Reserves, the prevention of accidental spills during extraction and transportation of petroleum, communication with hunters and local communities to prevent direct persecution by hunting and poaching, and placing notices near nests.

## Study and conservation of the Lesser White-fronted Goose *Anser erythropus* on the Putorana plateau, southern Taimyr: results and perspectives

Alexey A. Romanov

State Nature Reserve "Putoransky", Norilsk, Russia.

Present address: Izmailovsky proyezd, 20-1-15, 105037 Moscow, Russia. (email: ring@bird.msk.ru)

Romanov A.A. 2006. Study and conservation of the Lesser White-fronted Goose *Anser erythropus* on the Putorana plateau, southern Taimyr: results and perspectives. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 265.

On the Taimyr Peninsula in Siberia the main Lesser White-fronted Geese *Anser erythropus* breeding areas are concentrated in the Dudypa and Kheta River basins. The Putorana plateau is the southernmost stronghold of the species range in Taimyr. Until recently, knowledge of Lesser White-fronted Geese breeding areas on the Putorana plateau was based only on surveys made before 1990. At that time breeding of these rare geese was only confirmed at two lakes: Keta and Kutaramakan, and thus, the Putorana plateau was thought to be at the edge of the species' breeding range with only solitary pairs breeding there.

During this time the general status of the Lesser White-fronted Goose population was recognised as seriously deteriorating. This prompted the Goose, Swan and Duck Study Group (GSDSG) of Northern Eurasia and the mining and smelting enterprise "Norilsk Nickel" to initiate a joint project in 1999 to study Lesser White-fronted Geese on the Putorana plateau.

From 1999 to 2003 eight tectonic mountain lakes with depressions from 45 to 130 km long were surveyed, confirming for the first time that the Putorana plateau is a key area for Lesser White-fronted Geese breeding within the Taimyr part of the species range.

In the 30 000 sq. km area of the western part of this mountainous country, 200 Lesser White-fronted Goose pairs breed annually, comprising 10-15% of the Taimyr population. Their breeding range includes the whole western Putorana, stretching south up to 66°58'N. Therefore, the southernmost boundary of the range is situated 250 km further south than previously recognised.

From 1999 to 2003 Lesser White-fronted Geese continued to occur at many large water bodies on the plateau and successfully breed at some of them. Stable and relatively large breeding populations were found around the following lakes: Kutaramakan (30-40 breeding pairs); Dyupkun (100); Agata Nizhnyaya (30-40); and Severnoye (10-15). Dyupkun Lake probably hosts the largest breeding concentration on the Putorana plateau and certainly one of the largest on the Taimyr Peninsula.

The main landscape feature around all Putorana lakes is a flat, wide shoreline stretching for tens of kilometres, richly overgrown with willows, sedges and meadow herbs. These habitats provide Lesser White-fronted Geese with readily available and rich food, as well as safe shelters in case of danger. At many sites, flat shorelines are adjacent to vast near-shore shallows, which gradually dry out with an annual water level decline in the summer, resulting in late summer vegetation growth which provides the birds with food for longer periods.

Low levels of human disturbance and low predator pressure on broods are among the critical factors for the survival of breeding populations. The valleys of the Muksun River and the Glubokoye, Sobachye, and Nakomyaken lakes are probably still important as breeding areas, although for only a small portion of the population, but other lakes (Lama and Keta) suffer considerable human disturbance.

On the Putorana plateau, Lesser White-fronted Geese are breeding in both forest tundra and taiga areas when favourable habitats are available. Mean breeding density in the most favourable habitats is one pair per 5 km of the shore line. Mean brood size (n=18) was 4.2 goslings. The largest joint broods consist of 10 adults and 23 young.

The conservation perspectives for the unique Putorana plateau breeding populations are fairly good since the plateau is almost uninhabited due to extremely hard access. Furthermore, Kutaramakan and Dyupkun lakes are situated within the State Nature Reserve "Putoransky". However, this project had recognised that constant efforts in environmental education and raising awareness of the need for protection of the species are important for their conservation, for example, through publications in the federal and local media, and through the distribution of booklets and posters calling for the endangered species' protection. Future actions within the framework of the project include searching for new breeding sites on the Putorana plateau with the help of satellite imagery, migration studies using satellite telemetry, and establishing protected areas.

## Waterbird surveys in the Tobolo-Irtyshskaja forest-steppe and steppe of Western Siberia

Sergei A. Soloviev

Omsk State Pedagogical University, Russia. (email: solov\_sa@mail.ru)

Soloviev, S.A. 2006. Waterbird surveys in the Tobolo-Irtyshskaja forest-steppe and steppe of Western Siberia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 266.

The south-west of the West Siberian plain, Omsk oblast, is a region of Tobolo-Irtyshskaja forest-steppe and steppe. Waterbird populations using both African-Eurasian and Asian-Australasian flyways occur in this area of the Central Palearctic. Finsh (1877) reported in the 19th century that there were plentiful waterbirds in this area, with many ducks and swans being observed on all rivers and lakes. In the steppe areas of the study area (an area rich in herbs, sod-grass and gramineous steppe) there are also a number of large lakes. There are very few trees, except for some areas of birch. Records of waterbird species, which include globally-threatened species such as Dalmatian Pelican *Pelecanus crispus* and Black-winged Pratincole *Glareola nordmanni*, in some of the most important wetland areas from recent surveys are summarized below.

The 75 000 ha Steppe State Zakaznik (54°28'N; 75°35'E) has Whooper Swan *Cygnus cygnus*, Greylag Goose *Anser anser* and Common Crane *Grus grus* nesting on reservoirs. Up to 100 000 Greylag Goose and up to 5 000 Common Crane concentrate here on migration. White-tailed Eagle *Haliaeetus albicilla*, Red-breasted Goose *Branta ruficollis*, Lesser White-fronted Goose *Anser erythropus*, Avocet *Recurvirostra avosetta*, Black-winged Stilt *Himantopus himantopus*, and Common Curlew *Numenius arquata* have also been recorded. There was a large colony of Common Gull *Larus canus* and 12 pairs of Avocets on an island in Lake Chebakly, and flocks of 15-30 Ruff *Philomachus pugnax*, 20-50 White-fronted Goose *Anser albifrons* and two Demoiselle Cranes *Anthropoides virgo* were present around the lake. On Lake Terenkul there was a colony of Little Gulls *Larus minutus* and a pair of Mute Swan *Cygnus olor*, with Common Pochard *Aythya ferina*, Tufted Duck *A. fuligula*, Common Coot *Fulica atra*, White-winged Black Tern *Chlidonias leucopterus*, Red-necked Grebe *Podiceps griseigena*, and Marsh Harrier *Circus aeruginosus* present. Near Lake Ataechje the steppe form of Merlin *Falco columbarius* was observed. On Lake Zholtyrkol there were two Whooper Swans and one Black-winged Pratincole.

On the wet meadows of the Irtysh oxbow near Zarechje settlement in the "Novovorshavskiy site of Irtysh steppe bottom-land" nesting Oystercatcher *Haematopus ostralegus*, and White-winged Black Tern and three Great White Egret *Egretta alba* were recorded in June 2003.

The 2 300 ha Lake Alabota (53°59'N, 74°01'E), more than 1 000 White-fronted Geese were observed on 16 May 2002 and 59 Mute Swans were seen at the end of the summer. A colony of 15 pairs of Black-winged Pratincoles was found on 15 June, and up to 340 Greylag Geese breed here. Other waterbirds included Black-winged Stilt (26 birds), Demoiselle Crane (52 birds), Red-necked Grebe, Common Pochard, Garganey *Anas querquedula*, Shoveler *A. clypeata*, Ruff *Philomachus pugnax*, Avocet, Black-headed Gull *Larus ridibundus*, Little Ringed Plover

*Charadrius dubius*, Gadwall *A. strepera*, Northern Lapwing *V. vanellus*, Yellow-legged Gull *Larus cachinnans*, Marsh Harrier, Common Crane (20 birds), and Whooper and Mute Swan.

A chain of 22 saline lakes occur along the western bank of the river Irtysh from (54°57'N; 72°19'E) up to the Kazakhstan border. On Lake Piketnoe there was a pair of Mute Swans and Avocet (1), Black-winged Stilt (5), Common Curlew and a significant number of Common Pochard. A flock of about 10 Turnstones *Arenaria interpres* was seen on the slightly saline lake Krivoe on 5 June 2003, near the settlement of Severnoe in the area of Isilkulskogo. Here there was also a colony of 34 Avocet nests with clutch sizes of five (one nest), four (14 nests), three (six nests), two (two nests) and one (one nest). One nest (four eggs) of Black-winged Stilt was found on the same date, and chicks were seen on 12 June.

At Lake Bolshe-Murla (55°56'N, 74°32'E), in a valley of the Irtysh river, a White-tailed Eagle was seen on 20 June 2004.

At Mangutskii lake (55°49'N, 70°56'E), there were up to 80 Whooper Swans, 800 White-fronted Geese, various species of ducks including Goldeneye *Bucephala clangula*, White-winged Black Tern, two nesting pairs and 10 individual Black-tailed Godwits, and three White-tailed Eagles.

The 57 000 ha Bairovskii Republican Zakaznik (56°N, 73°E) has 68 lakes, with nesting Whooper Swan, Greylag Goose, Common Crane and Common Curlew. On the lake system "Saltaim-Tenis" (56°07'N 71°45'E), at Lake Tennis (36 000 ha) and Lake Saltaim (40 000 ha) there are the most northern colonies in the world of Dalmatian Pelican (200 individuals) and Common Cormorant *Phalacrocorax carbo*, along with breeding Grey Heron *Ardea cinerea* and Yellow-legged Gull.

On Lake Achikul (56°18'N, 71°50'E), there were Dalmatian Pelican (2-10 birds), Common Cormorant (eight birds), nesting Whooper Swan (25 birds), Grey Heron (four birds), Garganey (10 birds), Greylag Goose (30 birds), Hen Harrier *Circus cyaneus*, Marsh Harrier, Common Buzzard *Buteo buteo*, Spotted Eagle *Aquila clanga*, Hobby *Falco subbuteo*, Common Kestrel *F. tinnunculus*, Corncrake *Crex crex*, Northern Lapwing, Common Curlew (four birds), Common Tern *Sterna hirundo*, Common Gull and Yellow-legged Gull.

On the Verhneoshskiy river (56°10'N, 72°30'E) there were 46 Grey Herons, 42 Greylag Geese, 30 Whooper Swans, 292 Garganey and also Black-necked Grebe *Podiceps nigricollis*, Teal *Anas crecca*, Gadwall, Shoveler, Common Pochard, Tufted Duck, White-tailed Eagle, Black Kite *Milvus migrans*, Marsh Harrier, Pallid Harrier *C. macrourus*, Black-winged Stilt, Oystercatcher and Black-winged Pratincole.

## Waterbird populations in the Barabinsk Lowland, Russia, 1976-2003

Alexander P. Yanovsky

*Institute of Animal Systematics and Ecology of the Siberian Division of the Russian Academy of the Sciences, Novosibirsk, Russia.*

Yanovsky, A.P. 2006. Waterbird populations in the Barabinsk Lowland, Russia, 1976-2003. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 267-268.

The Barabinsk Lowland is both a waterfowl nesting site and situated on a major flyway. Data on the population dynamics of waterfowl are important for developing policies for nature protection and sustainable hunting. This area around Novosibirsk contains forest-steppe, woods, and wetland habitats. There are 12 600 ha of freshwater lakes and 8 800 ha of brackish and saline lakes, including Lakes Malye Chany (freshwater) and Bolshye Chany (brackish). Data is available for the period from 1976 to 2003, and was compiled from surveys of reservoirs, migration observations, monitoring of nesting sites, and hunting bag surveys. In total there were 2 556 hours of observations of migrating birds, 1 203 nests monitored, and 3 678 birds from hunting bags examined. Fourteen species of waterfowl were nesting in the area on a regular basis.

Mute Swan *Cygnus olor* are mainly found to the south of Lake Malye Chany. In the 1970s and 1980s Mute Swans progressively settled on an increasing number of lakes, although they are now less abundant than Whooper Swans *Cygnus cygnus*. Almost every year in the survey pairs of Mute Swan have been seen in the vicinity of Lake Malye Chany during the breeding season.

Whooper Swans are amongst the most common large waterbirds on the lakes of northern forest-steppe. To the north of the Trans-Siberian railway numbers gradually increased in the 1980s and early 1990s. In June 1994 nesting pairs were observed on one of three freshwater lakes, with a density of six adults, mainly nesting, per 1 000 ha of freshwater lakes.

Greylag Geese *Anser anser* usually nest in areas to the south of Lake Bolshye Chany, on the Bagan reservoir and the Karasuk lake systems. Nests have been found amongst reeds in the shallows of wetlands near to the islands and peninsulas of Lake Chany. Numbers increased in the late 1990s, especially in areas where grain fields are close to wetlands. Since then numbers

have decreased, due to droughts from 1998 to 2000 during which the surface area of lakes was reduced, and due also to the impacts of spring hunting.

Shelduck *Tadorna tadorna* occur to the north of Tatarsk, Barabinsk and Novosibirsk and often to the south and southwest of Lake Chany on saline lakes. Around Bagansk, Shelduck were observed in June 1994 at a density of about four adult individuals per 1 000 ha of saline lakes. However, breeding success was low, with only 2-12% of pairs having chicks. This appears to be due to the lack of suitable nesting places, and also the periodic drying of lakes.

Mallard *Anas platyrhynchos* were widespread, occurring on most reservoirs, including those in settlements. They have stable, high numbers where hunting is closed. In the 1970s, nesting on lakes and islands averaged about two males ha<sup>-1</sup>, and one to four males ha<sup>-1</sup> in boggy woods.

Teal *Anas crecca* nest to the north of Lake Chany and in a valley of the Ob river, sometimes close to reservoirs in thickets or woods. Numbers have remained relatively stable over past decades, owing to the stability of conditions in wooded areas.

Gadwall *Anas strepera* nest in the central Barabinsk lowland. Numbers have decreased less than those of other ducks, probably owing to their later arrival and their tendency to nest in more protected areas such as the islands of Lake Chany with its colonies of waterbirds, and lakeside scrub and birch woods. On the island of Uzkoredky in the northern part of Lake Chany numbers of males decreased from 67 in 1987 to only 16 in 2000, but numbers increased again to 43 in 2001, and 110 in 2003.

Wigeon *Anas penelope* nest mainly to the north of the Trans-Siberian highway in birch woods and southern taiga, and also in a valley of the Ob river. In some years, small numbers have also been observed in southern forest-steppe, nesting on lakes with larger islands.

Common Terns *Sterna hirundo* colonies provide protection for other breeding waterbirds. Photo: Sergey Dereliev.

Pintail *Anas acuta* prefer to nest in open habitats. However, these areas have frequently been converted to agricultural use, resulting in c. 80% of nests being destroyed and a large (30-fold) decrease in numbers since the 1970s and 1980s, with high levels of spring hunting also likely to have contributed to the population decrease.

During the 1970s, especially between 1976-1979, Garganey *Anas querquedula* was amongst the most abundant nesting ducks in the Barabinsk lowland and the wetlands of the upper Ob river. Since then numbers have decreased 20-fold, due to low nesting success in its preferred open habitats which are no longer available.

Shoveler *Anas clypeata* were numerous in the mid 1970s, but numbers are now reduced and variable, dependent on weather conditions, and now forming about 5% of numbers of *Anas* spp. present.

Pochard *Aythya ferina* mostly nests in typical lake forest-steppe and the upper Ob river. Numbers were stable in the 1970s, averaging 0.5-0.8 males ha<sup>-1</sup> in areas with small islands. Between the 1990s and 2000s numbers first slowly decreased and then, for no clear reason, have decreased rapidly, especially to the north of Lake Malye Chany.

Tufted Duck *Aythya fuligula* form nesting aggregations on lakes in woods and forest-steppe where there are colonies of gulls, usually Black-headed Gull *Larus ridibundus*, or Common

Tern *Sterna hirundo*. Although nesting density is variable, depending on spring water levels, numbers have generally decreased. In 1978 average density was 140 males ha<sup>-1</sup> on small islands on Lake Menzelinskoe, with an overall density on lakes of 0.05 males ha<sup>-1</sup>.

Goldeneye *Bucephala clangula* nest in hollow trees along the wooded shores of lakes and small rivers. Over the last decades hollow trees suitable for nesting have disappeared as a result of tree felling and the species now depends on artificial nest boxes along the wooded shores of reservoirs. From experimental studies the optimal number of nest boxes is 2-3 per km<sup>2</sup>, more than is recommended for northern and western Europe.

In addition to these regularly breeding 14 species, Red-crested Pochard *Netta rufina*, Ruddy Shelduck *Tadorna ferruginea*, and White-headed Duck *Oxyura leucocephala* nest occasionally on a small number of lakes in the southwest Barabinsk lowland. Bean Goose *Anser fabalis* and White-fronted Goose *Anser albifrons* occur annually on spring and autumn passage. Three species of *Mergus*, Smew *M. albellus*, Red-breasted Merganser *M. serrator* and Goosander *M. merganser*, occur on autumn migration, as occasionally do Long-tailed Duck *Clangula hyemalis* and Scaup *Aythya marila*. Velvet Scoter *Melanitta fusca*, Bewick's Swan *Cygnus bewickii*, Red-breasted Goose *Branta ruficollis*, Lesser White-fronted Goose *Anser erythropus* and Ferruginous Duck *Aythya nyroca* occur very rarely.

Tufted Ducks *Aythya fuligula* form nesting aggregations on lakes in woods and forest-steppe especially close to gull colonies. Photo: Paul Marshall.

## Past and current status of Anatidae populations in Kazakhstan

Sergey N. Yerokhov

Institute of Zoology of the Ministry of Education and Science, Akademgorodok, Al-Farabi Street 93, Almaty, 480060, Kazakhstan.  
(email: Syerokhov@nursat.kz)

Yerokhov, S.N. 2006. Past and current status of Anatidae populations in Kazakhstan. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 269-274.

### ABSTRACT

Thirty-nine species of Anatidae are known to occur in Kazakhstan, including several globally threatened species. Twenty-two species are present throughout the year; five occur only during the breeding, moulting and migration seasons; five only during the migration seasons; and seven only as rare visitors. The total number of Anatidae recorded annually in Kazakhstan has decreased from about 30 million in the first half of the twentieth century to 13 million in 1999-2003. There has been a steady degradation of wetland habitats in recent years, and this has been the main factor affecting the number and distribution of Anatidae. Economic hardship has led to increased levels of illegal hunting, and this has resulted in a decline in some species. Human disturbance, caused primarily by intensive fishing, also poses a serious threat to waterfowl populations. The high level of water consumption for industry and agriculture is another important factor, while inefficient technologies are leading to water pollution in many wetlands. Since the period of economic transition, government agencies and Non-Governmental Organisations (NGOs) concerned with the conservation of Anatidae and their habitats have been more active, and in 2003, the Government initiated a national Program for the Conservation, Reproduction, Sustainable Utilization and Study of Waterfowl.

### INTRODUCTION

The wetlands of Kazakhstan are the largest and most important in Central Asia for Anatidae (ducks, geese and swans). About 40 species of Anatidae occur in the wetlands of Kazakhstan, including many common species that may be hunted and several globally threatened and near threatened species, such as the Lesser White-fronted Goose *Anser erythropus*, Red-breasted Goose *Branta ruficollis*, White-headed Duck *Oxyura leucocephala* and Ferruginous Duck *Aythya nyroca*.

This paper presents the results of an analysis of the current status of some Anatidae populations, the trends in their numbers and the changes in their distribution within the most significant habitats. The main natural and human-related disturbance factors and threats are discussed, and recent measures that have been taken for the conservation and management of Anatidae in Kazakhstan are reviewed.

### METHODS

The data from 25 years of study of Anatidae in Kazakhstan were analysed, as were archive material at the National Institute of Zoology and the existing literature. In addition, an analysis was made of counts and estimates of quarry species provided by the Fauna Protection Inspectorates and Hunting Societies, and obtained by interview. The author studied state and governmental documents relating to the protection and utilization of waterfowl and their habitat, the laws of Kazakhstan on biodiversity, and

specially protected natural territories. The current evaluation of the numbers of Anatidae was made possible as a result of the implementation of the long-term program "Monitoring of Waterfowl in the Main Habitats of Kazakhstan" (1999-2003). In parallel, the author took part in a number of international projects including "Monitoring and Assessment of Lesser White-fronted Goose in the Autumn Migration Period in North Kazakhstan" and "The Current Status of White-headed Duck in Central Asia". Information obtained in these projects has been used in this report.

### RESULTS

#### Species of Anatidae in Kazakhstan

Thirty-nine species of Anatidae in 17 genera occur in Kazakhstan (Table 1). Changes in species diversity during the last 100 years relate only to the occurrence of rare species. At the end of the nineteenth and during the first half of the twentieth century, 40 species of Anatidae occurred in Kazakhstan (Dolgushin 1960). Subsequent research has failed to confirm the continuing existence of two species, the Harlequin Duck *Histrionicus histrionicus* and King Eider *Somateria spectabilis*. However, the Barnacle Goose *Branta leucopsis* was first recorded in Kazakhstan during the spring migration of 1999. Thus, the current list of Anatidae in Kazakhstan (Table 1) includes 39 species (Yerokhov 2003).

The distance of Kazakhstan from the sea determines the distribution of Anatidae within the country. Most of the breeding species are dabbling ducks and diving ducks, although the Greylag Goose *Anser anser*, Ruddy Shelduck *Tadorna ferruginea* and Common Shelduck *T. tadorna* also breed. During the migration seasons, and especially in autumn, large numbers of waterfowl that breed in coastal areas of the Arctic Ocean regularly stop over in the northern regions of Kazakhstan. These include the Greater White-fronted Goose *Anser albifrons*, Lesser White-fronted Goose, Red-breasted Goose, Goosander *Mergus merganser* and Smew *Mergellus albellus*.

#### Status and distribution

Most of the Anatidae species occurring in Kazakhstan are present during all stages in their annual biological cycle: 22 species breed, undertake their moult, occur on migration and can also be found in winter. Five species breed, moult and occur on migration, and another five species are found only as non-breeders in summer and during their seasonal migrations. The remaining seven species are rare visitors, and are recorded only occasionally and in small numbers.

Anatidae are very common throughout most of Kazakhstan's territory, and can be found in all landscapes including high mountainous areas, e.g. the Bar-headed Goose *Anser indicus* and Ruddy Shelduck. The important breeding and moulting areas are located mainly in the northern part of Kazakhstan. The most important

Mergansers	3
Total	39

stopover sites for migrating populations are in the southern part of the country, while the main wintering areas are in the south and south-east. Two major waterbird flyways, the Siberian-Black Sea-East African Flyway and the Central Asian-South Asian Flyway, pass through Kazakhstan. The former passes mainly through the northern, west-central, north-western and western regions of the country. The latter passes through the north-eastern, eastern, east-central, south-eastern and southern regions. However, no clear-cut geographical boundary can be drawn between these two flyways as there is considerable overlap (Fig. 1).

#### Population levels in the last century and at present

No information is available on the total numbers of Anatidae in Kazakhstan during the first half of the twentieth century. However, it has been estimated that the total number of geese during that period was about 8-10 million (Solomatina 1971). Assuming that the ratio of geese to ducks in Kazakhstan at that

time was close to the current ratio (1:2), we might suppose that the number of ducks was about 20 million, giving a total of 30 million for all Anatidae. However, even in the first half of the twentieth century, waterfowl specialists were reporting a considerable decrease in the number of many species, especially Greylag Goose and dabbling ducks (Gavrin 1969). Approximately 40 years later, in 1991-1994, the total number of Anatidae was estimated at about 17 million (Krivenko 1996). Since then, the pressure on Kazakhstan's natural resources has increased considerably, due to the transition to a market economy. The annual estimation of Anatidae populations has gained special relevance because of the importance of waterfowl hunting, and the recording of numbers of waterfowl has become more regular. Based on records from 1999-2003, the annual total of Anatidae in Kazakhstan was 13 million birds (Table 2). The main limiting factor during this period was a series of severe droughts in 1998-2001 resulting in serious degradation of wetland conditions in the northern and central parts of Kazakhstan. This, in turn, resulted in a considerable reduction in the numbers of birds.

## DISCUSSION

### Population trends

An analysis of information on the abundance of Anatidae in Kazakhstan reveals that the total numbers have decreased from perhaps as many as 30 million in the first half of the twentieth century to about 13 million in recent years. The current status of the 39 species of Anatidae occurring in Kazakhstan, based on observations in 1999-2003, is summarized in Table 3. In some species, the numbers have fluctuated widely from year to year, while in others, the numbers have remained relatively stable.

**Table 2.** The current numbers of Anatidae in Kazakhstan, based on counts in 1999-2003 (in thousands).

Region	Swans	Geese	Shelducks	Dabbling ducks	Diving ducks	Sea-ducks	Total
Ural-Caspian	10.0	560.0	15.0	1 800.0	750.0	3.0	<b>3 138.0</b>

### Natural threats

Anatidae populations in Kazakhstan are affected by the unstable hydrological regime of wetlands, and this is especially important in northern and central Kazakhstan. The lakes in this region are typically inland drainage systems that become much reduced in size during dry periods, and refill only during years of high snowfall and rainfall. This normally occurs on a cycle of 8-12 years. Three to five years after re-flooding, habitat conditions in these lakes are favourable for Anatidae. Some years later, as the area of the lakes becomes reduced and the salinity increases, conditions for Anatidae deteriorate considerably. By the end of the dry period, many of the lakes are less suitable for waterfowl, and the number of Anatidae in northern and central Kazakhstan decreases by 3-5 times compared to the normal period.

### Threats caused by humans

#### Transformation of habitats

Recent decades have been characterized by a steady degradation of wetland habitats for most species of waterbirds in Kazakhstan (Yerokhov & Stuge 1997), and this has been the main factor affecting the number and distribution of Anatidae. Typical habitats include freshwater, brackish and moderately saline lakes. The hydrological regime is maintained primarily by river flow or flood waters.

Over-regulation of the flow of most rivers, irretrievable consumption of water supplies and the redistribution of water cause unnatural fluctuations in water level. At the same time, there is considerable pollution from industrial, agricultural and domestic waste. About 40% of the annual inflow of rivers in Kazakhstan is irretrievably utilized or rendered unusable by pollution (Anon. 2004).

#### Unstable hydrological regime

Changes in water level in wetlands are seasonal and depend on the amount of water utilized for the generation of hydroelectric power and irrigation of arable land. About half of the sites where mass concentrations of waterfowl occur are artificial water-storage reservoirs. It is normal for there to be a considerable rise or fall in water level in such reservoirs during the waterfowl breeding season, and this has a negative effect on egg-laying and the survival of broods.

#### Fishing

Fishing activities have negative effects on the status and numbers of Anatidae at many of the most important wetlands in Kazakhstan. Economic challenges have encouraged a large number of people to take up fishing, the intensity of which has now reached an unprecedented scale. As a result, Anatidae are under double pressure. Hundreds of ducks, mostly young birds, perish in fishing nets, while the disturbance caused by fishing activities is an even more serious problem for the birds because of the human presence, noise of motor boats, etc. As a result, birds are forced to leave wetlands where fishing is intensive. For example, at Alakol and Sasykkol lakes in eastern Kazakhstan, the number of nesting Greylag Geese has fallen by 30-40 times within the last decade, and the number of nesting Gadwall *Anas strepera* and Red-crested Pochard *Netta rufina*, by 15-20 times (N. Berezovikov pers.comm.). A similar situation has been observed at other lakes in eastern Kazakhstan.

### Illegal hunting

Illegal hunting is quite common in some parts of Kazakhstan, and includes hunting with fire-arms or other means, the collection of eggs from nests, and the capture of ducks and geese during the moulting period.

### Uncontrolled visits and tourism

Uncontrolled access to lake shores and open-water areas for tourists and other visitors can be almost as serious as illegal hunting in terms of its negative impacts on waterfowl. Bird-watching activities are becoming more common, especially in central and south-eastern Kazakhstan. These activities often occur in areas where there is insufficient infrastructure to cater for the bird-watchers. At some sites around Alakol Lake, at the lakes along the Ile River and in the Tengis-Kurgaljin lakes, the problem of unregulated tourism has become more and more serious, and very few steps have been taken to address this.

### Conservation measures

At national level, the main political approaches to the conservation of biodiversity (including Anatidae) are determined by the Law on Protection, Rehabilitation and Use of Fauna (1993). In accordance with this law, the Government of Kazakhstan has adopted a List of Rare and Endangered Animal Species which contains 11 species of Anatidae (see Table 3). In 2002, a proposal from waterfowl specialists led to the inclusion of the globally threatened Lesser White-fronted Goose in this list. A special clause in the above-mentioned Law contains the provision for a Red Book of Kazakhstan. Another significant legal instrument is the Law on Specially Protected Natural Territories (SPNT), which lists the most significant waterfowl habitats in a special SPNT category: internationally significant wetlands. To date, the highest level of reserve status has been assigned to only three wetlands of global significance: Tengis-Kurgaljin lakes, Naursum Lake and Alakol Lake. The Tengis-Kurgaljin lakes have been designated as a Ramsar site under the Ramsar Convention on Wetlands (1975), as have the Irgiz-Turgai lakes. By a decision of the Government of Kazakhstan in 2003, a special Fishery Committee has been established which will implement a more efficient regulation of fishing activities and reduce their negative effects on waterfowl. In 1999, the Government of Kazakhstan developed and adopted a National Strategy and Action Plan for Conservation and Balanced Utilization of Biological Diversity. Other priority measures foresee the establishment in Kazakhstan of a network of specially protected wetlands as habitats of migratory birds. In addition, in recent years more emphasis is being placed on the efficient management of waterfowl resources that are open to hunting. One practical step is the Government's Program of Conservation, Reproduction, Sustainable Utilization and Study of Waterfowl, affected in 2003.

A joint project of the Government of Kazakhstan and Global Environment Facility entitled "Integrated Conservation of Priority Globally Significant Wetlands as Habitats of Migratory Birds - Demonstration in three Sites" is focused on the demonstration of comprehensive approaches to the conservation of waterfowl populations and their habitats. Three globally significant wetlands, Tengis-Kurgaljin lakes, the delta of the Ural River, and the Alakol lakes system, located on the most important migration routes of waterfowl in Kazakhstan, have been selected as demonstration sites. The project, which is envisioned

to have a seven-year term, commenced in 2004 within the UN Sustainable Development Program in Kazakhstan.

In 2002, the Program of Mandatory Environmental Education was adopted at national level with a view to providing training in basic environmental knowledge, primarily through an introduction to biodiversity and the problems of biodiversity conservation for students and high school children as well as specialists in various fields of activity.

At local level, the main efforts for the conservation of Anatidae are largely focused on the efficient management of hunting resources. Temporary difficulties resulting from the economic reform have forced some groups of people, especially rural populations, to exploit natural resources, particularly fish and waterfowl, and this had led to violations of the law. Since 2003, regional authorities concerned with the management of hunting have been obliged to perform annual monitoring in waterfowl reserves, and this will be used as a basis for the establishment of hunting quotas.

Considerably more attention is now being given to strengthening the existing protected areas and establishing new protected areas at local level in the most significant habitats for Anatidae. In 2000, all such territories were subject to state registration. Specific users responsible for their management and conservation have been appointed. At present, there are 14 locally protected wetlands (zakazniks) and over 100 "rest zones", including the lakes where waterfowl hunting is fully prohibited or restricted, in Kazakhstan.

Kazakhstan has recently become involved in international co-operation in the conservation and study of Anatidae species in Central Asia. The legal framework for such co-operation is determined by a special international agreement concluded in

1995 by the Ministries of Environment of Kazakhstan, Kyrgyzstan, Uzbekistan and Tajikistan. The priority objectives of regional co-operation include efficient management of trans-boundary water resources, resolution of the consequences of shrinkage of the Aral Sea, and conservation of biodiversity in the region. Kazakhstani experts are playing an active role in developing the initiative proposed by Wetlands International for joint actions along the Central Asian Flyway. In particular, in recent years they have taken part in such projects as: 'The Present-day Status of White-headed Duck (*Oxyura leucocephala*) in Central Asia'; 'Assessment of the Present Conditions of the World Population of Ferruginous Duck (*Aythya nyroca*)'; and 'The Record of Wintering Waterfowl in Central Asia'. Since 2003, Kazakhstan and other regional partners (Russia, China and Islamic Republic of Iran) have started to implement the GEF/UNEP project 'Conservation of the Network of Effectively Protected Territories on the Migration Flyways of the Western Population of Siberian Crane *Grus leucogeranus* and Other Globally Endangered Waterfowl Species' - a project envisaged to continue for six years.

Kazakhstan was one of the first countries to accede to the Convention on Biological Diversity (1994), and is at the final stages of approving the necessary documents to accede to the Ramsar Convention on Wetlands (1975). Approval has also been given for Kazakhstan to accede to the Convention on the Conservation of Species of Migratory Wild Animals (1979). For many years, Kazakhstan has been co-operating with other countries in the region within the framework of international memoranda on the conservation of endangered species such as the Siberian Crane, Slender-billed Curlew *Numenius tenuirostris* and Sociable Lapwing *Vanellus gregarius*.

Kazakhstan is co-operating in a range on international conservation collaborations including the Convention on Migratory Species' Memorandum of Understanding on the Siberian Crane *Grus leucogeranus*. ## PROJECTIONS FOR THE FUTURE

As a result of global warming, the southern limits of the breeding ranges of species that breed only in northern and north-eastern Kazakhstan, i.e. Eurasian Wigeon *Anas penelope*, Northern Pintail *A. acuta*, Tufted Duck *Aythya fuligula*, scoters *Melanitta* spp. and Goosander, will move to the north or north-east and beyond the boundaries of Kazakhstan. However, species with a more southerly or westerly range in Kazakhstan, such as the Ruddy Shelduck, Red-crested Pochard, White-headed Duck and possibly Marbled Teal *Marmaronetta angustirostris*, will increase in number during the breeding season.

Industrial and agricultural development will lead to increased water consumption, and there will be an increase in the number of polluted water bodies. However, economic growth will enable the Government to allocate sufficient finance for in-depth scientific studies of Anatidae species. The scientific knowledge obtained from these studies will be used to develop practical measures for the efficient management and conservation of Anatidae. Solving environmental and protection problems will be given higher priority. In addition to economic development, further development and improvements will be made in the legal and legislative systems in relation to natural resources, particularly as they relate to waterfowl and their habitats.

Slowly but steadily, the overall level of environmental knowledge will increase among the population of Kazakhstan. Attitudes towards the exploitation of the nation's natural heritage will change with increasing understanding of the fragility and vulnerability of the environment and the full dependence of biodiversity upon human activities. Existing voluntary public associations (NGOs) and the development of new NGOs in Kazakhstan will make a larger contribution to the conservation of waterfowl and their habitats. Anatidae in Kazakhstan have a promising future.

## ACKNOWLEDGEMENTS

The author gives credit to his colleagues, Kazakh ornithologists, who have taken an active part in the study of Anatidae (Eduard Gavrilov, Nikolai Berezovikov, Anatoly Gistsov, Vladimir Vilkov, Nikolai Andrusenko, Vasily Zhulyi and others). Recent

surveys in northern Kazakhstan were made possible with the support and co-operation of the Regional Environmental Agency in Hame, Finland, and especially Dr. Erkki Kellomiaki. For many years, the Goose, Swan and Duck Study Group of Northern Eurasia and the Duck Specialist Group of Wetlands International have helped in the development and funding of surveys. With their support, the author has been able to report on the results of surveys at annual meetings. In recent years, fruitful co-operation has been developed with government agencies in Kazakhstan, the Forestry and Hunting Committee, hunting inspectorates and hunting societies, individual hunters and naturalists. The author wishes to thank all those who have contributed in the development of this report, and looks forward to co-operating with them in the future.

## Creating protected areas on Lake Balkhash and Ile River Delta in the Kazakhstan Republic

Altay Zhumakan-Uly Zhatkanbayev

Institute of Zoology of the Ministry of Education and Science, Akademgorodok, Almaty, 480060, Kazakhstan.

Zhatkanbayev, A.Z-U. 2006. Creating protected areas on Lake Balkhash and Ile River Delta in the Kazakhstan Republic. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 275-276.

The Republic of Kazakhstan is a new, independent state created after the disintegration of the Soviet Union. Occupying an area of 2 717 300 km<sup>2</sup>, it is the ninth largest country in the world. Due to its large expanses of arid and largely uninhabitable territory, Kazakhstan is an unevenly and sparsely populated country of c.15 million people. The climate in most areas is predominantly arid, although nearly all types of climate occur, with the exception of tropical and subtropical.

Flat lands occupy up to 90% of the Republic, of which, 63% fall within semi-arid and fully arid zones. A Government Nature Reserve (zapovednik) is the highest form of protection for natural areas, protecting typical landscapes and also particularly valuable or vulnerable areas. These reserves are one example of the Soviet (now considered Russian) system of protecting natural territories, and have been preserved in the majority of the other newly independent post-Soviet states, with the exception of the three Baltic States, Estonia, Latvia and Lithuania, which have changed their systems of protected territories. In the 1980s and 1990s, during the Soviet and post-Soviet periods of development, the North American system of National Parks for protected areas became popular, there are already six in Kazakhstan under the control of central government. Additionally, in Kazakhstan and neighboring Kyrgyzstan, the German Union for Nature Protection (NABU) is attempting to introduce Biosphere Reserves. However, no Biosphere Reserves have yet been created in Kazakhstan.

Currently there are ten Nature Reserves (zapovedniks) in Kazakhstan with a combined area of 950 000 hectares, about 0.35% of the Republic's territory. Many people working in conservation would like to increase this amount of protected land to match those of other countries. Unfortunately, in the typical Soviet desire to pursue high figures, the quality of such protected areas has been forgotten. Quality, nonetheless, should always prevail over quantity. Kazakhstan currently lacks the ecological, social and economic prerequisites to increase the number of Nature Reserves or the amount of protected land. In today's conditions, even the most basic attributes are lacking, and have been for some time. In many of the existing reserves, the protected status of the land is not observed in any sense and there are inadequate numbers of staff to carry out preservation work or conduct a full state programme of scientific work. In some reserves there are no scientific staff at all, and the necessary funding and equipment is lacking. In practically all zapovedniks there is opposition to the protected status of the land by those who favor traditional, historical uses of the biological and other natural resources by local communities. Additionally, in almost all local nature reserves, some type of economic activity or use of natural resources is permitted in violation of existing nature protection legislation. This situation has arisen as a result of the top-down management of the

reserves during the long Soviet period of their existence, and it reflects the need to improve, or transform, the existing system. It is urgent for this to take place in the near future in order to ensure the necessary economic, social and environmental conditions for development in Kazakhstan.

Of the ten zapovedniks, five are situated in the Tian Shan mountains, in the southern and southeastern part of the Republic, and the Altai mountains, in the eastern part. Five are located in zones of varying aridity: Usturt, Barsa-Kelmes, Nauryzym, Korgalzhin and Alakol. Seven of the ten were established during the Soviet period, and all of them, including the most recently established, were created according to the principle of protecting typical, representative landscapes. The preservation and rehabilitation of threatened animal species and plants was a secondary issue.

The region around Lake Balkhash is the most attractive area for creating new reserves. During the Soviet years the Kazak National Academy of Sciences developed a long-term plan for the development of a network of protected natural territories, and provided scientific grounds for creating a flat-land reserve of 210 000 hectares formed from three areas, including both desert and wetland areas, in this region of the Southern Balkhash.

These new zapovednik would preserve not only representative landscapes but also a wide assortment of Kazak desert animals, including those listed in the 1996 Red Data Book of Kazakhstan, such as Bobrinski's Bat *Eptesicus bobrinskii*, Persian Gazelle *Gazella subgutturosa*, Asiatic Wild Ass *Equus hemionus*, Marbled *Vormela peregusna*, Short-toed Snake-Eagle *Circaetus gallicus*, Steppe Eagle *Aquila rapax*, Imperial Eagle *Aquila heliaca*, Houbara Bustard *Chlamydotis undulata*, Black-bellied Sandgrouse *Pterocles orientalis*, Pin-tailed Sandgrouse *Pterocles alchata*, Pallas's Sandgrouse *Syrhaptes paradoxus*, Eagle Owl *Bubo bubo* but also high endemic species that are the typical inhabitants of desert territories: Thick-tailed Pygmy Jerboa *Salpingotus pallidus* and Ile's Pander's Ground-Jay *Podoces panderi ilensis*. The need for specially protected areas for small vertebrates, however, is not as important as for large hoofed animals and especially many waterbird species, which are often hunted by poachers.

The Ile River drains the northern Tian-Shan mountains and enters Lake Balkhash, creating a delta of c. 817 000 hectares, which consists of an extensive network of river channels, bordered by dense riparian scrub, lakes of standing and running water, reed beds and desert areas. The typical wetland area of c. 168 000 hectares is the largest in Kazakhstan.

Currently, this almost completely natural area hosts breeding sites of such globally threatened and near-threatened bird species as Dalmatian Pelican *Pelecanus crispus*, White-Headed Duck *Oxyura leucocephala*, Ferruginous Duck *Aythya nyroca*,

White-tailed Eagle *Haliaeetus albicilla*, Pallid Harrier *Circus macrourus*, Black-winged Pratincole *Glareola nordmanni*, White-winged Woodpecker *Dendrocopus leucopterus* and Pale-backed Pigeon *Columba eversmanni*.

Ten native fish species *Schizothorax argentatus argentatus*, *Diptychus dybowskii*, *Diptychus maculatus*, *Phoxinus phoxinus phoxinus*, *Perca schrenki*, *Noemacheilus strauchi strauchi*, *Noemacheilus labiatus*, *Noemacheilus dorsalis*, *Noemacheilus stoliczkai stoliczkai* and *Noemacheilus sewerzowi* occur amongst the total of 28 species which inhabit the Ile-Balkhash basin since 18 species have been artificially introduced here. Two of the native fish species, (*S. a. argentatus* and *P. schrenki*) are globally threatened, and *S. a. argentatus* is almost extinct.

In 1996, the commercial fishery on Lake Balkhash and Ile River Delta, consisted respectively (in tons): *Abramis brama* (3424 and 29), *Stizostedion lucioperca* (535 and 3), *Silurus glanis* (298 and 80), *Cyprinus carpio* (127 and 10) and *Aspius aspius* (93 and 13). The fishery on Lake Balkhash is better developed than in the delta and is increasing now that it has opened up to the newly evolving private sector with the economic changes brought about following the break-up of the USSR.

The major factor affecting waterfowl, other birds and general wildlife in the delta is the increasing annual burning of reeds and riparian scrub by local hunters, fishermen and farmers to provide fresh areas for fishing, grazing, harvesting of reeds and open areas for hunting Muskrats *Ondatra zibetica*. Burning and illegal hunting are uncontrolled and occur throughout the delta, even in the wetter parts. An integrated approach to land and water-use management in this largest wetland in Kazakhstan is needed, particularly the regulation of water flow through the Kapshagay dam, so as to reintroduce natural flow regimes. Fires and poaching are a major threat for wildlife, but much of this can be overcome if local people can be encouraged to avoid burning and hunting, especially during the breeding season for wildlife. There is a need for raising awareness, promoting educational programmes and encouraging environmental tourism, which could bring real benefits to the wetland and the local communities. Finally, as result of conservation efforts, the designation of protected areas as national natural parks or nature reserves (zapovednik) is important in these largest and highest priority wetlands in Kazakhstan, such as Lake Balkhash and Ile River Delta.

Kreuzberg-Mukhina, E.A. 2006. The effect of habitat change on the distribution of waterbirds in Uzbekistan and the possible implications of climate change. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 277-282.

### ABSTRACT

In recent decades, a significant change has been observed in the climate in Central Asia. To some extent, this has been caused by the large-scale development of irrigated agriculture in the region leading to redistribution of water resources and transformation of ecosystems. Degradation of the Aral Sea and creation of new water-storage reservoirs in the desert regions have affected the climate at both local and regional level. At the same time, significant warming has been observed in the global climate. An analysis of data on the current status of waterbirds wintering in Uzbekistan has shown that waterbirds are sensitive indicators of the climate change that has occurred in the region. Historically, two wintering zones (warm and cold) have been recognized in Uzbekistan, divided by the 0°C isotherm in January. Most of the waterbirds that overwinter in Uzbekistan occur in the warm wintering zone, which was formerly confined to southern regions of the country. Waterbirds occur in the cold wintering zone mostly in autumn, before the appearance of ice cover on the reservoirs. As a result of the warming in climate, the northern limit of the warm wintering zone is shifting permanently to the north. This paper discusses the response of waterbirds to the creation of new wintering habitat and warming in climate in Uzbekistan during the last two decades.

### INTRODUCTION

The region of Central Asia covers about four million km<sup>2</sup> and has a human population of about 45 million. In recent decades, it has become evident that a significant change is occurring in the region's climate. On the one hand, this is a reflection of global climate warming processes. On the other hand, large-scale development and irrigation projects in Central Asia have led to climate change in the region through their influence on desertification and salinization processes and transformation of ecosystems. New artificial water-storage reservoirs have been constructed in arid agricultural regions, and these have partially compensated for the loss of extensive wetland habitats in the basin of the Aral Sea. The degradation of the Aral Sea and the creation of new reservoirs within its basin have both had an influence on the climate at local and regional level.

Historically, the wetlands in the Aral Sea deltas served as stopover sites for large numbers of waterbirds migrating between breeding grounds in Western Siberia and Kazakhstan and wintering areas in south-west Asia, Africa and the Indian subcontinent (Isakov 1975, Gavrilov 1979, Dolnik 1982). As a result of the desiccation of the Aral Sea and degradation of wetlands in the Amu-Darya and Syr-Darya deltas, the richest biological resources in this region were destroyed. At the same time, the

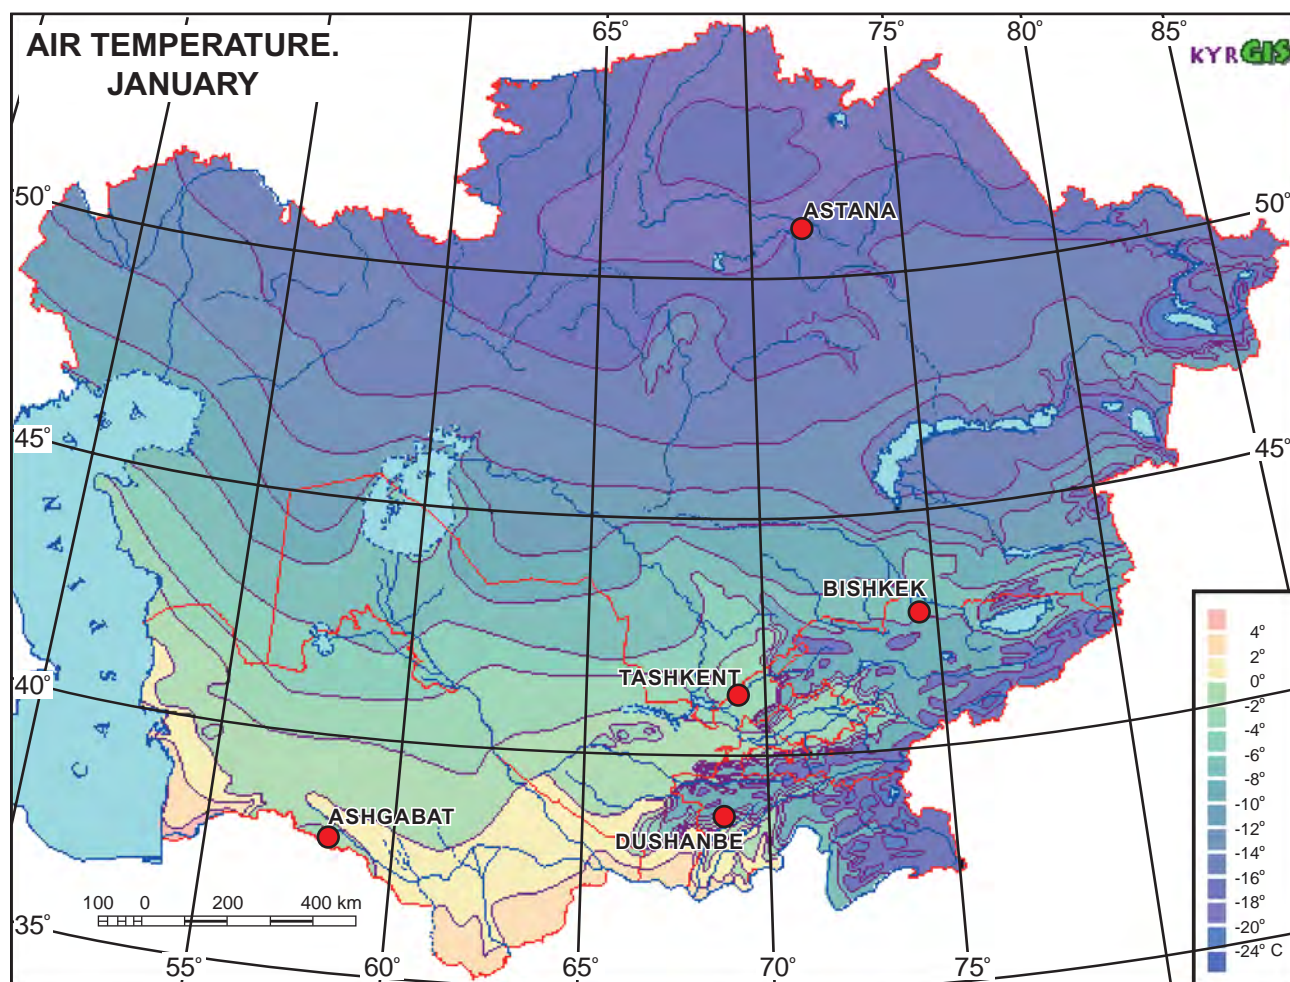

Fig. 2. Average January air temperatures in Central Asia.

appearance of new artificial wetlands in the south of the region, which had historically been very dry, resulted in a redistribution of waterbirds during the migration seasons and in winter.

It is evident that there has been a warming of the climate in Uzbekistan in recent decades (Fig. 1) and as a result of this warming, new wintering sites have become available for many species of waterbirds. Mid-winter waterbird counts conducted in the late 1980s and during the last few years (2000-2004) have shown that the limit of the warm wintering zone has shifted northwards by 300-500 km since the 1980s. In contrast, meteorological records suggest that during the preceding 100 years, the January isotherm shifted northwards by only about 200 km (data from National Institute of Hydro-meteorological Research).

An analysis of data on the current status of waterbirds wintering in Uzbekistan has shown that waterbirds are sensitive indicators of the climate change that is taking place throughout the region. The redistribution of wintering waterbirds is not only of scientific interest, but also has an influence on the development of local economies and is of considerable practical value. However, the development of appropriate conservation measures for waterbirds has been hampered by the current lack of national and regional strategies and wetland management plans, a lack of knowledge, a lack of training, education and awareness programmes, and an absence of dialogue with stakeholders concerning wetland resources. It is essential, both for the conservation of threatened waterbird species and for the sustainable

use of waterbirds as a game resource, that a long-term programme for the monitoring and management of wetlands and waterbirds in Uzbekistan be initiated on the basis of proper scientific assessment.

## METHODS

A special investigation of the status and distribution of waterbirds in Uzbekistan was conducted in 1986-1988 as part of a national programme for the compilation of information on game species (Shernazarov 1996, Atajanov *et al.* 1999, Nazarov & Mukhina 2002). This investigation involved aerial censuses in the Zeravshan, Syr Darya and Amu Darya basins, and covered 39 water-storage reservoirs during the autumn migration season and 23 water-storage reservoirs during the winter months. In 2000, aerial censuses of wintering waterbirds were carried out at a total of 25 water-storage reservoirs mostly in the south of Uzbekistan, although some sites in the north of the country were also counted (Atajanov *et al.* 2000). In addition, in 2000-2004, ground counts of wintering waterbirds were conducted at 30 water bodies in Uzbekistan (Lanovenko & Kreuzberg 2002). In general, the same important wintering sites were covered each year, although coverage in 1986-1988 was somewhat more extensive than in 2000-2004. During the course of these mid-winter surveys, data were gathered on the numbers and distribution of 50 species of waterbirds. The present analysis is based on the published results of these surveys.

## RESULTS

### Changes in the numbers of waterbirds wintering in Uzbekistan

Historically, a warm wintering zone and a cold wintering zone have been recognized in Uzbekistan, divided by the 0°C isotherm in January (Kashkarov 1994, 1999). The dividing line between the two zones runs to the north of the lower course of the Zeravshan River (Fig. 2). About 80% of all waterbirds wintering in Uzbekistan are found in the southern regions of the country. The northern regions, which support the remaining 20%, are characterized by unstable conditions and significant fluctuations in waterbird numbers (Atajanov *et al.* 1999). The mid-winter waterbird surveys in the 1980s revealed that during this period the total number of wintering waterbirds was between 200 000 and 300 000 (Kashkarov 1999, Nazarov & Mukhina 2002). The aerial survey in 2000 revealed that there had been a significant increase in the total number of wintering waterbirds to about 978 000 (Atajanov *et al.* 2000). Of these, 327 300 (33.5%) were in the cold wintering zone, and 651 200 (66.5%) in the warm wintering zone (Lanovenko *et al.* 2001). The increasing trend in the numbers of waterbirds wintering in Uzbekistan continued in 2002–2004. Taking into account the relatively poor coverage of ground surveys at large reservoirs, the numbers of wintering waterbirds recorded in 2002–2004 were significant. In 2002, when only the 14 largest reservoirs were counted, 374 600 waterbirds (72.7% of the total) were recorded on reservoirs in the southern regions of Bukhara and Surkhandarya (warm wintering zone), while 102 400 (27.3%) were recorded in the Aydar-Arnasay wetland system in the north (cold wintering zone). Thus, it appears from these surveys that the total number of waterbirds wintering in Uzbekistan has been increasing over the past two decades, and that the birds are becoming more evenly distributed between the warm and cold wintering zones.

A comparison of the results of the aerial surveys in the 1980s with those of the similarly comprehensive aerial survey in 2000 reveals that there have been some changes in the relative abundance of the most abundant wintering species in Uzbekistan (Table 1). Data on 44 species of waterbirds were gathered during the mid-winter surveys in 1986–1988 (Nazarov & Mukhina 2002). Among game species, the Common Coot *Fulica atra* was the most numerous, accounting for 40% of all waterbirds counted. The Mallard *Anas platyrhynchos* and Common Teal *A. crecca*

were also numerous, and represented about 30% and 10% of all birds counted, respectively. Other species of Anatidae, such as Red-crested Pochard *Netta rufina*, Common Pochard *Aythya ferina*, Tufted Duck *A. fuligula*, Smew *Mergellus albellus* and Goosander *Mergus merganser*, together comprised about 10% of the total (Kashkarov 1999). In 2000, data were collected on 38 species of waterbirds (Atajanov *et al.* 2000). Among these, the Common Coot made up 43.0% of all birds counted, the Mallard 11.7%, and the Common Teal 3.8%. Other common species in 2000 included the Greylag Goose *Anser anser* (3.3% of all birds counted), Common Pochard (3.3%), Red-crested Pochard (1.6%), Great Cormorant *Phalacrocorax carbo* (1.6%), and pelicans *Pelecanus* spp. (0.5%). In the 1980s, the six most abundant species accounted for almost 81% of the total waterbirds wintering in Uzbekistan, while in 2000, the nine most abundant species accounted for only about 70% of the total. This demonstrates greater diversity in the wintering concentrations of waterbirds in 2000 than in the 1980s.

Although aerial surveys permit coverage of most of the water-storage reservoirs in Uzbekistan, including areas that are inaccessible from the ground, it is necessary to note some shortcomings of these surveys. For example, it is difficult to identify and count some species, such as divers (Gaviidae) and grebes (Podicipedidae), which do not take off from the water during the surveys. Ground surveys conducted in January 2000 at reservoirs in the Djizak, Samarqand and Bukhara regions (mostly in the warm wintering zone) enabled data to be gathered on 49 species of waterbirds. These included a total of 1 822 grebes belonging to five species, as compared with only 72 individuals counted during the aerial survey (Atajanov *et al.* 2000). Concentrations of grebes were observed on many reservoirs in Uzbekistan during the ground surveys in 2001–2004 (Kreuzberg-Mukhina & Snegur 2002).

The numbers of waterbirds on the reservoirs of Uzbekistan can show wide fluctuations during the winter months depending on fluctuations in temperature. The largest concentrations of waterbirds are observed after unexpected and sharp falls in temperature. For example, at the beginning of December 2001, following sharp frosts in northern regions of the country, huge flocks of ducks appeared on reservoirs in the south. At this time, a concentration of over 36 000 Red-crested Pochards was recorded on Karakyr Lake in the Bukhara region, and migrating flocks of 831 Goosanders and 225 Red-breasted Mergansers

**Table 1.** The most abundant species of waterbirds wintering in Uzbekistan in the 1980s and in 2000.

Status: B – breeding bird; M – passage migrant; W – winter visitor.

Species	Status in Uzbekistan	Proportion in 1980s (%)	Proportion in 2000 (%)
Pelican species <i>Pelecanus</i> spp.	B, M, W	*	0.5
Great Cormorant <i>Phalacrocorax carbo</i>	B, M, W	*	1.6
Great Egret <i>Egretta alba</i>	B, M, W	*	0.9
Greylag Goose <i>Anser anser</i>	B, M, W	1.0	3.3
Mallard <i>Anas platyrhynchos</i>	B, M, W	27.6	11.7
Common Teal <i>Anas crecca</i>	M, W	9.7	3.8
Red-crested Pochard <i>Netta rufina</i>	B, M, W	0.9	1.6
Common Pochard <i>Aythya ferina</i>	B, M, W	1.5	3.3
Common Coot <i>Fulica atra</i>	B, M, W	40.0	43.0
Other waterbirds	-	19.3	30.3

\*: Present in very small numbers and included in "Other waterbirds".

**Fig. 3.** Numbers of wintering waterbirds (in thousands) on several lakes in the Bukhara region, Uzbekistan. Counts were conducted in: A – January 2000; B – February 2000; C – January 2002; D – January 2003; E – January 2004. Blue – Dengizkul Lake; Green – Zekry Lake; Pink – Tudakul Lake; Yellow – Kuyumazar Reservoir.

*Mergus serrator* were observed on reservoirs in the Khorasm region. By January 2002, these birds were more widely dispersed within the various wetlands of the Bukhara region. In relatively warm winters with stable temperatures, the waterbirds are more evenly distributed throughout the wetlands of Uzbekistan and do not form such large concentrations.

Furthermore, the number of birds at a particular reservoir can remain stable or fluctuate from year to year depending on local ecological conditions. For example, at four wetlands in the Bukhara region (Dengizkul Lake, Zekry Lake, Tudakul Lake and Kuyumazar Reservoir), the number of wintering birds changed both within a winter (2000) and also from year to year (Fig. 3). At Dengizkul Lake, the first wetland to be designated as a Ramsar site in Uzbekistan, the number of birds fell from 287 000 in January 2000 to only 16 000 in January 2004 as a result of the unstable water regime in the lake. At the small Zekry Lake, where the number of wintering birds depends on the inflow of irrigation water from agricultural land, numbers fluctuated widely from 27 000 in 2000 to 8 000 in 2003 and 44 000 in 2004. At Tudakul Lake, which has a stable water regime, the number of wintering birds was relatively stable in 2000–2004, with numbers fluctuating between 21 000 and 25 000. At Kuyumazar Reservoir, also with a stable water regime, the wintering population of Mallard increased from about 30 000 in 2000 to about 140 000 in 2004. Thus it appears that the waterbirds wintering in Uzbekistan are responding quickly both to changes in the climate and to ecological changes at the wetlands.

### The shift in wintering zones and response of waterbirds to climate change

The ground and aerial surveys of wetlands in Uzbekistan in 2000–2004 revealed that new wintering areas were being established in areas that had not previously supported large numbers of waterbirds. The surveys also led to the discovery of species which had not previously over-wintered in Uzbekistan or had been recorded only in very small numbers, such as the Common Crane *Grus grus*, Black Stork *Ciconia nigra*, Ruddy Shelduck *Tadorna ferruginea* and White-headed Duck *Oxyura leucocephala*. Until recently, even regular over-wintering by species of grebes was unknown in Uzbekistan. The increase in numbers of wintering birds has been most pronounced in geese, swans, pelicans, cormorants, herons, White-tailed Eagle *Haliaeetus albicilla* and White Stork *Ciconia ciconia* – species which formerly wintered in Uzbekistan in very small numbers.

An analysis of the data has revealed that major changes have occurred in the winter distribution of a number of waterbird species in Uzbekistan. Five such species are discussed below.

The total wintering population of the Greylag Goose in Uzbekistan was formerly estimated at between 2 000 and 5 000 individuals (Nazarov & Mukhina 2002). However, current assessments of the wintering population range from 50 000 to 100 000 individuals (Atajanov *et al.* 2000). Most of these geese spend the winter in the reed-beds of Karakyr Lake where, according to the hunting inspectorate, over 100 000 individuals have been recorded during the winter season. About 28 000 Greylag Geese were counted at this lake during the mid-winter survey in 2000 (Atajanov *et al.* 2000). Between 12 000 and 17 000 geese were recorded annually from 2001 to 2003 in the border zone between Uzbekistan and Afghanistan (Kreuzberg-Mukhina & Lanovenko 2003), and over 20 000 geese were recorded flying out to feed in fields of cereals in the Kashkadarya region in January 2004. Significant numbers of wintering geese also congregate on wild cereals in the Kyzylkum desert between Aydar Lake and the Nuratau range. It is evident, therefore, that the number of Greylag Geese wintering in Uzbekistan has increased by at least 10–15 times in recent decades. Irrigated cereals and wild cereals, which now continue to grow throughout the winter months, provide suitable feeding conditions for the geese, and the proximity of wetlands to the feeding areas encourages the birds to remain in these areas.

In the past, the Ruddy Shelduck was recorded in Uzbekistan only in very small numbers in southern regions of the country (Kashkarov 1987). Its numbers never exceeded several hundred individuals. In recent years, this duck has been extending its range in winter to water-storage reservoirs in the vicinity of agricultural land (Kreuzberg-Mukhina & Lanovenko 2001, Lanovenko *et al.* in press). Estimates from the various provinces of Uzbekistan indicate a wintering population in recent years of between 1 000 and 15 000 individuals. However, this is likely to be an underestimate, as this species, which spends much of its time on agricultural land, is easily overlooked during the counts.

The White-headed Duck was formerly an extremely rare species in Uzbekistan, recorded in very small number only at the beginning of the twentieth century (Kashkarov 1987). The unexpected rediscovery of the White-headed Duck at Sudochie wetland in autumn 1999 was followed by a series of records of this globally threatened species in Uzbekistan (Kreuzberg-Mukhina & Lanovenko 2000). The species was first recorded at Dengizkul Lake during the winter of 2000 (Lanovenko *et al.* 2000, Kreuzberg-Mukhina 2003). The number of wintering birds increased rapidly, and an almost unbelievable total of 5 135 White-headed Ducks was recorded at this lake in January 2003. The birds were more widely dispersed in January 2004, when a total of 1 194 were recorded at Karakyr, Tudakul, Khadicha, Zekry and Dengizkul lakes. The optimum conditions for White-headed Ducks wintering in Uzbekistan have yet to be determined, but it is clear that this is another species that is spreading from the south and taking advantage of water-storage reservoirs to extend its wintering range.

In February 2001, about 5 500 Common Cranes were recorded on abandoned agricultural land and wheat fields near the Amu Darya River in the border zone between Uzbekistan and Afghanistan (Lanovenko & Kreuzberg-Mukhina 2002). This

was the first observation of Common Cranes wintering in Central Asia. Previously, the nearest wintering areas of Common Cranes were in India (Flint 1987). Surveys along the Amu Darya River in the winters of 2002 and 2003 recorded totals of 15 500 and 15 600 Common Cranes, respectively. In 2004, however, the cranes were found over 500 km to the north of Surkhandarya region – in Bukhara, Kashkadarya, Samarkand and Djizak regions. In that year, there were about 2 500 cranes in Kashkadarya region alone.

The Northern Lapwing *Vanellus vanellus* was formerly recorded as a wintering species only in southern regions of Uzbekistan. In recent years, this species has been observed in suitable habitat throughout southern and central regions of Uzbekistan, and is slowly extending its range northwards. Thus, while in 2001 Northern Lapwings were observed only in Surkhandarya region in the south of country, in 2003 and 2004, they were recorded near lakes Aydar and Achinskoe in Djizak and Kashkadarya regions.

Similar changes have been observed in the wintering distribution of the Great Crested Grebe *Podiceps cristatus*, Black-necked Grebe *P. nigricollis*, Great Cormorant, Pygmy Cormorant *Phalacrocorax pygmeus*, Dalmatian Pelican *Pelecanus crispus*, Grey Heron *Ardea cinerea*, White Stork, Black Stork, Mute Swan *Cygnus olor* and some other species. In general, these species have shown a tendency to spend the winter at recently constructed water-storage reservoirs.

## DISCUSSION

### Climate change and the possible consequences for waterbirds

It has been predicted that as a result of the warming in climate, by the year 2030 the boundary between the dry tropical and temperate climatic zones will have shifted northwards by a further 150–200 km, while altitudinal climatic zones will have moved upwards by 150–200 m (Spektorman 2002). By the same time, the duration of the frost-free period will have increased by 8–15 days. An increase of 1.5–2.0°C in air temperatures in the central Kyzylkum desert will result in a change from the existing cold winter regime to a regime of relatively mild winters throughout which plant growth is possible. It is already apparent that such changes are creating suitable conditions for over-wintering by many species of waterbirds in parts of the cold deserts of Central Asia that were formerly frozen in winter. At the same time, the construction of large water-storage reservoirs and other artificial wetlands in these arid regions has created appropriate ecological conditions for wintering waterbirds. One might therefore expect there to be an extension in the wintering zone of waterbirds in Central Asia, an increase in the numbers and diversity of waterbirds wintering in the region, and the establishment of permanent over-wintering sites for some species and groups of species. The tendency for birds to return to the same areas in successive winters has been observed in the Dalmatian Pelican, Great Egret, Grey Heron, Mute Swan, Greylag Goose, Mallard and some other species. In contrast, the grebes and many species of ducks change their wintering areas both within winters and from year to year.

A similar change in the climate has been observed at other seasons, but the existing ornithological data are insufficient for any analysis to determine if there have been comparable changes in species distribution and numbers during the migration and breeding seasons.

Large-scale abstraction of water from the Amu Darya and Syr Darya rivers for irrigation purposes led to the Aral Sea crisis. This has been discussed elsewhere (Anon. 1999, Gorelkin *et al.* 2002, Agaltsova & Borovikova 2002, Tuchin *et al.* 2003), but it is worth adding here that the expected climate change will have further negative consequences for wetland ecosystems in the region, such as increasing evaporation rates, increasing salt migration, exhaustion of underground water resources, decreasing soil fertility, increasing mineralization of stagnant lakes, and an acceleration in the eutrophication processes in water-storage reservoirs. Furthermore, there are no climate change scenarios that show an increase in the flow of the Amu Darya and Syr Darya rivers. On the contrary, it is expected that there will be a decrease in flow during the growing season, and this might be expected to worsen the crisis in the Aral basin. As a result of global warming, there will be an increase in the occurrence of extreme climatic events such as periods of drought and high summer temperatures, further affecting the water regime and with additional negative consequences for natural ecosystems and people (CAREC 2003).

## CONCLUSION

During the last two decades, there has been a significant increase in the extent of agricultural land in Uzbekistan, while at the same time, a rise in winter temperatures has enabled the growth of desert plants to continue throughout the winter. It is clear that both of these factors have had an influence on the wintering status of many waterbird species. It seems that waterbirds are sensitive indicators of the changes that are occurring in the structure of ecosystems as a result of climate change. In view of the high value of many waterbird species in local economies in Uzbekistan, there is an urgent need to implement special measures for the proper management and wise use of waterbirds in the region.

The changes in climate that are occurring in Central Asia are aggravating the ecological problems in the Aral Sea basin and require appropriate response measures. If socio-economic development is to be sustainable, it is necessary to co-ordinate development activities with a comprehensive water policy that includes reconstruction of agriculture, the use of water-saving technologies, and the management and conservation of water resources.

## ACKNOWLEDGEMENTS

First of all, the author wishes to express her gratitude to the international organizations that have sponsored surveys of wintering waterbird in Uzbekistan: the Agricultural Department of the Royal Netherlands Embassy in Moscow (2001–2003), the Ramsar Small Grants Programme (1998–2000), and Wetlands International (2003–2004). The idea for this analysis of information on wintering waterbirds in relation to climate change came from Dr D. Yu. Kashkarov (1937–2003). The collection of data on wintering waterbirds in Uzbekistan was undertaken by many specialists from the Institute of Zoology, National University and hunting inspectorates of Bukhara, Tashkent, Djizak, Samarkand, Navoi, Kashkadarya and Surkhandarya provinces of Uzbekistan. Special thanks should be given to colleagues from the Institute of Zoology who participated in the mid-winter waterbird counts in 2001–2004: Dr E. Shernazarov, Dr E. Lanovenko, A. Filatov, S. Zagrebin, A. Ten and D. Snegur. Special thanks should also be

given to Dr N.Ye. Gorelkin from the National Institute of Hydro-meteorological Research for kindly providing information on climate change and the current status of water-storage reservoirs in Uzbekistan and elsewhere in Central Asia.

Kreuzberg-Mukhina, E.A. 2006. The Aral Sea basin: changes in migratory and breeding waterbird populations due to major human-induced changes to the region's hydrology. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 283-284.

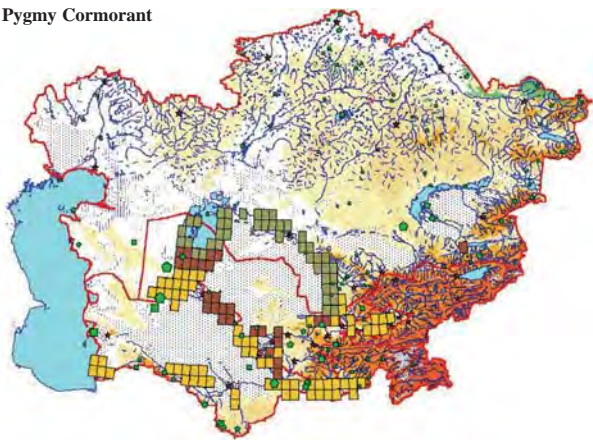

Most of Central Asia is located in an arid zone within the inland drainage area of the Aral Sea basin. In the mountain systems of Tien-Shan and Pamir-Alai the seasonal thaw of snow and glaciers, combined with rain, feeds the two biggest rivers, the Amu Darya and Syr Darya. Between 1960 and 1980 the widespread development of dams and irrigation systems began to divert substantial amounts of water from the Amu Darya and Syr Darya rivers for agricultural irrigation, mainly for cotton production, and this has had major ecological impacts of an unparalleled scale on the Aral Sea and its catchments, including on waterbirds.

The water level of the Aral Sea itself has fallen by 16 m, with major increases in salinity and drying out much of the former lake bed and the deltas of the Amu Darya and Syr Darya rivers. These ecologically rich deltas, originally wetland habitats rich in biodiversity, are threatened by desertification and significant

**Fig. 2.** Changes in the breeding and non-breeding distribution of four globally-threatened waterbirds (Pygmy Cormorant *Phalacrocorax pygmaeus*, Great White Pelican *Pelecanus onocrotalus*, Marbled Teal *Marmaronetta angustirostris*, and Glossy Ibis *Plegadis falcinellus*). Legend: Green cells are the past breeding area of species distribution; brown cells are the current breeding area, yellow cells are the non-breeding areas. Bright green cells are protected areas.

loss of waterbird species. These Aral Sea basin wetlands were very important for breeding colonial waterbirds such as pelicans, cormorants, herons, egrets, swans and ducks. In the early 1960s there were approximately 2 600 lakes in the Amu Darya delta but this had fallen to only 400 by 1985. Decreases in river flows and delta lake area are shown in Fig. 1. These changes have had major impacts on the climatic, ecological, economic and social conditions of the Aral Sea region.

Recognition of these impacts has led to some wetland restoration efforts (e.g. in the Sudochie wetland). In addition, many new artificial water-bodies have been created associated with water management for the 7 million ha of irrigated land. These include 94 reservoirs and 24 000 km of channels (Gorelkin 1988, Gorelkin *et al.* 2002). These new water bodies have to some extent replaced the functions of the original lake systems as migratory sites for waterbirds using migratory flyways from Western Siberia and Kazakhstan to Caspian and African wintering areas, and are also used as recreational areas for fishing and hunting by local communities.

However, the loss of wetlands has led to major changes to the species composition, numbers and distribution of waterbirds. At the beginning of the 20th century the Aral Sea and its neighbouring territories supported 319 bird species, 179 of which were nesting (Zarudny 1916, Gladkov 1936, Kostin 1956). By the early 1970s the number of species had dropped to 168 and only 32 species were nesting in the coastal strip of the Syr Darya delta (Gubin 1999). Between 1999 and 2002, during ecological monitoring of the Sudochie wetland, 230 bird species were recorded in the Amu Darya delta. These included 101 waterbird species, but only 68 species (41 of which were waterbirds) were recorded nesting (Kreuzberg-Mukhina & Lanovenko 2003).

The wetland systems surrounding the new human-made waterbodies, such as Aydar-Arnasay lake system, Kairakum, Chardara, Tudakul, Karakir, Dengizkul, Khadicha reservoirs, have provided refuges for many migratory waterbirds. Although some species have attempted breeding in these new wetlands, breeding success has been relatively poor and waterbird diversity in these new wetlands during summer is generally low. However, some species have expanded their breeding ranges southwards along the Amu Darya and Syr Darya river valleys.

Recent surveys of the Aral Sea basin have found waterbirds gathering in unexpected places, and include the discovery of new major breeding, moulting and wintering areas for globally threatened species including White-headed Duck *Oxyura leucocephala*, Dalmatian Pelican *Pelecanus crispus* and Pygmy Cormorant *Phalacrocorax pygmaeus*. Major wintering areas for Eurasian Crane *Grus grus*, Greylag Goose *Anser anser* and Lesser White-fronted Goose *Anser erythropus* now occur in the upper parts of Amu-Darya river on the border between Uzbekistan and Afghanistan, within newly-irrigated areas.

Despite this, overall there has been a major decline in the distribution of a number of globally and regionally threatened waterbirds (Fig. 2).

#### ACKNOWLEDGEMENTS

Water-bird species data gathering in the Aral Sea basin was conducted with financial support of many international organizations including NABU (German Union of the Nature Protection) (1995-1998), the Chicago Zoological Society (1995-1997), the Global Environmental Facility (1999-2002), the Agricultural

## The importance of Uzbekistan's wetlands for wintering waterfowl of the Central Asian Flyway

Yevgeniya Lanovenko

Institute of Zoology, Uzbek Academy of Sciences, A.Niyazov str., 1, 700011, Tashkent, Uzbekistan. (email: filatov@comuz.uz)

Lanovenko, Y. 2006. The importance of Uzbekistan's wetlands for wintering waterfowl of the Central Asian Flyway. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 285-286.

The current ecological situation in Central Asia is very different from the early part of the last century, especially regarding waterbird habitats. The Aral Sea region has experienced both major habitat loss and re-creation as a result of human activities. This paper shows that both natural and artificial wetlands are attractive for wintering waterbirds which spend the winter in central and southern regions of Uzbekistan, within the migration flyway from North-Western Asia to Iran-Caspian and Indian-Pakistani wintering grounds.

In the second half of the 20th century anthropogenic transformations of arid ecosystems took place throughout Central Asia. This especially affected the flat lands of Uzbekistan, which were developed for agriculture. Development of an irrigation and drainage network in arid areas has resulted in changes in levels of groundwater and the creation of a large number of filtration and waster-water lakes. The degradation of the Aral Sea and the deltas of the Amudarya and Syrdarya rivers has resulted in major loss of habitats for nesting and migrating birds in Central Asia. Consequently, the importance of existing and

newly created lakes increased. Over 200 000 waterbirds overwinter on the inland wetlands of Uzbekistan (Kashkarov 1994).

Uzbekistan is situated in the middle and south-eastern part of the Turanian plain. Research was undertaken in the south-eastern part i.e. central and southern regions of Uzbekistan. This region has comparatively mild climatic conditions for wintering waterbirds, and 10 to 33% of the total number of waterbirds in the Central Asian-Caspian region overwinter there (Kashkarov 1994). Wetlands in the southern regions of Central Asia and southern Uzbekistan are situated in the zone of warm Central Asian wintering grounds, whereas wetlands in northern Uzbekistan are in the zone of cold Central Asian wintering grounds and are frequently frozen which results in high fluctuations in numbers of wintering birds over different years.

Wetlands studied included large and small lakes, water reservoirs and two stretches of the Syrdarya river: a stretch in Uzbekistan between the Tajikistan and Kazakhstan boundaries (approximately 80 km long), and a stretch on the border with Afghanistan (approximately 20 km long).

**Table 1. Distribution of wintering waterbirds in Uzbekistan wetlands in January.**

Region	Wetland	No. of waterbirds counted		
		2000	2003	2004
Region of cold wintering grounds		412 346	241 171	331 373
Mid-stream of the Syrdarya River	Syr Darya river	19 456	128 028	97 578
	Aydar-Arnasay lakes system	284 539	96 643	60 708
	Tuyabuguz water reservoir	-	16 500	28 914
Bukhara region	Ayakagitma	23 281	-	-
	Karakir lakes system	85 070	-	144 173
Region of warm wintering grounds		559 419	317 092	442 146
Bukhara Region	Kuyumazar and Tudakul water reservoirs	55 345	143 392	168 533
	Shorkul	13 864	-	-
	Solyonoye and Zamonbobo lakes	16 379	-	-
	Khadicha Lake	8 395	-	1 620
	Deukhona Lake	5 813	6 018	3 262

	Uchkyzyl water reservoir	-	9 915	8 638
	Aktepe water reservoir	-	21 267	26 331
	Kumkurgan water reservoir	-	36 351	27 117
Total		971 765	558 263	773 519

Aerial surveys were carried out in 2000 on 32 Uzbekistani wetlands in both cold and warm wintering ground zones, with over 900 000 wintering waterbirds counted (Lanovenko *et al.* 2001). Mixed surveys (by foot and motorboat) counted 558 263 waterbirds wintering on 13 wetlands in 2003, and 773 519 waterbirds on 15 wetlands in 2004. All censuses were carried out in January (Table 1).

More than 50 waterbird species were recorded, nine of which are globally threatened: Dalmatian Pelican *Pelecanus crispus*, Lesser White-fronted Goose *Anser erythropus*, White-headed Duck *Oxyura leucocephala*, Ferruginous Duck *Aythya nyroca*, White-tailed Eagle *Haliaeetus albicilla*, Red-breasted Goose *Branta ruficollis*, Marbled Teal *Marmaronetta angustirostris*, Pallas's Sea Eagle *Haliaeetus leucoryphus* and Pygmy Cormorant *Phalacrocorax pygmaeus*. The creation of the new waterbodies has modified the territorial distribution of waterbirds in the Central Asian region and are especially important for White-headed Duck and White-tailed Eagle.

In Table 1, comparison with the 1990s population estimates (Perennou *et al.* 1994), indicates that 17% of Red-crested Pochard from the Western-Central-Asian/South-Western Asia population, 33.8% of Mallard from Western Siberia/Southern-Western Asia population, 42.8% of Ruddy Shelduck *Tadorna ferruginea* from Western-Asian/Caspian/Iranian-Iraq population, and up to 30% of White-headed Duck from Southern-Eastern Europe/Turkish/Southern-Western Asia are wintering in Uzbekistan.

In cold weather conditions, as in 2000 and 2003, waterbirds concentrated on the larger wetlands and deeper rivers. In relatively warm weather, as in 2004, waterbirds distributed over a larger number of shallow small lakes and fields near the deep rivers and big lakes.

In 2004, a very warm winter with good water levels in lakes and water reservoirs, the distribution of some species changed. White-headed Duck, for example, had previously concentrated

only on Dengizkul Lake, but in 2004 it was recorded also on the many small, shallow lakes in Bukhara region and at the Aydar Arnasay lakes system in the Syrdarya river basin.

These surveys illustrated the importance of Uzbekistani wetlands for wintering waterbirds on the Central Asian flyway with the identification of nine wetlands as having international importance for the support of wintering waterbirds. Three of these have Special Protected Area status, which corresponds to IUCN protected areas category IV. Only one of these, Dengizkul Lake, has Ramsar status as a Wetland of International Importance.

The surveys were made possible by a Ramsar Small Grant Fund in 2000, and in 2003 and 2004 through support from the Dutch government in the framework of the Central Asian Flyway Project (Wetlands International, WWF Russia). The enthusiasm of the members of the Working Group on Uzbekistan's Wetlands contributed greatly to the success of these surveys.

## A review of the wetlands of Afghanistan

Ahmad Khan

University of Wisconsin at Madison/The International Crane Foundation, 11376 Shady Lane Road, Baraboo, Wisconsin 53913, USA.  
Present address: Mohallah Ibrahim Khel, Village Udigram, District Swat, Pakistan. (email: snowleop@psh.paknet.com.pk)

Khan, A. 2006. A review of the wetlands of Afghanistan. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 287-291.

### ABSTRACT

Afghanistan is a landlocked arid country with a rich biodiversity represented in various life forms and their habitats. The existence of water in arid climates such as that of Afghanistan plays a significant role not only in maintaining human livelihoods but also in creating pristine ecosystems that provide essential services to the local communities. Such wetland habitats in an arid country are important resting, feeding and staging areas for a number of migratory bird species. This paper reviews the wetlands of Afghanistan from the perspective of current status, conservation issues and recommendations for initiatives in the future.

### INTRODUCTION

Afghanistan is a landlocked country of about 65.2 million ha in Central Asia. The country's natural resources include forests (2.2 million ha), arable land (7.9 million ha) and rangelands (5.0-14.7 million ha). Altitudes range from 400 m above sea level in the Seistan basin to over 6000 m in the Zebak. The country lies at the confluence of the Palearctic and Indo-Malayan biogeographical realms, and is endowed with rich biodiversity. The climate is characterized by arid and semi-arid conditions with hot summers and cold winters (ICIMOD 1997). Afghanistan's diverse habitats host 119 species of mammals, 400 species of birds, two species of amphibians and 4 000 species of vascular plants. The country is divided into three distinct regions, the Hindu Kush highlands, the Northern Plains and the Southern Plains (Smith *et al.* 1973), and this has given rise to the ethno-cultural division of the country into Pukhtoon, Hazara, Uzbek and Tajik.

Soviet troops invaded Afghanistan in 1979, hampering any development activity and resulting in decades of war. The war in Afghanistan not only brought suffering to communities already living at subsistence level, but devastated structures and institutions. The management and conservation of the country's natural resources, including wetlands and their associated biodiversity, were not spared.

The wetland habitats of Afghanistan consist of three major types: rivers, lakes and marshes, and man-made reservoirs. Since most of Afghanistan is very dry, the few wetlands that exist are of considerable ecological and social importance. Most of the watercourses are liable to great seasonal variation in water level, and they are subject to intensive human use. Many of Afghanistan's rivers drain into depressions where they have no outlet, resulting in the formation of large shallow saline lakes and marshes. Many thousands of birds use the internationally significant wetlands of Ab-i-Estada, Dasht-i-Nawar, Band-i-Amir and Kol-e-Hashmat Khan (ICIMOD 1997).

### METHODS

This review of the wetlands of Afghanistan is based primarily upon my thesis research on assessment of the post-war status of

Lake Ab-i-Estada. I used a combination of approaches including literature review, field surveys, formal and informal interviews, and personal observations to collect information about the lake. The literature review was carried out in various libraries including those of the University of Kabul (Afghanistan), University of Wisconsin (USA), University of Peshawar (Pakistan) and United Nations branch in Islamabad (Pakistan). Interviews with local communities were carried out during field surveys at Lake Ab-i-Estada. In addition, I visited the wetlands of Dasht-i-Nawar, Band-i-Amir and Kol-e-Hashmat Khan. Information on protected areas, including key wetland habitats in central Afghanistan, was derived from interviews and personal observation.

### DISCUSSION

#### Important wetlands of Afghanistan

The drainage systems in Afghanistan mostly end in endorheic (closed) basins (UNEP 2003). The Amu Darya, Helmand, Arghandab, Gardez, Ghazni, Mahara and other rivers receive their input from rainfall, snowmelt and glaciers, and create lakes and marshes which are important wetland ecosystems. The rivers are a source of water for irrigation, while the lakes raise the humidity in the surrounding areas and reduce the need for irrigation of crops – a much needed saving in arid climatic conditions. The small number of wetlands formed by these rivers support a wide variety of wetland-dependent birds, particularly migratory waterbirds. Most of the wetlands are used by migratory birds for feeding and resting, while some are used for breeding (UNEP 2003, Sauey 1985). In addition to their importance for birds, these wetlands have great importance for the human communities living around them.

#### Band-i-Amir

Band-i-Amir consists of a chain of six lakes formed by travertine dams in the Hazarajat Mountains of the western Hindu Kush, in Bamyan Province (IUCN 1991). These lakes, named Ghulaman, Qambar, Haibat, Panir, Pudina and Zulfiqar, are noted for their distinctive scenic beauty and are also home to a variety of waterbirds. Qambar Lake has been drained and converted to marshland, providing suitable habitat for rails, coots and birds dependent on reed-beds. Ghulaman Lake has thick reed vegetation and provides habitat for waterbirds such as rails and coots. The four other lakes are deeper, and are frequented by diving ducks and grebes. The area is one of the most beautiful landscapes in Afghanistan, and has been a popular tourist attraction since the 1950s, with day tours visiting the site from Bamyan (IUCN 1991). In response to a request from the Afghan Tourist Organization (ATO), the site was declared a National Park in 1973. The National Park covered an area of 41 000 ha, but could not be notified in the official gazette. There has been little impact on the physical condition of this National Park since the 1970s,

and the lakes remain in good shape (UNEP 2003). However, lack of awareness of the importance of the site, unorganized tourism, the influence of warlords in the area, illicit fishing through dynamiting and netting, and the extreme poverty of the local communities are some of the key conservation issues here.

### Dasht-i-Nawar Lake

This lake lies in a vast depression at high altitude in the Koh-e-Baba range, an offshoot of the Hindu Kush (Fig. 1). It was formerly a perennial lake with a huge area of mudflats and numerous islands. The lake provided breeding grounds for the Greater Flamingo *Phoenicopterus (ruber) roseus* and a staging area for thousands of migratory waterbirds of various species. The Government of Afghanistan declared the lake a Waterfowl and Flamingo Sanctuary in 1974. In 1999, however, the lake dried up completely due to a severe drought. A study of the lake in 2002 revealed that there were several small ponds fed by spring waters which provided some habitat for waterbirds during drought years. Several species of ducks, including Mallard *Anas platyrhynchos*, Common Teal *A. crecca* and Common Pochard *Aythya ferina*, were present on the ponds in early September 2002 (UNEP 2003). In comparison with other wetlands in Afghanistan, the problems at Dasht-i-Nawar are of relatively low intensity, and the wetland has high resistance to extreme conditions because of the presence of springs as a permanent source of water. However, a lack of awareness and lack of recognition of the important values of the wetland are key issues.

### Kol-e-Hashmat Khan

Kol-e-Hashmat Khan, in the south-eastern outskirts of Kabul, is situated at an elevation of 1 973 m and has an area of 191 ha. This lake, which is surrounded by dense reed-beds, was one of the most important and well-protected wetlands until the onset of war in 1979. The lake was formerly a royal hunting ground and was declared a Waterfowl Reserve by King Zahir Shah in the 1930s. Over 150 species of migratory birds have been recorded in the area, and the lake has supported as many as 30 000–35 000 waterbirds. From 1973 until the war, the protection of Kol-e-Hashmat Khan was the responsibility of the Guard-i-Jamhuriat (military). The lake dried out in 1999 due to the severe drought in the region. Prior to the war, it received water from a branch of the Logar River, but this was dammed in various places and became silted up. In addition, water from the Logar River was diverted for irrigation. The local community has encroached on the lake, and settlements have extended all around it. Recent reports suggest that the government has decided to drain the wetland to accommodate the ever-increasing human population of Kabul.

### Ab-i-Estada

The Gardez, Ghazni and Mahara rivers and a few unclassified streams drain into a large depression in the Koh-e-Baba and Koh-e-Pughman foothills of the Hindu Kush, and form the large saline lake of Ab-i-Estada (literally “standing water”; Fig. 2). Located between 32°30'N and 67°50'E and at an altitude of 2 070 m, this lake was a Waterfowl and Flamingo Sanctuary prior to the war in 1979. The wetland covers 27 000 ha, including 13 000 ha of surface water and 14 000 ha of mudflats. The width of the mudflats surrounding the lake varies from 0.5 km on the western shore to 7 km in the east. The lake has two small islands near its south-eastern shore. The tiny island of

Kuchney ghundai (500 m<sup>2</sup>) is 0.3 km from the shore, while the island of Loya ghundai (2 500 m<sup>2</sup>) is 2.2 km from the shore (Shank & Rodenburg 1977, Khan 2000). In the central basin of the watershed (over 19 400 km<sup>2</sup>), there are dams on the Gardez River (Band-i-Sardeh) and Ghazni River (Band-i-Sultan).

Bird counts at Ab-i-Estada and in the surrounding area have included 122 species of 84 genera, 45 families and 17 orders (Paludan 1959, Shank & Rodenburg 1977; local information and pers. obs). The importance of the lake for migratory birds is due to its location on an important flyway between breeding grounds in Siberia and Kazakhstan and wintering grounds in Pakistan and India – a flyway characterized by the paucity of stopover sites providing water and wetland habitats. The lake was formerly a very important stopover site for the critically endangered Siberian Crane *Grus leucogeranus* (Khan 2001). Wader species such as the Pied Avocet *Recurvirostra avosetta*, Black-winged Stilt *Himantopus himantopus*, Kentish Plover *Charadrius alexandrinus* and Greater Sandplover *C. leschenaultii* have bred at the lake (Niethammer 1970). The two small islands have provided breeding habitat for Greater Flamingos as well as for Slender-billed Gulls *Larus genei* and Gull-billed Terns *Gelochelidon nilotica*.

### Past history of wetland management in Afghanistan

The wetlands of Afghanistan attracted international attention in the late 1960s, and the significance of Ab-i-Estada and Dasht-i-Nawar was recognized at the International Conference on the Conservation of Wetlands and Waterfowl (Ramsar, Iran, 1971) at which the final text of the Ramsar Convention on Wetlands was adopted. Following this conference, the Government of Afghanistan and custodian Department of Wildlife and National Parks declared Band-i-Amir as a National Park in 1973, and Ab-i-Estada and Dasht-i-Nawar as Waterfowl and Flamingo Sanctuaries in 1974 (Shank & Rodenburg 1977). The proposal to declare Ab-i-Estada as a National Park in 1993 (IUCN 1993) did not materialize because of political unrest in the country.

The boundaries of the reserves were delineated and clearly defined. At Ab-i-Estada, the reserve boundaries were drawn by R.G. Petocz to maintain, wherever possible, a 2 km zone around the lake, while including all mudflats and excluding all cultivated areas. Consequently, the boundaries extended some 7 km from the lake in the east where there are extensive mudflats, whereas in the west, where farming is most intensively practiced, the boundary approached to within 0.5 km of the lakeshore in some places (Shank & Rodenburg 1977).

A ban on hunting was strictly enforced to protect the fauna of the protected areas in Afghanistan, and protection staff were recruited for the purpose. The government at the time appointed 10 guards for protection purposes at Ab-i-Estada, six from the army or republican guard (Jandrama) and four from the local community. Four wildlife guards were appointed for the protection of Kol-e-Hashmat Khan Waterfowl Reserve. Similarly, guards were posted for the protection of wildlife at Band-i-Amir National Park and Dasht-i-Nawar Waterfowl and Flamingo Sanctuary. These guards were responsible for patrolling the protected areas to control hunting and report any illegal hunting. There was a fine of 500 Afghanis for illegal hunting. The untrained guards (wildlife protection officers) at Ab-i-Estada were later supplemented with professional wildlife guards trained in Iran (Shank & Rodenburg 1977).

A system of water regulation was introduced at Ab-i-Estada and Kol-e-Hashmat Khan to maintain the water surface during the dry summer months. Water was allocated to Ab-i-Estada from the upstream Band-i-Sardeh during the summer months, and no diversion of water upstream of the lake was allowed for any purpose. Similarly, water was allocated to Kol-e-Hashmat Khan from the Kabul and Gardez rivers during the dry months of the year (Khan 2000).

### War and the management of wetlands in Afghanistan

Prior to the war, the interest of the Government of Afghanistan in the conservation of its natural resources had been increasing and by 1970 had attracted international attention. However, all its efforts were hampered by the invasion of troops from the former Soviet Union in 1979. Since then, the conservation status of the country's natural resources has been drastically weakened due to various reasons which can be summarized as follows:

- massive emigration from the country resulting in a critical loss of trained professionals;
- restricted access to former protected areas and high security risks;
- dissolution of the country into small kingdoms under different warring factions;
- increased availability and accessibility of arms (rifles, machine guns, automatic rifles, rocket launchers and missiles) and ammunition;
- destruction of infrastructure such as roads, bridges and water supply systems;
- destruction and loss of existing records and a halt to research and all other information gathering;
- uncontrolled exploitation of natural resources due to disputed ownership; and
- lack of alternative resources.

The problem of uncontrolled shooting of wildlife was further increased due to the great flow of arms and ammunition into the country, making them widely available and accessible. During the war, individuals and groups of fighters reportedly used birds and mammals for target practice. Forests were burned to expose enemies or cut to provide funds for the purchase of weapons.

### Effects of war (1979-2001) on the wetlands

Little is known about the status of wetlands in Afghanistan between 1979 and the present. Most of the information available has been provided by verbal accounts from local communities. During the period of fighting, most people left the affected areas and took refuge elsewhere within Afghanistan, while some fled the country. Information from the local community at Ab-i-Estada indicates that about 60% of the community became refugees, while between 23% (UNIDATA 1992) and 33% (UNHCR 1990) of the local community at Dasht-i-Nawar were refugees in Pakistan. Very few people, mostly the old and children, were left behind. About 2.2% of the local people around Dasht-i-Nawar were killed and another 3.2% were disabled (UNIDATA 1992). Government troops were deployed in the area around Ab-i-Estada and are reported to have hunted freely at the lake. Soviet troops in helicopters are reported to have fired several times on waterbirds at this lake, mostly in the flamingo colonies.

The wetlands lost their protection when they lost the guards that had been posted there. Six of the guards at Ab-i-Estada reportedly left the area, and the four guards from the local villages were old and have since died. A tower built at Ab-i-Estada for the effective protection of the lake was completely destroyed. Two of the guards at Kol-e-Hashmat Khan died during the war, while the other two were restored to their duties by the Taliban Government in 1998. Local communities were able to hunt waterbirds and collect eggs with no controls. As a likely result of these activities, there was an alarming decline in the central population of the Siberian Crane at this time. The population of 100 in 1967-68 (Sauey 1985) had declined to 57 by 1976 and to only 23 by 1989 (New York Times 1989). All tourism organized by the Afghanistan Tourism Organization ceased during the war. The wetlands also lost their traditional water allocation systems, and local communities began to encroach on the land (pers. obs). The community upstream of Ab-i-Estada began diverting water from the Gardez and Ghazni rivers for irrigation, and this might have contributed to the drying up of the lake. The local community around Kol-e-Hashmat Khan occupied land at the margins of the lake, thus reducing its area.

### Current status of wetlands in Afghanistan

#### Land ownership

The local communities at Ab-i-Estada, Kol-e-Hashmat Khan, Dasht-i-Nawar and Band-i-Amir have no claims to ownership of the land, and admit government ownership (according to personal discussions with the local communities in 1999, 2000 and 2002). However, a number of nomadic groups (Kochis) who migrate into these areas with their livestock claim that they have traditional grazing rights which are recognized as legal by the government (Khan 2004). This grazing, along with grazing by livestock belonging to the local communities, could result in a change in vegetation structure around the wetlands. The local community at Dasht-i-Nawar came into conflict with the Kochis on the use of this area in 1999.

#### Legal protection and management

At present, there are no protection staff at any of the wetlands. The local communities at Ab-i-Estada and Kol-e-Hashmat Khan regularly hunt waterbirds for fresh meat. At Ab-i-Estada, almost every man in the local community is a part-time hunter, and at least 10% are full-time hunters (Khan 2000, 2004). Falcon trapping was introduced into the Ab-i-Estada area by falcon trappers from Pakistan, and is becoming a common activity. In 2002, there were numerous falcon-trapping camps operated by people from the surrounding villages (Khan 2000, UNEP 2003). At Band-i-Amir, unorganized local tourism creates problems of water pollution and disturbance to migratory birds. On the other hand, informants state that the previous rules regarding wildlife protection have been put back in place and will be implemented when the government has sufficient funds to do this (Khan 2000, 2004, UNEP 2003).

#### Grazing and collection of fuel wood

At present, grazing and the collection of fuel wood in the vicinity of Ab-i-Estada are open to anyone. Nomads exercise their grazing rights during the summer months, and local people take year round benefit of the wetland's status as "no man's land". The uncontrolled grazing activity is likely to have brought

Over-grazing by domestic stock, and deforestation are major issues throughout much of Central Asia. These hillsides have been heavily grazed by goats and sheep leading to soil erosion; note the high concentration of livestock on the right. A short distance up the valley, in the Chatkal State Nature Reserve, Uzbekistan, the hillsides are fully wooded (see p. 885). Photo: David Stroud.

about changes in vegetation cover and species composition of the plant communities. Some effects of the overgrazing and collection of fuel wood on the vegetation have already been reported (Goudie 1986).

#### River flows and traditional water management

The Ghazni and Gardez rivers are the main sources of water for Ab-i-Estada. The Band-i-Sardeh (dam) on the Gardez River was constructed by the Soviets under the Sardeh Irrigation Project (1967-76) to irrigate 18 752 ha of land. This dam can potentially provide water to irrigate about 80 000 ha in Khawaja Omri, Deh Yak and Ghazni districts; however, at present only 40% of this area is under cultivation because of the poor state of the irrigation canals. The reservoir of the Band-i-Sardeh covers an area of about 9 600 ha when full; however, at present only half of the capacity is being used (UNIDATA 1992). A second dam, the Band-i-Sultan, restricts the flow of the Ghazni River and diverts water for irrigation. Both these dams have decreased the flow of water in the rivers that reach the lake. The full effects of the change in the lake's hydrology caused by these marked reductions in water flow have not yet been studied.

Downstream from the two dams, the local communities of Dilla and other villages have constructed small dams on the Ghazni and Gardez rivers to divert water for the irrigation of agricultural land. This additional diversion of water increases the adverse impacts on the hydrology of the lake, particularly in dry years when no water may reach the lake, especially from the Ghazni River. In the past, a few days of water flow were reserved

for the lake during the dry summer months, but this practice is no longer in operation.

#### CONCLUSIONS AND RECOMMENDATIONS

There are very few wetlands in Afghanistan's arid landscape that provide habitat for large numbers of waterbirds in addition to functioning as a source of water for drinking, irrigation and other human needs. Band-i-Amir, Dasht-i-Nawar, Kol-e-Hashmat Khan and Ab-i-Estada are the most important wetland habitats in Afghanistan for migratory waterbirds and must be protected. There were good rains and heavy snowfalls in the watersheds of these wetlands in 2002 and 2003, and as a result, Kol-e-Hashmat Khan and Dasht-i-Nawar have been restored. Ab-i-Estada has received some water and here the wetland habitats have recovered to a considerable extent (officials of the Save the Environment-Afghanistan pers. comm.). The Government of Afghanistan must now consider re-designation of these wetlands as protected areas with appropriate legal status.

There is a need to develop comprehensive management plans for these wetlands based on a preliminary management plan for Ab-i-Estada and Dasht-i-Nawar prepared in 1977 (Shank & Rodenburg 1977) and guidelines developed by the University of Wisconsin at Madison (Khan 2004). The management plans should emphasize the following objectives:

- Strengthening institutional structures for a "watch and ward" system for the wetlands, with provision for the participation of local communities;

- Protecting migratory birds visiting the wetlands for breeding, feeding, resting and staging;
- Maintaining the essential hydrological inputs and hydrodynamics of the lakes;
- Encouraging, facilitating and supporting research on various aspects of the wetlands and rural life in surrounding areas;
- Creating awareness amongst the local communities through various approaches;
- Integrating development issues with conservation of the wetlands and their resources;
- Developing cross-boundary co-operation and networks for the conservation of wetlands important for migratory waterbirds.

## ACKNOWLEDGEMENTS

I was able to accomplish this work with support from the International Crane Foundation (George Archibald, Claire Mirande and Jim Harris), University of Wisconsin (Prof. Tim Moermond and Prof. Stan Temple), Save the Environment-Afghanistan (Abdul Wali Madaqiq, Ghulam Muhammad and Naseer Ahmad Ahmadi), WWF-Pakistan (Chairman of Scientific Committee and Chief Technical Advisor Ashiq Ahmad Khan, and Director General Ali Hassan Habib), the NWFP Wildlife Department (Dr Muhammad Mumtaz Malik), and other friends and colleagues. I am grateful to Gerard Boere for the invitation to attend the Waterbirds around the world Conference and for sponsoring my participation.

Sheikh, K.M. & Kashif, N. 2006. Strategic role of Pakistan wetland resources: prospects for an effective migratory waterbird conservation network. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 292-293.

### ABSTRACT

Pakistan, situated in the north-west of Southern Asia, provides staging grounds for large numbers of migratory birds from Siberia, Central Asia and Europe. Common and threatened species overwinter in wetlands throughout the country. There have been few studies to monitor the migratory bird populations and their use of wetlands, primarily due to the absence of an effective network that could successfully generate accurate ecological data and information. Current flyway management systems rely on information from local hunters, erratic wildlife surveys and raw estimates. Information gaps exist for key wetland sites including Mangla Lake, Rawal Lake, Zangi Nawar Lake, the high mountain wetlands in northern Pakistan including the Naltar wetland complex, wetlands of Deosai plains and many others. There have been several reports of Black Storks *Ciconia nigra* and cranes; with flocks of Marbled Teal *Marmaronetta angustirostris* reported from drought-hit areas where wetlands have recently revived due to heavy rains. Linkages and partnerships with neighboring countries are also weak. The establishment of an information system through the creation of banding/research stations is recommended. These could then serve as potential nature-based tourism localities to raise public awareness and further sustainable and wise use of wetlands. However, strong support from international wetland organisations would be necessary to build capacity in Pakistan wetland communities. The network would also help in creating much needed knowledge exchange systems, improving public awareness and environmental education for wetlands and waterbirds.

### INTRODUCTION

Pakistan lies in the northwestern part of southern Asia bordering with Afghanistan, Iran, China, India and in the south, the Arabian Sea. Wetland habitats, both natural and man-made, cover approximately 7 800 km<sup>2</sup> (9.7% of the total area of Pakistan). The Indus river system and its flood plains form the main inland wetland areas. From the northern mountains to the southern coast, wetland areas provide refuge for large numbers of wintering migratory birds. Ducks, geese and swans pass through the high mountains to reach lowlands rich with lakes and man-made wetlands. Bar-headed Geese *Anser indicus* fly over high altitude passes as high as 6 000 m and above in a single flight. The most breathtaking experience for bird-watchers is in the Indus Delta and its coastal mangrove forests where the entire area is a magnet for terns, gulls, fish-eagles and Osprey *Pandion haliaetus*, although in some remote areas these birds are still traditionally hunted by local indigenous communities.

Waterbird migration patterns and distribution have not been well studied in Pakistan. There have had been sporadic efforts to

research and count birds, but no consistent or reliable data is available to assist in the development of conservation policy. Lack of ringing facilities and basic field data is also a major problem. Wetlands International's Asian Waterbird Census (Li & Mundkar 2004) covered 94 wetlands in Pakistan between 1997 and 2001, with wider coverage in some past years such as 1993 when 269 sites were covered; and with the help of various experts and contacts, provides valuable data on waterbird populations and their distribution and status, but its coverage is still incomplete. WWF have reported that Pakistan's wetlands and their rich biological resources are threatened by over-exploitation, habitat destruction and polluted environments. The main causes for wetland degradation are ineffective management, poor stakeholder participation and lack of coordination for management strategies.

### METHODS

Between 1991 and 2001 various wetland studies were undertaken to collect detailed information on habitat ecology, species diversity, limnology, feeding habits of various migratory species, conservation measures, hunting activities and a census of migratory birds. The studies included field projects, indirect and direct consultations with relevant government departments; professional field biologists and site managers, as well as a literature review. The wetland sites and areas studied during this period included Zangi Nawar lake, Lulukdan wetlands, Zhob river, Haleji lake, Indus Delta, Indus river, Taunsa Barrage, Chashma barrage, Rangla wetland complex, Kharal lake, Gamaghar lake, Ucchali complex, Namal lake, Mangla reservoir, Tarbela reservoir, Borith lake, Naltar wetland complex, Gilgit river, Hunza river and many others.

### RESULTS

Pakistan has more than 670 species of birds, of which one third are waterbirds, with most of these being migratory species, including geese, ducks, swans, waders and other waterbirds. Species that require urgent attention include Siberian Crane *Grus leucogeranus*, Sarus Crane *Grus antigone*, Dalmatian Pelican *Pelicanus crispus*, Sociable Plover *Vanellus gregarius*, Lesser White-fronted Goose *Anser erythropus* and Pallas's Fish Eagle *Haliaeetus leucoryphus*.

The convergence of three high mountain ranges gives rise to a great variety of landscapes and wetland habitats (glacial lakes, running streams, nullahs or dry watercourses). The unique canal system and combination of man-made and natural wetlands attract millions of birds in unique patterns and congregations at numerous sites throughout Pakistan. Some of the important wetland sites are: Ucchali Lake situated in the Salt range, impor-

tant for globally threatened White-headed Duck *Oxyura leucocephala*; Zangi Nawar lake in the deserts of southern Pakistan in Balochistan province which is important for the globally threatened Marbled Teal *Marmaronetta angustirostris*; and mountain wetlands important for the globally threatened Ferruginous Duck *Aythya nyroca*. Many wetlands in the western and southern parts of the country, such as the Indus river delta, Zhob river (for Siberian Crane) and Haleji Lake, are important for millions of waterbirds either wintering or using them as staging grounds.

There is a lack of consistency in the data for many important sites, and most sites lack regular monitoring of migratory species. Although there have been efforts to survey wetlands sites and their resources, there is a real lack of an effective network of specialists who could successfully generate accurate data and information for developing conservation policies for flyways. Most information has been derived from local hunters, sporadic wildlife surveys and wild estimates. Local efforts to determine the routes of migratory species, their role in ecosystem functioning and demands for conservation action have been erratic. Some waterbird species such as White-headed Duck and Marbled Teal received attention and projects have been launched for their protection and recovery but migratory behavior and flyway routes of many species have not been studied due to the absence of an efficient network that could have linked the information.

There have been several reports of Black Storks *Ciconia nigra* in the northern areas as well as sightings of flocks of Cranes *Grus* spp. in the southern parts of the North-West frontier, Punjab and Balochistan. Some flocks of Marbled Teal have been reported from the southern parts of the country where wetlands had dried up due to long periods of drought but now after many years some wetlands have revived due to recent heavy rains. However, many wetland sites have not been visited for a long time and need urgent attention. One example is Kharal Lake, which formerly supported White-headed Ducks but is now drying out due to human activities causing wetland habitat deterioration and a consequent decline in its biodiversity.

There are major information gaps for important wetland sites such as Mangla Reservoir, Rawal Lake, Zangi Nawar Lake and the high mountain wetlands in northern areas e.g. Naltar lakes and many wetlands of Sindh and Punjab province. IUCN and other conservation organizations, especially WWF and the Ornithological Society of Pakistan (OSP), along with scientists and conservationists have been actively working to provide the

necessary backing for the protection of sites and efforts are underway to develop a national wetland conservation strategy along with an enabling policy framework.

## DISCUSSION

It has long been felt that migratory birds require a specific system and an association of active field scientists who would work on a regular basis to document migratory species records. Such a 'Bird Conservation Network' would require support from various international wetland agencies to help establish an effective information and monitoring system to inform decisions and assist in developing an effective policy framework. The network would enable comprehensive and coordinated species surveys and monitoring which could lead to species recovery plans and further conservation actions as well as supporting the wise use of wetlands. To establish such a network, it is recommended that:

- a team of dedicated amateur and professional researchers, university students, hunters and managers from all parts of Pakistan establish a network for recording up to date information on the distribution and movements of migratory birds. Representation from all regions covering all habitats would be necessary to ensure equal progress in developing and delivering effective conservation action.
- two bird ringing and recording stations are established: one in the northern mountains (Karamabar valley or Chitral Valley) and another in the freshwater or coastal and marine parts of the country (Sindh or Balochistan areas falling within the central Asian flyway or along the Zhob river in Balochistan).
- a regional research project is developed including Pakistan, Iran, India and Afghanistan with scientists, volunteers and researchers to share information and develop useful conservation strategies.

## ACKNOWLEDGEMENTS

We thank the many local communities, local authorities, conservation organisations and hunters for their support in the surveys, providing valuable information and help in visiting their areas.

## Decreases in size of lakes and numbers of birds in selected wetlands in Pakistan

Zulfiqar Ali<sup>1</sup> & Muhammad Akhtar<sup>2</sup>

<sup>1</sup>Department of Wildlife and Ecosystem, University of Veterinary and Animal Sciences, Lahore, Pakistan.  
(email: zulfiqarali68@yahoo.com)

<sup>2</sup>Zoology Department, University of the Punjab, Lahore, Pakistan.

Ali, Z. & Akhtar, M. 2006. Decreases in size of lakes and numbers of birds in selected wetlands in Pakistan. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 294-295.

Pakistan has an estimated 780 000 ha of wetlands and over 225 important wetland resources have been documented. These freshwater and marine wetlands, which include 19 Ramsar sites, support unique assemblages of biodiversity including globally important habitats, species and genomes. However, in general, these wetlands are degrading under a broad spectrum of anthropogenic threats, most of which are a direct consequence of poverty, but many of which are also exacerbated by human ignorance and mismanagement.

Pakistan lies at the crossroads of Asia's major Palaearctic bird migration routes. At different times in the annual cycle there are substantial concentrations of passage migrants, influxes of winter visitors from northern breeding grounds and summer breeding migrants from the Indus Plains or northern alpine regions.

The Indus Flyway is one of the world's major migration routes, running from Siberia to various destinations in Pakistan over the Karakorum, Hindu Kush and Suleiman mountain ranges, along the Indus River and down to the delta. It is important for its diverse species and large numbers of birds that use this flyway, including globally threatened species such as White-headed Duck *Oxyura leucocephala*, Houbara Bustard *Chlamydotis undulata* and Siberian Crane *Grus leucogeranus*. Based on regular counts at different Pakistani wetlands, it is estimated, that between 700 000 and 1 200 000 birds arrive in Pakistan via the Indus Flyway every year.

This study, conducted from 1993 to 2003, collected data on avian diversity at selected wetlands in Pakistan, and made an overall assessment of ecosystem health. Censuses were made by the point counts method (Haldin & Ulfvén 1987). Depending on

the size of each lake one to five count points per lake were selected from which the whole area could be observed with the aid of a telescope. Using GPS coordinates, elevation was recorded and the morphometry of lakes assessed.

Nine sites were selected from Punjab Pakistan, including the Uchalli Wetlands Complex (Jahlar, Khabbaki and Uchalli Lakes) which is a Ramsar Site. It was estimated that overall surface area of these nine lakes was reduced by 46% between 1993 and 2003. The total number of birds recorded in 1993 was 177 671, but by 2003 this had reduced to 89 010 (Table 1). Significant losses were observed at the Salt Range Wetlands Complex where the morphometry was reduced by 56%, and there was a reduction in bird numbers from 35 090 in 1993 to only 5 275 by 2003.

These lakes are not only shrinking in surface area but are also experiencing deterioration of water quality. This poses a serious health hazard to wildlife in general, and birds in particular. Due to a number of ecological changes mainly induced by human pressure, the health and very life of these lakes is threatened.

Think of a world without birds; singing, humming, flying, fluttering, flocking, diving, hopping, dipping, gliding, playing around, and spreading colour in the sky, on the ground and on water, making each day interesting and beautiful - the fascination never ends. Bird migration superbly demonstrates the complexity and the wonder of the web of life. The evolution of individual migratory strategies of many different bird species over the past tens of thousands of years represents the delicate balance of nature, which is very sensitive to the impacts of human activity.

**Table 1.** Maximum bird counts and changes in extent of nine Punjab (Pakistan) lakes from 1993 to 2003.

Name of Site	Maximum bird count 1993	Maximum bird count 2003	Size reduction
Rawal Lake	7 652	3 089	30%
Kallar Kahar Lake	6 793	1 246	30%
Jahlar Lake	721	370	40%
Khabakki Lake	9 624	342	100%
Uchalli Lake	13 291	1 591	60%
Nammal Lake	4 661	1 726	50%
Rangpur Marsh	8 752	9 256	0%
Chasma Reservoir	122 950	71 008	0%
Kharar Lake	3 227	382	100%
<b>Total</b>	<b>177 671</b>	<b>89 010</b>	<b>46%</b>

Wetlands are of vital importance not only for birds, but also for Pakistan, as their importance to human populations in arid zones is huge. The microclimate around wetlands creates favourable conditions for the settlement of communities which depend on the wetlands for their livelihood. They exploit the wetlands directly for products such as water, food and fuel, they benefit indirectly from wetland services such as groundwater recharge, storm protection, flow regulation, flood alleviation, sediment and nutrient retention, not forgetting the less tangible attributes of wetlands, such as biodiversity and aesthetic beauty. It is the use of all these various services that gives wetlands their high economic value and supports the local people directly, as well as providing goods and services to the world outside the wetland. Wetlands protect our environment, our property, our safety and the economy.

To ensure a better future for these important wetlands, the following recommendations are made:

- wildlife monitoring programmes should be conducted on a regular basis to determine population trends;
- raising awareness, environmental education and capacity building should be promoted to enable people to manage their natural wetland resources sustainably;
- eco-tourism should be developed for international recognition of the area's beauty and biodiversity;
- effective measures should be taken to prevent water pollution, especially due to land-based sources;
- effective solid waste management programmes should be initiated; and
- strategies to manage and protect wetlands from degradation and to safeguard migratory birds should be implemented.

## The decline in wader populations along the east coast of India with special reference to Point Calimere, south-east India

S. Balachandran

Bombay Natural History Society, Hornbill House, S.B. Singh Road, Mumbai, 400 023, India.  
(email: balachand@hotmail.com & bnhs@bom4.vsnl.net.in)

Balachandran, S. 2006. The decline in wader populations along the east coast of India with special reference to Point Calimere, south-east India. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 296-301.

### ABSTRACT

The main wintering grounds for waders (shorebirds) in the Central Asian/South Asian Flyway are located in India, especially along the east coast. Until the 1990s, Point Calimere was the most important site for waders on the east coast, supporting hundreds of thousands of birds throughout the migration season. Point Calimere is now degraded as a result of human interference, and a decline of over 70% has been noted in the wader populations. This decline has become apparent by comparing trapping data and transect counts from the early 1980s and early 1990s with those from 1998-2002. The decline has been reflected in wader numbers at other important habitats on the east coast, particularly Pulicat Lake and the Gulf of Mannar, which ringing recoveries have shown are used by the same wader populations. The decline has been highest in the two commonest sandpipers, Curlew Sandpiper *Calidris ferruginea* and Little Stint *C. minuta*. These species are now becoming uncommon at many sites where they formerly occurred in many thousands. Several thousand Pied Avocets *Recurvirostra avosetta* and Black-winged Stilts *Himantopus himantopus* wintered at Point Calimere in the 1980s, but these have now become scarce. Two species, the Crab Plover *Dromas ardeola* and Eurasian Oystercatcher *Haematopus ostralegus*, have not been sighted since 1992. The major causes of the decline are discussed, and some recommendations are made for further research and restoration of the important wetlands at Point Calimere.

### INTRODUCTION

The Central Asian/South Asian Flyway lies entirely within the Northern Hemisphere and is the shortest flyway in the world. It is also the most poorly known flyway, and for a high proportion of its wader populations, nothing is known of population size or trends. India is the major wintering area for waders in this flyway, but information on wader populations is patchy and mostly over a decade old. Thus, contemporary knowledge of waders is almost absent. Between 1970 and 1990, the Bombay Natural History Society (BNHS) carried out bird ringing on a large scale in various parts of the country, and highlighted the importance of a number of wetlands and the status of migratory birds dependent on those wetlands. This work accumulated a vast amount of data on migration patterns and flyways, seasonal movements, biometrics, moult, longevity, weight changes etc. The study helped to obtain comprehensive information on breeding areas, staging areas (both within India and abroad) and wintering areas that are globally important for the protection of migratory birds.

Recoveries of ringed birds have shown that most of the migratory waders occurring in India are from northern and central Siberia, although some populations from north-eastern and eastern Siberia also winter in India. Birds ringed in India have been recovered in the former USSR during spring passage

at over 60°N and over 117°E, and during autumn passage at lower latitudes between 60°E and 80°E. The recoveries have generated good data for some species, especially two *Calidris* sandpipers (Curlew Sandpiper *C. ferruginea* and Little Stint *C. minuta*) and the Ruff *Philomachus pugnax*. However, the available data are still insufficient to arrive at a meaningful conclusion with regard to the migration patterns of many species. The BNHS study was not able to document the total population of waterbirds in the wetlands under investigation. These and other gaps in knowledge can be filled only with the active collaboration of all countries within the Central Asian/South Asian Flyway.

### Migration patterns of waders in India and overlap in flyways

Among waders, the Arctic-breeding species such as Little Stint and Curlew Sandpiper undertake a loop migration within India before departing in spring. Most waders migrate to India during early autumn, mainly through the north and north-west. From here, some birds continue on south-west to wintering areas in Africa (as confirmed in the Ruff), while others move south-east to the east coast of India, as demonstrated by a Curlew Sandpiper that was ringed at Bharatpur (north-west India) and recovered in the same winter at Point Calimere (south-east India). A similar migratory divide between birds wintering in India and those wintering in south-west Asia and Africa may also occur in Kazakhstan, as most of the recoveries during autumn passage of birds ringed in India have been from Kazakhstan. The spring passage of waders along the east coast of India is relatively well known (Ali 1981, Balachandran 1998, Hussain 1991).

Although the bulk of the waders wintering in India follow the Central Asian/South Asian Flyway, some ringing recoveries provide evidence of overlap with the East Asian/Australasian and West Asian/East African Flyways in eastern and western India, respectively. The recovery of a birds ringed at Point Calimere, in Australia and birds ringed at Bharatpur, in Africa are examples of this overlap. Thus, it is possible that there are migratory divides in both eastern and western India, with some birds moving on to their respective wintering grounds in the Southern Hemisphere.

### Recent migration and related ecological studies in India

Systematic studies of bird migration in India through bird ringing came to an end when the bird migration projects sponsored by the US Fish and Wildlife Service were concluded in 1992. There was no ringing of waterbirds in India between 1993 and 1997, but in 1998, ringing was resumed on a small scale through a project sponsored by the US Fish and Wildlife Service to train volunteers in bird ringing and related studies. Under this

Fig. 1. Major habitats for waders in India.

programme, nearly 4 800 waterbirds were ringed in various parts of the country between 1998 and 2002. The bulk of the catch (68%) was at Point Calimere in the south-east.

In the last two years, a few locally sponsored ringing programmes have been organized at Basai Wetland near Delhi, and two 10-day programmes have been organized at Point Calimere through the BNHS Conservation Fund (Daniel & Balachandran 2003). The Himachal Pradesh State Government has recently sponsored a 20-day training programme on bird ringing at Pong Dam, a Ramsar site. Through these programmes, over 1 000 waterbirds have been ringed and data generated on the current status of waterbirds at these wetlands.

Regular bird ringing has been carried out at Chilika Lake for the last two years as part of a three-year project on waterbird populations sponsored by the Chilika Development Authority, Government of Orissa. Over 5 000 birds have been ringed, most of them waders. A bird atlas of Chilika Lake is now being prepared, based on the distribution of waterbirds (including waders) in different zones of the lake. Various conservation measures have been suggested for the creation of additional habitat for migratory waterbirds as well as the breeding birds, and these are being followed up and implemented by the government.

## MATERIALS AND METHODS

The numbers of waders ringed and recorded at four wetlands on the east coast of India (Point Calimere, Gulf of Mannar, Pulicat Lake and Chilika Lake) under the Bird Migration Project of the BNHS between 1980 and 1992 were taken as the baseline data to assess the size of the wader populations during the 1980s and 1990s. The ringing and census data obtained at Point Calimere and Pulicat Lake under the Bird Banders' Training Programme of the BNHS between 1998 and 2003 and the bird counts carried out in Chilika Lake by the BNHS between 2001 and 2003 were compared with the earlier data to assess the decline in wader populations. The numbers of each species ringed and the capture rate per day were also used for comparison.

## MAJOR WADER HABITATS ON THE EAST COAST MONITORED FOR BIRD MIGRATION

### Point Calimere Wildlife Sanctuary and the adjoining Great Vedaranyam Swamp

The Point Calimere Wildlife Sanctuary (10°18'N, 79°51'E) is situated on a low promontory on the Coromandel Coast (southern Deccan Plateau) in the Bay of Bengal (Fig. 1). The adjoining Great Vedaranyam Swamp stretches parallel to the Palk Strait for about 48 km, and is separated from it by a sand-bank. Its north-south dimensions vary from about 10 km at its broadest in the east, to about 8 km in the central part and about 6 km in its western portion. Five freshwater channels connected to the Cauvery River empty into the swamp. There is a gradual slope from north to south. The total area is about 349 sq. km.

In about two-thirds of the swamp, the habitat varies seasonally. During the monsoon and periods of south-westerly winds, there is a continuous expanse of fresh, brackish or saline water extending to the northern tip of the swamp. At other times, the area of open water gradually dries up from north to south. During the drying stage, there are exposed flats and shallow pools. The extreme eastern promontory of the swamp, comprising Kodikkarai and Kodikkadu Reserve Forest, has been declared a wildlife sanctuary. This sanctuary, the Point Calimere Wildlife Sanctuary, supports both littoral and terrestrial life zones (Ali 1980, Manakadan 1992). It comprises 26 sq. km of tropical dry evergreen forest intermingled with scrub jungle and mangrove vegetation, and intersected by numerous tidal inlets and creeks.

Exploitation of the Great Vedaranyam Swamp for salt extraction and other marine-based industries is fast growing. Two private chemical firms have been operating in the leased swamp areas adjoining the wildlife sanctuary. The manufacture of salt involves three stages. Sea water is pumped into reservoirs and then condensed before it is finally allowed to flow into salt-pans, where the salt crystallizes. The reservoirs alter the ecosystem to some extent since they are, in the absence of tidal fluctuation, more or less stagnant. The composition of the littoral communities and microfauna is drastically altered under such conditions. The condensers have a relatively high salinity and temperature which create an ecological barrier for most marine organisms from April to October. Only the monsoon makes this environment temporarily habitable for marine organisms.

Point Calimere and Great Vedaranyam Swamp are an important wintering and staging area for over 1 000 000 waders and other waterbirds, and are the only site that has been intermittently monitored by bird ringing studies for the last three decades. The swamp is of great importance as a staging area for migrants on their way to and from Sri Lanka and other wintering grounds.

### Chilika Lake

Chilika Lake, a designated Ramsar site, is the world's second largest brackish-water lagoon, situated between 19°28'N and 19°54'N and between 85°05'E and 85°38'E (Fig. 1). The water surface of the lake varies from a maximum of 1 165 sq. km during the monsoon to a minimum of 906 sq. km during the summer. The various habitats include marshes, mudflats, freshwater pools and areas of open water with varying depths and salinity.

**Table 1.** Declines in the catches of waders at Point Calimere, India.

Species	No. ringed in one season and maximum catch in a single day			Average catch/day		
	1980-82	1990-92	2000-02	1980-82	1990-92	1999-03
<i>Charadrius mongolus</i>	1 063 (45)	658 (48)	705 (34)	7	8	7
<i>Calidris minuta</i>	9 876 (376)	1 137 (170)	513 (40)	56	20	5
<i>Calidris ferruginea</i>	3 569 (180)	1 330 (110)	599 (35)	20	14	6
<i>Philomachus pugnax</i>	564 (80)	184 (47)	74 (17)	3	2	1

During the dry season (December to May), a large island is exposed (Nalabana Island), and this has extensive mudflats which attract over 300 000 waterbirds. This island was declared as a Bird Sanctuary in 1987. The island supports the largest concentrations of waders in the lake, and is also utilized by several ground-nesting birds for breeding.

Despite its large size, the lake has no areas of shallow water and mudflats until Nalabana Island emerges in December. Hence, small and medium-sized waders are scarce until December. The numbers of most wader species begin to increase from late December and reach a peak in late January. For the smaller waders, the lake serves mainly as a staging area during the northward migration in spring. However, the large and long-legged Black-tailed Godwit *Limosa limosa* has been seen in good numbers from November to March, indicating that this species utilizes the lake during the winter.

#### Gulf of Mannar Biosphere Reserve

The 21 islands in the Gulf of Mannar extend from Rameshwaram Island in the north to Tuticorin in the south, and comprise an island ecosystem that is unique on the east coast of India (Fig. 1). These islands, along with their marine environment between latitudes 8° 47' and 9° 15' N and longitudes 78° 12' and 79° 14' E, have been notified as India's first Marine Biosphere Reserve. Most of the islands support a luxuriant growth of mangroves, while the sandy shores offer excellent nesting grounds for sea turtles. The sea bed around the inshore islands is carpeted with sea-grass beds which not only serve as feeding grounds for Sea Cows *Dugong dugong*, but also harbour a diverse animal community including birds. The highly productive fringing and patchy coral reefs that surround the islands are a treasure house of colourful marine fishes. Extensive inshore areas exposed during low tide at Manali and Hare islands are frequented by coastal waders, especially those species that prefer sand-flats such as the Crab Plover *Dromas ardeola*, Eurasian Oystercatcher *Haematopus ostralegus*, Grey Plover *Pluvialis squatarola*, Lesser Sandplover *Charadrius mongolus*, Greater Sandplover *C. leschenaultii*, Bar-tailed Godwit *Limosa lapponica*, Eurasian Curlew *Numenius arquata*, Ruddy Turnstone *Arenaria interpres*, Great Knot *Calidris tenuirostris*, Red Knot *C. canutus* and Sanderling *C. alba*. Other areas with major concentrations of waterbirds are Dhanuskodi Lagoon on Rameswaram Island and Pillaimadam Lagoon on the mainland near Mandapam. These lagoons are frequented by thousands of small waders, mainly Lesser Sandplover, Little Stint and Curlew Sandpiper, as well as Greater Flamingos *Phoenicopterus (ruber) roseus*. During the 1980s, the Gulf of Mannar as a whole supported about 50 000 waterbirds (Balachandran 1990 & 1995).

#### Pulicat Bird Sanctuary

Pulicat Lake is situated on the south coast of Andhra Pradesh (13°25'-13°55'N, 80°03'-80°19'E), on the eastern seaboard of India (Fig. 1). It covers an area of about 450 sq. km, and is the second largest brackish-water lagoon in India after Chilika Lake in Orissa. The lake was declared as a bird sanctuary by the Andhra Pradesh Forest Department in 1976. The entire area is a vast, brackish to saline lagoon with extensive mud- and sand-flats. The sanctuary is bounded on its eastern side by the spindle-shaped Sriharikota Island, 185 km in length. This island was probably formed by recession of the sea, and is mostly flat with a few sand dunes ranging from 4.5 to 6 m in height. Over 200 000 waterbirds were recorded at Pulicat Lake in 1988 and 1989, including over 30 000 Greater Flamingos. The most abundant waders were Lesser Sandplover, Black-tailed Godwit, Little Stint, Curlew Sandpiper and Ruff.

#### POPULATION DECLINES IN WATERBIRDS

##### Point Calimere

The decline in waterbird populations at Point Calimere is very conspicuous not only to ornithologists, but also to laymen in the area. Any local villager, especially anyone over 40 years of age, can recall the drastic changes that have occurred in the numbers of waders and other waterbirds in the Great Vedaranyam Swamp. The disappearance of the fabulous clouds of waterbirds (waders, ducks, terns, flamingos, egrets) that passed through the villages on their way between feeding and roosting sites up until the late 1980s is a visible indicator of the decline. The appearance of large mounds of salt on the mudflats, which were once thronged by thousands of waders, ducks and flamingos, is an indication of the habitat loss and degradation.

As no simultaneous counts were made throughout the swamp, it is difficult to quantify the decline. The data generated from the small areas sampled for bird counts during the 1980s and personal observations of the waterbird populations in the past and present have helped to provide qualitative estimates for some of the common species. Furthermore, the bird ringing data collected between 1980 and 1991 and the recent skeletal ringing data collected between 1998 and 2003 have helped in estimating the scale of the decline.

The ringing and census data from Point Calimere indicate that there has been a decline of over 70% in certain species of waders since the 1980s. This decline in wader populations is apparent from changes in the numbers of birds caught per day, in the total numbers of birds caught per season, and in the numbers of birds counted in areas that were monitored in the 1980s and 1990s. The number of birds caught per day has decreased for several species of wader, despite a doubling of

**Table 2.** Population estimates for common waders at Point Calimere, India.

Species	1980s	1990s	2000-03
<i>Himantopus himantopus</i>	>15 000	3 000	>1 000
<i>Recurvirostra avosetta</i>	>7 000	>500	<100
<i>Charadrius mongolus</i>	>10 000	>75 000	<40 000
<i>Limosa limosa</i>	>50 000	>40 000	>15 000
<i>Calidris minuta</i>	>200 000	>100 000	<20 000
<i>Calidris ferruginea</i>	>150 000	>80 000	<25 000
<i>Philomachus pugnax</i>	>100 000	30 000	<10 000

effort per day in recent years (Table 1). The population estimates for the common waders from the 1980s, 1990s and 2000-2003 indicate that although there was a decline in all species between the 1980s and 1990s, this has become much more pronounced in recent years (Table 2). Certain species that prefer the inter-tidal zone have either disappeared or declined drastically (e.g. Crab Plover, Eurasian Oystercatcher and Sanderling), as also have some inland waders (e.g. Spotted Redshank *Tringa erythropus*, Ruff and Black-winged Stilt *Himantopus himantopus*).

The most affected species are the two Arctic-breeding *Calidris* sandpipers, Little Stint and Curlew Sandpiper, which were formerly the most abundant winter visitors at Point Calimere. The reservoirs, inter-tidal zone and other brackish areas at Point Calimere provided enormous feeding areas for these species, with numbers of Little Stint in the 1980s exceeding 200 000 and those of Curlew Sandpiper, 150 000. During the last four years, however, neither of these species has been recorded in numbers exceeding 25 000. It appears that these two species formerly benefited from the shallow water levels in the reservoirs which carried many littoral organisms (crustaceans, polychaetes) into the environment. The plentiful rains also helped to increase the productivity of these habitats during the wet season. The extension of salt-based industries, the diminishing rainfall and disturbances caused by fishermen have now altered these habitats.

### Causes for the decline in wader populations at Point Calimere

#### Poaching

There is intensive illegal hunting of Little Stints and Curlew Sandpipers by professional bird-trappers who depend on birds for their livelihood. These bird-trappers operate outside the sanctuary limits, and employ three traditional methods of trapping: clap-traps, mesh-nets (similar to gill-nets and operated at night) and nooses. The gregarious Little Stint and Curlew Sandpiper are particularly vulnerable to clap-traps, as they forage on mudflats with shallow water, i.e. in areas that are ideal for the use of this type of trap. It is interesting to note that in a single day in 1980, one clap-trap yielded 376 Little Stints for ringing. Similarly, 180 Curlew Sandpipers have been caught by this method in a single day.

The scale of the poaching was formerly huge. In the 1980s and 1990s, over 100 trappers were operating these highly effective traps throughout the migration season from August to March in the Muthupet and Adirampatinam areas outside the wildlife sanctuary. In recent times, however, the number of trappers involved in poaching has fallen, as trapping is no longer as productive as it was due to the fall in numbers of waders.

### Depletion of groundwater and saltwater intrusion

The extraction of groundwater has increased manifold in recent years to cater to the needs of the floating population of fisherfolk who are on the increase. Groundwater recharge is inadequate because of the consistently diminishing rainfall in the area over the last two decades.

The flushing and dilution of the highly saline water stored in the reservoirs, condensers and salt-pans have been hampered by embankments constructed in the swamp by chemical companies and other salt-works. Formerly, the incursion of seawater into large areas of the swamp caused by the strong summer winds not only made the swamp habitable for waterbirds during the summer months, but also helped to prevent the mudflats from drying out completely.

The saline incursion has made the area unsuitable for raising traditional crops such as paddy, while water in the freshwater wells is no longer potable. The hyper-saline conditions have not only altered the texture of the mudflats in the reservoirs, but have also affected the adjacent habitats for birds.

### Cessation of monitoring activities by the BNHS

The presence of a BNHS monitoring station at Point Calimere from 1979 to 1992 maintained a check on the activities of the salt-based chemical companies operating in the area. However, since the cessation of research activities by the BNHS at the end of 1992 due to a lack of funds, there has been little to restrain the chemical companies in their alteration of the habitat for commercial goals.

Ringling and bird censusing activities were resumed at Point Calimere in 1999, and since then, researchers have been present for 20-30 days each season. This has helped to monitor habitat changes in the area. During the migration season of 2003/04, following a relatively good monsoon, the chemical companies drained the water from the reservoirs to strengthen the earthen embankments. The continuing habitat changes have resulted in extensive compaction of the soft muddy substrate, making it less productive for the smaller organisms which form the bulk of the food resources for waders in the area. It is imperative, therefore, that in deciding the future of Great Vedaranyam Swamp, the greatest care be exercised in striking a balance between the commercial demands of the salt industry and the requirements of the migratory birds.

### Wader populations at other sites.

Large declines have also been observed in the numbers of many species of waders wintering at Pulicat Lake and in the Gulf of Mannar since the 1980s (Tables 3 & 4). The declines were most apparent in coastal waders, and those species preferring inland and brackish habitats, such as the Black-tailed Godwit and Ruff, were less affected (Table 3). In contrast, the numbers of waders at Chilika Lake have remained high (Table 5), and here there was an increasing trend during the three migration seasons between 2001 and 2004. The possible increase at Chilika may be due to a movement of birds away from Point Calimere and other sites in the south. However, the numbers of Little Stint, the most abundant wader on the east coast of India, have never exceeded 100 000 in recent years. This indicates that there has been a decline in the South Asian wintering population of this species, possibly because of the degradation of its key wintering site at Point Calimere.

**Table 3.** Population estimates for common waders at Pulicat Lake, India.

Species	1988-89	1998-99
<i>Himantopus himantopus</i>	>5 000	3 000
<i>Recurvirostra avosetta</i>	>1 000	>400
<i>Charadrius mongolus</i>	>25 000	>15 000
<i>Limosa limosa</i>	>20 000	>18 000
<i>Calidris minuta</i>	>60 000	>35 000
<i>Calidris ferruginea</i>	>35 000	>20 000
<i>Philomachus pugnax</i>	>40 000	30 000

**Table 4.** Population estimates for common waders in the Gulf of Mannar, India.

Species	1985-88	1993	2001

<i>Calidris minuta</i>	>8 000	>3 000	>2 000
<i>Calidris ferruginea</i>	>10 000	>8 000	>5 000

**Table 5.** Peak counts of common waders at Chilika Lake, India (2001-2004).

Species	Peak count
<i>Himantopus himantopus</i>	5 000
<i>Recurvirostra avosetta</i>	>500
<i>Charadrius mongolus</i>	56 000
<i>Limosa limosa</i>	55 000
<i>Calidris minuta</i>	24 000
<i>Calidris ferruginea</i>	54 000
<i>Philomachus pugnax</i>	10 000

## DISCUSSION

It is well known that many long-distance migrant waders are highly dependent on a series of key staging areas – essential “stepping stones” – between their wintering areas and more northerly breeding areas (see, for example, Stroud, and Baker, this volume). Up until the late 1980s, Point Calimere served both as a major wintering site for waders and as a key staging area for waders wintering elsewhere in India. This area now appears to be inhospitable for the bulk of the migratory wader populations because of anthropogenic pressures. The transit populations of waders en route to other wintering areas in autumn and their breeding areas in spring have disappeared. This is mainly due to the prevalence of dry and highly saline conditions during both autumn and spring as a result of intense industrial activities. Thus, the degradation of this crucial “stepping stone” for migrant waders has had a great impact on the biogeographical populations of the species dependent on it.

This is especially apparent in the drastic decline of the Curlew Sandpiper and Little Stint on the east coast of India. These species were never observed at any of the coastal wetlands of India in such huge concentrations as those observed at Point Calimere. The linkage between this coastal wetland and other major wader habitats both within India and abroad has been well established through ringing recoveries. Recoveries outside India involve not only other countries in the Central Asian/South Asian Flyway, but also countries in neighbouring flyways. Hence, the role of this wetland in maintaining the global populations of some wader species is unquestionable.

The occurrence of globally threatened waders, such as the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*, Spotted Greenshank *Tringa guttifer* and Asian Dowitcher *Limnodromus semipalmatus*, at Point Calimere also emphasizes its global importance. Hence, there is an urgent need for more and better population monitoring. In the first instance, and as a minimum requirement, an adequately funded national monitoring programme needs to be established, to develop an internationally co-ordinated research initiative to discover more about the causes of the declines.

## RECOMMENDATIONS

- 1) A permanent bird migration study centre should be established in India to impart training on bird migration and related studies, and to strengthen collaboration with other countries in the Central Asian/South Asian Flyway and neighbouring flyways in the dissemination of knowledge on bird migration.
- 2) The monitoring of flyway populations in collaboration with other countries in the Central Asian/South Asian Flyway should be improved by strengthening and streamlining the mid-winter waterbird counts and through joint expeditions.
- 3) Species study groups should be formed for the species identified for further research under the Indo-Russian Protocol.
- 4) Further analyses of the status of waders in the Central Asian/South Asian Flyway should be carried out, using existing data and information, to highlight common patterns and processes in the declining populations.

### Recommendations relevant to Point Calimere

- 1) Dialogue should be initiated between the Wildlife Department, local communities, environmentalists and corporate bodies operating in the area, as a confidence building measure.
- 2) Areas of common concern and mutual benefit for industrial ventures, conservationists and other stakeholders should be identified, to reduce loss and modification of habitat as a result of commercial activities.
- 3) Detrimental practices, especially with regard to the salt/chemical industry, should be highlighted and appropriate mitigation measures elaborated after mutual consultation with such industries in the Great Vedaranyam Swamp.
- 4) A Joint Working Group comprising the stakeholders (Wildlife Department, local communities, corporate bodies and NGOs) and specialists should be set up to monitor modification of the habitat in the Great Vedaranyam Swamp. The

Joint Working Group would suggest and implement measures for the restoration of the swamp.

- 5) Restoration measures should be implemented in the known traditional wintering and passage sites for waders with the involvement of local communities and NGOs.

#### ACKNOWLEDGEMENTS

I am grateful to Wetlands International for sponsoring my trip to Scotland to present this paper at the Waterbirds Around the World Conference. I would like to thank my colleagues, namely Mr V. Kannan, Mr P. Sthiyaselvam, Ms Vibhuti Dedhia, Dr Ranjit Manakadan, Mr Gopi Naidu and Ms Divya Fernandus, for assisting in the preparation of this paper.

## Important Bird Areas in western India

Aeshita Mukherjee<sup>1</sup> & Burkhard Wilske<sup>2</sup>

<sup>1</sup> AINP on Applied Ornithology, Gujarat Agricultural University, Anand, India. (email: aeshitam@rediffmail.com)

<sup>2</sup> Max Planck Institute of Chemistry, Mainz, Germany.

Mukherjee, A. & Wilske, B. 2006. Important Bird Areas in western India. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 302.

This paper briefly discusses recent population estimates of some wetland bird species in some potential Important Bird Areas (IBA) in the state of Gujarat in western India.

The Important Bird Areas Programme (IBA) of Bird Life International identifies sites of international significance for bird conservation. They are part of a wider, integrated approach to conservation that embraces site, species and habitat protection and will be used to reinforce and existing protected areas network. The IBA Programme aims to gather and disseminate information on key bird species and sites through the active participation in conservation of communities living in and around IBAs.

Over 1 200 bird species across the world are currently under threat of extinction, which is about 12% of the world's bird species. In India, 78 bird species are globally threatened, and to address this, the Indian IBA Programme was launched by the Bombay Natural History Society in March 1999. One of the major aims is to identify and protect IBAs throughout the country using a set of standard global criteria.

Work has been carried out in western India in the state of Gujarat, which has an arid to semiarid climate. There, canal-linked reservoirs play an important role in sustaining both human and bird life, including a large number of migrant waterfowl. These are adapted to wetlands, but they occupy the ecosystems that are highly productive and dynamic with abundant resources available. These migratory movements may be non-stop or may include some stopover point between the wintering and breeding areas, depending on the habitat conditions and the flyways being followed. The Saurashtra Region of Gujarat is a paradise for the wintering cranes, particularly the Demoiselle Crane *Grus virgo* and the Common Crane *Grus grus*. The present study started by focusing on the estimation of the size of crane populations and identification of internationally important sites. Both site specific and broad based strategies were then suggested for future management, including designation as Ramsar sites.

We recorded about 65 000 Demoiselle Cranes, with the largest concentration being 39 080 at Ghee Dam, Jamnagar. Shian Dam, 20 km from Ghee Dam, supported more than 10 000 Demoiselle Cranes and 3 500 Common Cranes (Mukherjee & Parasharya 1999). At the Charakla Salt Farm, Jamnagar, we recorded more than 200 Black-necked Grebes *Podiceps nigricollis*. This species is an uncommon winter visitor and this record was the largest number ever recorded in India (Parasharya & Mukherjee 1998).

At Porbander, a coastal town of Gujarat, we recorded White-cheeked Terns *Sterna repressa* (35), White-winged Black Terns, *Chlidonias leucopterus* (3) and Little Terns, *Sterna albifrons* (2). These three species are uncommon to this area. Additional records of the Slender-billed Gull *Larus genei* from the Gujarat coast also add to the importance of the area (Parasharya *et al.* 2000, Parasharya & Mukherjee 2001).

## Importance of wetlands for conservation of bird life in the dry lands of western India

Aeshita Mukherjee<sup>1</sup> & Burkhard Wilske<sup>2</sup>

Mukherjee, A. & Wilske, B. 2006. Importance of wetlands for conservation of bird life in the dry lands of western India. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 303-304.

This study discusses the habitat requirement of the waterfowl population in canal-linked reservoirs of Kheda District, Gujarat, India. We also attempted to identify factors that contribute to the attraction of waterfowl to these reservoirs and to suggest management and planning strategies for maintaining waterfowl in environments supporting high human population densities.

The need for maintaining and enhancing urban and suburban populations of wildlife has greatly increased in recent decades (Washington 1978), but planning for wildlife in urban areas is often stifled by inadequate support from resource agencies and lack of awareness and expertise in wildlife matters by urban planners (Davey 1967, Geis 1980). The solution to this dilemma is either to encourage greater collaboration between wildlife regulatory agencies and municipal planners or, as discussed in this paper, to familiarize the planners with the wildlife resources through literature relevant to both the disciplines (Greer 1983).

Canal-linked reservoirs play an important role in sustaining both human and bird life in the dry lands of India. The population of waterfowl at artificial wetlands, mainly reservoirs and canals, was studied in Gujarat, western India, from 1988 to 2000. Observations were made in January each year from 1998 to 2000 at three reservoir study sites when the migratory waterfowl population was greatest: 112 waterbird species were observed. Habitat size and complexity were important factors influencing the species diversity, while factors contributing to waterbird presence included abundant food supply and safe roosting sites. In addition to reservoirs, flooded set-aside farmlands were of immense importance to more than 30 000 waterbirds of 66 species, suggesting that fallow inundated fields serve as a key supplementary habitat for the waterbirds, especially during the dry period. Both site specific and broad based strategies are suggested for future management.

Narda Reservoir is a 57 ha storage reservoir designed for irrigation purposes with a discharge which averages 65 cfs. The water quality is good and is used for fisheries. In summer, the reservoir becomes shallow and overgrown with aquatic vegetation. The surrounding area is agricultural landscape and the main crop grown is paddy rice *Oryza sativa*.

Pariej Reservoir is a 445 ha perennial water storage reservoir for the district, fulfilling the drinking water requirement of the surrounding 52 villages. The surrounding area is mostly saline and as a result no crops are grown. Due to water seepage from the reservoir, the whole area is waterlogged and behaves as a permanent marsh with a heavy growth of the reed *Typha angustata* and other aquatic vegetation. Commercial fishing is practiced in this reservoir.

Kanewal Reservoir, with an area of 625 ha, is the largest reservoir in the district. The land surrounding the reservoir is salt

affected and remains dry during summer. During the monsoon, the whole area is inundated and migratory waterfowl enjoy a temporary wetland. The reservoir provides drinking water to 57 villages, and there is occasional fishing.

Waterfowl counts were made in alternate weeks in January from 1988 to 2000. Plant composition and vegetation cover for the entire study area was also recorded using the quadrat (1 m x m) method.

Paddy rice and wheat are the principal cultivated crops in the district. Undisturbed vegetation was found mostly on the banks of reservoirs. A total of 19 plant species were found around Narda Reservoir, predominantly *Echinocloa colonum*. *Cyperus rotundus* was dominant around Pariej Reservoir. *Typha angustata* was the next most abundant and provided breeding grounds for three species of bittern. At Kanewal Reservoir, *Najas graminea* was most abundant, followed by *Typha angustata*.

Observations at the three sites showed that the waterfowl initiated their activity in early morning about 30 min before sunrise. Most of the activities (foraging, preening, swimming and feeding) ceased within 15 min after initiation. The movements of the birds were a function of their feeding preference. Morning counts were best because they included all birds utilizing the reservoir, and there was little human disturbance.

At Narda Reservoir, the waterfowl were attracted due to shallow aquatic vegetation, specially *Cyperus* species. Migratory waterfowl arrived by October and diversity increased significantly to between 12-36 species over the winter months. The density of ducks ranged between 0.2-15.4 per ha, and for other waterbird species was 1.7-78.2 per ha. Coots *Fulica atra* were the most abundant species. Ducks were mostly found feeding in the adjacent paddy fields because these provided secure food supplies and a relatively fixed water depth (less than 1 m).

Pariej Reservoir had a comparatively higher diversity than Kanewal and Narda, with between 36 and 85 species. The Dalmatian Pelican *Pelecanus crispus* was attracted to this reservoir due to its abundant fish supply. However, coots were dominant all year. Gadwall *Anas strepera*, Northern Shoveler *Anas clypeata*, Northern Pintail *Anas acuta*, Eurasian Wigeon *Anas penelope* were also common and regularly observed; the density of ducks ranged from 0.3-9.0 individuals per ha and other waterbirds between 9.6-59.1 per ha. The reservoir is a potential breeding site for Great-crested Grebe *Podiceps cristatus*.

Kanewal Reservoir, having short grass and emergent vegetation, attracted many migratory waterfowl, with densities of 1.0-9.0 individuals per ha. Ducks congregated mostly to feed on tubers of *Najas minor*. The number of species varied from 26 to 95 because this is the only water body in the area, and is shallow with abundant food. The density of other waterbirds was 20.0-64.0 individuals per ha. Dalmatian Pelicans, Red-crested

Pochards *Netta ruffina* and Demoiselle Cranes *Grus virgo* were regularly attracted to the reservoir.

Each site differed with respect to size and habitat complexity. These interrelationships suggest that for feeding, several distinct locations with different habitat qualities are needed. The study also suggested that these reservoirs are not totally dependent on each other but acted as independent micro-habitats in the sustenance of migratory waterfowl.

In conclusion, the following action is required:

- Familiarize land managers and planners with wildlife resources in the biologically managed environment.
- Elucidate the habitat requirements of waterfowl populations using reservoirs and adjacent areas.

- Attempt to focus the factors influencing waterfowl attraction to these reservoirs and possible ways to manage them.

## Status of migratory shorebirds at Bhitarkanika and Chilika wetlands on the east coast of India

Anup Kumar Nayak

Wildlife Warden, Bhitarkanika; 1865/1866, Nuasahi Nayapalli (near Post Office), Bhubaneswar-751012, Orissa, India.  
(email: [bravo\\_123@sancharnet.in](mailto:bravo_123@sancharnet.in))

Nayak, A.K. 2006. Status of migratory shorebirds at Bhitarkanika and Chilika wetlands on the east coast of India. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 305-307.

This paper describes the status of migratory shorebirds at Bhitarkanika wetland based on counts conducted in July 2002-2003 and Chilika wetlands based on counts made in January 2001, 2002 and 2003.

Bhitarkanika wetland extends to over 672 sq km in the north eastern part of Orissa State on the east coast of India and is the second most viable mangrove eco system in India after Sundarban. Bhitarkanika was declared a Wildlife Sanctuary in 1975 and a Ramsar site in 2002, but has been little studied. The Sanctuary area is divided into seven areas: Raipatia, Jaudia, Satabhaya, Barunei mouth and chataka, Udabali Island, Babubali Island and sand bars, mudflats along Bhitarkanika and Maipura rivers and Dangmal and Bhitarkanika meadows.

Visits were made twice a month during July 2002 to July 2003 by observers in boats or vehicles, and all shore birds sighted were listed. A total of 37 species of shorebirds and seven other important species were identified during the 13 months of observation.

A small number of over-summering shore birds were observed up to June 2003. Golden Plover *Pluvialis fulva* and Terek Sandpiper *Xenus cinereus* were present all year except for June and July. Whimbrel *Numenius phaeopus* were sighted most of the year, and may be breeding somewhere within Bhitarkanika. Early migrants included Great Knots *Calidris tenuirostris* which were seen in flocks of about 500 during

August to December, and Ruff *Philomachus pugnax* were found in large numbers as early as October 2002, indicating they were heading south.

Chilika is the largest brackish water lagoon in India, and is situated along the east coast of Orissa. Surveys were carried out on 12th and 13th of January 2001, 2002 and 2003 by boat. Results are given in the Table 2.

The presence of rare shorebird species like the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*, Asian Dowitcher *Limnodromus semipalmatus* and Broad-billed Sandpiper *Limicola falcinellus* in Chilika wetland emphasizes the importance of this wetland along the east coast of India. The Bombay Natural History Society (BNHS) has recommended that the Bhusandpur and Tinimuhan areas of about 60 sq km be declared as a new bird sanctuary in addition to the existing sanctuary at Nalaban island. Large numbers of Fulvous Whistling Duck *Dendrocygna bicolor*, Lesser Whistling Duck *Dendrocygna javanica* and Cotton Teal *Nettapus coromandelianus* and other migratory birds support such an action.

The threats faced by the Chilika lagoon are due to siltation, shrinkage of the area, choking of the inlet channel, proliferation of invasive fresh water species like Water Hyacinth *Eichornia crassipes*, increased aquaculture activities, eutrophication and nest trampling by buffaloes.

Common Sandpiper *Actitis hypoleucos* occur frequently at Chilika Lake. Photo: Paul Marshall.

## Residential, population and conservation status of Indian wetland birds

Arun Kumar, P.C. Tak & J.P. Sati

Zoological Survey of India, Dehra Dun- 248 195 (Uttaranchal), India.

Kumar, A., Tak, P.C. & Sati, J.P. 2006. Residential, population and conservation status of Indian wetland birds. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 308.

Wetland birds play a significant cultural and social role in local communities as well as being an important component of wetland ecosystem. Increasing attention to the conservation of wetlands in India has resulted in extensive research; this paper assesses the current status of 310 Indian wetland birds (Kumar *et al.* in press) with the emphasis on threatened species.

Out of 310 Indian wetland species 130 (c. 42%) are migrant, 173 resident, however the status is unknown for seven species. Of the migrants, 107 are winter migrants, six have some passage population(s), 13 are summer migrants, and the remaining four are purely passage migrants. Of the 173 resident species, 53 are completely resident, 38 are part resident and part winter migrant, and 50 undertake local movements chiefly depending on water conditions. In terms of abundance, Indian wetland birds can be categorized as Very Common (four species), Common (26), Locally Common (115), Un-Common (45), Rare (67), Very Rare (five), Vagrant (47) and Probably Extinct (one).

Wetland drainage and conversion is the major threat for Asian waterbirds, including the infilling (or 'reclamation') of intertidal coastal wetlands, principally for agriculture and aquaculture. The most recently published checklist was the "Threatened Birds of Asia: the BirdLife International Red Data Book (2001)", followed by "Saving Asia's Threatened Birds: A Guide for Government and Civil Society (2003)".

The Waterbird Population Estimates Third edition by Wetlands International (2002) lists 2 271 biogeographical populations of 868 species. The largest number of waterbird populations (697) is found in Asia, followed by Africa (611) and the Neotropics (540). Out of 310 Indian wetland birds, seven species are endemic, three fall in to the Restricted Range Species category and one comes under data deficient category; 11 are Biome-Restricted Species of which five species are from Eurasian High Mountain (Biome 05), three from Sino-Himalayan Subtropical Forest (Biome 08), one from Indo-Chinese Tropical Moist Forest (Biome 09), and two from Indo-Malayan Tropical Dry Zone (Biome 11) (Jhunjhunwala *et al.* 2001).

Regarding distribution and status, 51 species occur in wetlands, six in forests, five in grasslands, and one is a seabird. Of the 51 wetland species, five are found in wetlands of Tibetan Plateau (W09), 15 in North Indian Wetlands (W12), five in South Indian and Sri Lankan Wetlands (W13), 16 in Assam and Sylhet Plains (W14), and 10 in Bay of Bengal Coast (W15); of six forest dwelling species, one occur in Sino-Himalayan Mountain Forests (F04), two in Indian Peninsula and Sri Lankan Forests (F05), and three in Indo-Burmese Forests. Of the five grassland species, four are found in Indo-Gangetic Grassland (G02) and one in South Asian Arid Habitats (G03). Only one species is a seabird (S01).

Altogether 23 species are listed under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES 2002). A total of 51 species come under the

Convention on Migratory Species (CMS); 21 are listed under Schedule-I and 231 under Schedule-IV of the Wildlife (Protection) Act, 1972 (WL(P) Act).

Approximately 12% of Asian birds are globally threatened with extinction. Many species are edging close to extinction through disturbance or habitat loss as well as intensive hunting pressure. An analysis of threatened wetland birds indicates that of a total of 242 species, 82 species are in Asia and 39 in India. Of the 310 wetland bird species in India, 51 (ca. 16%) are Threatened of which 34 are Globally Threatened (four Critical, seven Endangered, 23 Vulnerable); 16 Near Threatened (NT) and one Data Deficient (DD). Of the 51 Threatened species, 39 show a declining population trend, while three are increasing, five are stable, and the trends of three species are indeterminate. The remaining one species, Pink-headed Duck *Rhodonessa caryophyllacea* globally threatened, has probably disappeared from India.

Of the 34 globally threatened species, only 16 are listed under CITES (11 in Appendix I and five in Appendix II), while the others are not listed in CITES Appendices, thus imposing no restriction on their trade. Eight of the 34 species are listed under Schedule-I of the WL (P) Act, while 22 are relegated to Schedule-IV; two species, Masked Finfoot, *Heliornis fulica* and Indian Skimmer, *Rynchops albicollis* (with an estimated total population for the South Asian region of 5 000 birds each), are not included under the WL (P) Act at all. Similarly, two of the most highly threatened Indian Waterbirds, Sarus Crane *Grus antigone* and Black-necked Stork *Ephippiorhynchus asiaticus*, are again listed under Schedule-IV with threshold populations of 90 and four respectively.

A broad range of national policies on forestry, agriculture, wetlands and fisheries can have significant impacts on biodiversity conservation. By ensuring that policies and laws at local, provincial and national levels also take into account the principle of conservation, threats to species can be minimized.

## Protection of habitat of Sarus Crane *Grus antigone* in the Bhoj wetland, India

Pradip Kumar Nandi

Lake Conservation Authority of Madhya Pradesh, Paryavaran Parisar, E-5, Arera Colony, Bhopal - 452016, India.  
(email: nandipk56@rediffmail.com)

Nandi, P.K. 2006. Protection of habitat of Sarus Crane *Grus antigone* in Bhoj wetland, India. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 309-310.

The Bhoj wetland is comprised of upper and lower lakes, and was declared as a Ramsar site in 2002. The southern part is the preferred site for all birds including the Sarus Crane. More than 160 Sarus Cranes (>1% of the reported total population in India) have been counted here, and the wetland has been identified as an IBA. The current population status of the Sarus Crane is described in this note.

In Asia, out of 2 700 bird species, 323 are reportedly threatened due to habitat degradation; in India alone, 130 species are of conservation concern. About 20% of those species are reportedly threatened due to degradation of wetland habitat. The Sarus Crane *Grus antigone*, the world's tallest flying bird (Archibald *et al.* 2003), is the only resident breeding Crane in India and Southeast Asia, has suffered a rapid population decline within a few decades (Choudhury *et al.* 1999). The current range of the Indian Sarus Crane includes the plains of northern, north-western, and western India and the western half of Nepal's Tarai lowlands. Gole (1989) estimated <13 000 Sarus Cranes in its entire distribution range in India. Degradation of wetland habitats, poaching, nest destruction, changes in agricultural practices and conflict with farmers in the catchment of the wetlands have been the main factors behind this decline, which seems likely to continue unless appropriate protection measures are taken (Gole 1989, Meine & Archibald 1996, Kaur & Choudhury 2003).

The Upper lake in Bhopal is the oldest large man-made lake in India and is now an part of an important wetland. It has a submergence area of about 36 sq km at full tank level and a catchment area of 361 sq km spread over two districts, Bhopal and Sehore. Sixty percent of the catchment area of the lake is predominantly agricultural. The lake has been subjected to pollution due to discharge of untreated sewage and runoff carrying silt and agricultural chemicals. Various preventive and curative measures including fringe area plantation over about 1 000 ha land were undertaken under an integrated conservation and management plan.

No systematic study of the avian fauna was conducted until March 2000-September 2001; one of the objectives was to record the population and spatial distribution of Sarus Cranes within different areas of the Upper lake.

The study area was divided into three zones based on the topography, pattern of land use and levels of anthropogenic interventions. The eastern and northeastern zones have water up to 9 m; the area is highly disturbed and is used extensively for water related recreational activities. A 5 ha forest cushions the south-eastern zone with a protected zone: encompassing about 5 km of the total 56 km periphery of the lake, this area sports the richest biodiversity. Since there is little impact from human habitation, most nesting birds including the Sarus Crane were observed here.

The third section comprises of the western and southwestern zones of the lake. This zone is studded sporadically by rural

Fig. 1. Monthly variation in the population of Sarus Cranes in the south-western zone of Upper lake during 2000-01.

Fig. 2. Monthly variation in population of Sarus Cranes in the south-eastern zone of Upper lake during 2000-01.

settlements, a number of which are located within 2-3 km of the full tank level of the lake, with extensive fallow land and recent patches of buffer zone plantation created by the Capital Project (Forest Division) Bhopal during 1989-2004 under the conservation and management plan. The key feature of this zone is its low depth of water, low direct human disturbance and less pollutant influx due to restricted urbanization.

Direct total counts were done from widely spread out fixed vantage points. Since the Sarus Crane is a huge bird and visible from a distance, we presume our counts are accurate as only a very small proportion of the lake periphery (<10%) within the selected zones (South East, South West and West) was unapproachable. Bi-hourly counts from 0600-1800 hrs four times a month, during the four-month period of significant population change, and once in a month for other period of the study, were conducted. The highest of these counts were finally termed as the minimum monthly populations of the species.

In 2000, the Sarus Crane population in the southwest to western zone was found to be fewer than 10. However, during February to May of 2001, it showed a dramatic increase, with a

peak of 161 in the month of April (Fig. 1). No such change was observed in the south-eastern zone, where the observed population was fewer than 10 during the entire period of the study (Fig. 2).

One breeding pair of Sarus Cranes was observed and monitored in the south western region where they had made a nest on a mound created while work for deepening and widening of the spill channel was undertaken. This nest was seen first in November 2000, and the family of three monitored to the end of the study in September 2001.

During the study period, mechanized removal of silt from the southern part of the lake was in progress, but the noise and dust did not appear to deter Sarus Cranes from foraging within 50 m of the machines.

Sarus Cranes are mostly non-migratory in India, but often make short seasonal movements between dry and wet season habitats. Indian Sarus Cranes have adapted to the dense human population, and interact closely with people in areas where traditions of tolerance prevail. Their optimal habitat includes a combination of small seasonal marshes, floodplains, high altitude wetlands, human-altered ponds, fallow and cultivated lands, and rice paddy. Often they focus their foraging on underground tubers of native wetland vegetation such as *Eleocharis* spp. Breeding pairs nest in a wide variety of natural wetlands, along canals and irrigation ditches, beside village ponds and in rice paddies. More than other Crane species, Sarus Cranes also utilize wetlands in open forests as well as open grasslands. Where possible, nests are located in shallow water where short emergent vegetation is dominant, and the use of human-dominated wetlands is common in India. In this case, the fringe area plantation may have been a positive factor in the Sarus Crane favouring the Upper lake.

Absence of the Sarus Crane in the north and north east zones of the Upper lake indicates a dislike of the high level of human disturbance and the lack of contiguity of usable habitat. A dramatic increase in population of Sarus Cranes in summer of 2001 could be attributed to the shrinkage of wetland habitat in and around Bhopal due to a poor rains in consecutive years. This phenomenon may assume greater importance and calls for appropriate protection measures for the habitat around the Upper lake.

The future of the Indian Sarus Crane is closely tied to the quality of small wetlands in India that experience heavy human use and suffer from high rates of sewage inflow, extensive agricultural runoff, high levels of pesticide residues, and intensification of agricultural systems. The magnitude of the decline in Sarus Crane population is such that it has been categorized as a threatened species, and there are proposals to move the species from the schedule IV to schedule I of the Wildlife Protection Act (1972, amended in 1991) and take some special measures for its

Sarus Crane *Grus antigone*. Photo: P.K. Nandi.

conservation. In the case of the Upper lake, the following initiatives may be taken:

- Declaration of the entire buffer zone plantation area around Upper lake and the shallow part of the lake as a conservation area.
- Public Awareness Programmes: Citizens of Bhopal and the adjoining villages need to be encouraged to take part in the conservation programme.
- Creation of Sarus Watch groups: under the guidance of wild life experts, students may be encouraged to form voluntary groups who will monitor the Sarus Crane population throughout the year and help villagers understand the need to protect this bird.
- Encourage commercial companies to help protect vulnerable species and their habitat as part of their social responsibility: Infrastructure development due to the lake conservation plan implementation has encouraged tourism, and the Capital Project (Forest Division) is also encouraging eco-tourism.

## Nesting sites and breeding success of Black-necked Crane *Grus nigricollis* in Ladakh, India

Pankaj Chandan<sup>1</sup>, Parikshit Gautam & Archana Chatterjee

<sup>1</sup>Senior Project Officer, WWF-India, Field Office, Hemis Complex, Zangsti Road, Leh - 194101, Ladakh, India.  
(email: pchandana@wwfindia.net)

Chandan, P., Gautam, P. & Chatterjee, A. 2006. Nesting sites and breeding success of Black-necked Crane *Grus nigricollis* in Ladakh, India. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 311-314.

Ladakh contains some of the world's most unique and spectacular wetlands and is the only known breeding ground of Black-necked Crane *Grus nigricollis* in India. The study area was situated in the Changthang region of eastern Ladakh, part of the Trans-Himalayas of the Tibetan Plateau. (Fig. 1). This harsh environment, at an altitude of 4 000 m and above, is a cold, sparsely vegetated desert, with a short summer season, home to only highly adapted flora and fauna. Strong and unpredictable winds make the area highly inhospitable, with summer temperatures from 0° C to 30° C and winter from -10° C to -40° C (Mishra & Humbert-Droz 1998). The region has numerous brackish and freshwater wetlands, which apart from their hydrological importance, are home to a wide variety of flora and fauna. Most of these wetlands are of glacial origin and remain frozen from December to March. A unique nomadic tent

dwelling tribe, the Changpas, roam the wetlands of Ladakh in search of pasturelands.

To identify appropriate wetlands to survey, a thorough literature review was carried out and based on this information, 22 wetlands were identified for an intensive survey. Surveys were undertaken from 2000 to 2003: a limited survey of a few wetlands in 2000 and 2001 and a survey of all wetlands in 2002 and 2003. All known and probable nesting and feeding sites were visited from April to November during each year. Data was collected on the number of nests, eggs laid, hatching success and survival of fledglings. Rapid surveys were made in March and April, and October to November to establish arrival and departure dates. The day a Black-necked Crane was first sighted was treated as arrival date (Oring & Lank 1982), and the last day when the species was sighted was considered as its departure date (Bhupathy *et al.* 1998).

April- November 2003	22	60	16	10	This study

Data for estimating breeding productivity was collected from 15 pairs of birds in 2002 and 16 pairs in 2003. The reproductive output of each nest was followed through the various stages of the life cycle, from the clutch laid, through hatching/fledging and recruitment into the breeding population. As there were few sub-adults present, these were included in the adult category. Productivity was calculated as the number of young reared per successful female in the population in a year. The Mayfield (1961) method (successful nests / all nests) was used to determine nesting success.

Black-necked Cranes arrived in the wetlands of Changthang, their only known nesting area in India, in the last week of March or first week of April and leave in the last week of October or first week of November, along with their chicks. Other waterbirds also bred in these wetlands: Bar-headed Goose *Anser indicus*, Brown-headed Gull *Larus brunicephalus*, Great-crested Grebe *Podiceps cristatus*, Ruddy Shelduck *Tadorna ferruginea* and Lesser Sand Plover *Charadrius mongolus*.

Table 1 summarises numbers and breeding records from previous surveys and this survey. In 2002 and 2003, totals (adults and chicks) of 59 and 60 birds respectively were recorded; the highest number ever recorded in Ladakh. Six new breeding sites were found (Table 2). A total of 15 nests were found in 2002, and 16 in 2003. Nesting success was 33.3% in 2002 and 31.5% in 2003, less than recorded in previous years: 60% in 1995, 43% in 1996, 37.5% in 1997. In each year 10 chicks were reared – a productivity of 0.66 in 2002 and 0.62 in 2003, lower than in previous studies of Black-necked Cranes in Ladakh between 1992 and 1997 - 0.75 – 1.2 young per pair (Chacko 1995, 1996, Pfister 1998), but within the range of productivity reported for other crane species of 0.23–1.39 young per pair (Pomeroy 1980, Walkinshaw 1981, Neumann 1987; Tarboten *et al.* 1987, Mafabi 1991, Prange & Mewes 1991, Winter 1991).

The 2002 April to December survey of 22 wetlands found Black-necked Cranes nesting in all wetlands except for Tsomoriri and Kyun Tso 1, Kyun Tso 11 and Pangong Tso. Three new nesting sites (Yaya Tso, Chukil Koma and Staklung)

were recorded, the Yaya Tso site (altitude 4 720 m) was the highest recorded breeding location in India. Of the 15 breeding pairs, 14 laid two eggs each and one pair laid only one egg. At many nests, eggs were eaten by feral dogs. Of the 12 chicks that hatched two were lost: the chick at Jung Demo was eaten by a feral dog, but the cause of the loss a chick at Lungparma could not be ascertained. In October, 10 healthy chicks and 49 adults were recorded in different wetlands. A Crane tagged at Hanle, Ladakh in 1995 was recorded in 2002 in a breeding pair, but the nest was abandoned after the egg was eaten by a dog.

Although the 2000 and 2001 surveys covered only four wetlands (Tsomoriri, Tsokar, Startsapuk Tso & Puga), nesting at the northern end of Tsomoriri in 2000 was the first record for the area. This nest was washed out by a major water level rise. No nesting was recorded at Puga or Tsokar in 2000, but in 2001, one nest was found at each wetland; again first nesting records for these sites. The Tsokar nest was unusual as it was built within an area of mounds near Thukjay village, rather than the more usual sites with open visibility. All four eggs at the Tsokar and Puga sites were eaten by dogs. However, the nest at Startsapuk Tso successfully produced two chicks during 2000 and 2001.

In January 2003, a pair of Cranes was recorded overwintering at Lam Tso Chumur wetland which was completely frozen, their survival due to nomads in that area feeding them. This is the first recorded case of a pair of Black-necked Cranes staying during the harsh Ladakh winter.

Although our more extensive surveys found a larger breeding population than previously recorded its overall breeding productivity appears to be declining. This seems to be due to increased human activities such as unplanned development and grazing. However, our frequent observations of dogs taking eggs during incubation suggest that this is the major threat to the breeding population of cranes in Ladakh.

#### ACKNOWLEDGEMENTS

The success of this study in such a hostile environment with its challenging terrain and severe climate is entirely due to the whole hearted support of numerous individuals and organizations.

### 3.6 East Asia-Pacific Flyway. Workshop Introduction

Taej Mundkur

Wetlands International - South Asia, A-25, 2nd Floor, Defence Colony, New Delhi - 110 024, India.

Mundkur, T. 2006. East Asia-Pacific Flyway. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 315.

Oyster farm in Luoyuan Bay, Fujian Province, China. The inter-tidal mudflats of the Chinese coast, as elsewhere in East Asia, are subject to a very high intensity of use by populations of dependent humans as well as waterbirds. Photo: Mark Barter.

The waterbirds of Asian-Australasian flyways are the most poorly known of the world's waterbird migration systems, and the greatest number of globally threatened waterbirds occurs here. This flyway extends across the most densely populated part of the world, where there are extreme pressures not only on unprotected wetlands but also on protected sites (many of which also either contain or provide the livelihoods of very large numbers of people). Effective protection of wetlands of major importance is a critical need, as in other regions of the world. There are huge, and crucial, challenges in ensuring effective wise-use of key sites, as well as ensuring that consumptive uses of waterbirds are sustainable.

The symposium reviewed existing policies, case studies and problems within the East Asian flyway, and discussed the effectiveness of the different approaches.

The following recommendations were made:—

- Networks of internationally important sites provide a sound foundation for flyway conservation initiatives. Chan presented the example of the North-east Asian Crane Network as a model. Voluntary conservation initiatives can provide a successful model for migratory waterbirds and wetland conservation. Significant voluntary effort has been expended in recent years to better understand wader conservation needs. Recent work was outlined by Straw *et al.* and Huettmann *et al.*
- Conservation of migratory waterbirds must be achieved increasingly through delivery of sustainable development.
- Conservation of migratory waterbirds must address the needs of local communities and national governments if they are to be successful in the longer term.
- Developing networks of wetland education centres should be promoted to create greater local awareness and support, and provide the foundation for conservation of migratory waterbirds through strong and functional flyway site networks. Young summarised the role of Asian wetland centres in the conservation of wetlands and migratory waterbirds.
- Management of migratory waterbirds requires sound monitoring information covering their annual life cycles. Development and strengthening of such monitoring programmes requires long-term investments across flyways. Li *et al.* describe a range of recent initiatives.

## Shorebird migration studies in Kamchatka

Yuri N. Gerasimov

Kamchatka Branch, Pacific Institute of Geography, Russian Academy of Science Rybakov 19a, Petropavlovsk-Kamchatsky, 683024, Russia.

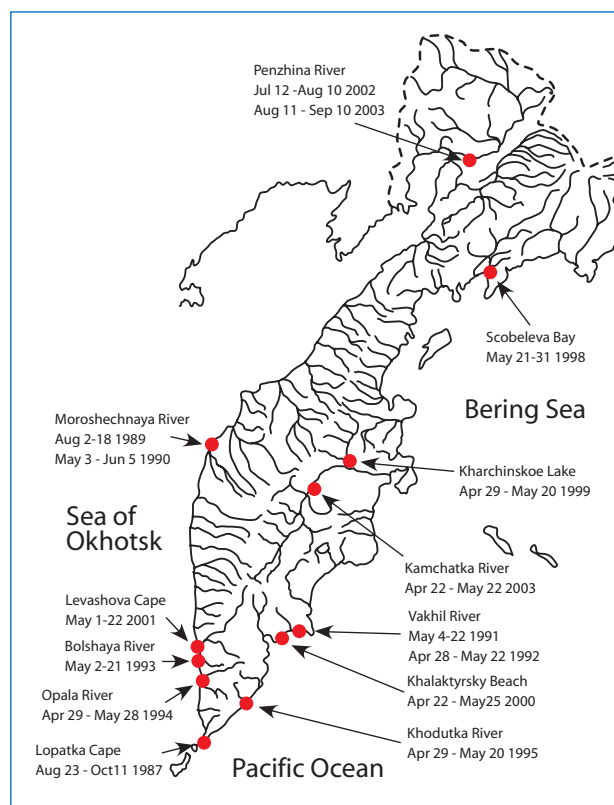

Gerasimov, Y.N. 2006. Shorebird migration studies in Kamchatka. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 316-318.

Kamchatka, a large (1 200 km long) peninsula in far eastern Russia, is of great importance as a staging and breeding area for many species of shorebirds on the East Asian flyway, with a total of fifty species of Charadriidae being recorded there. Research on shorebird migration in Kamchatka began in the mid 1970s, becoming more intensive from 1989 onwards when special counts of shorebirds during northward spring migration were started (Gerasimov 1980, 1988, Lobkov 1980, 2003), for further information and additional references see Gerasimov (2005). From 1990 to 2003 nine counts were made at eight different locations on the peninsula. Each count was carried out over a 15–30 day period during late April to early June, with additional daily counts being made on mudflats in Korf Bay. In addition, for southwards (northern autumn) migration, a large study was undertaken at the Penzhina Estuary in 2002 (12 July–10 August) and 2003 (11 August–10 September), at the northern end of the peninsula, as part of the implementation of the Action Plan for the Conservation of Migratory Shorebirds in the East Asian-Australasian Flyway: 2001–2005 (Shorebird Working Group of Wetlands International 2001). Five to six hour counts on mudflats were undertaken along a fixed 10 km shoreline length. Additionally, shorebirds were counted flying past the study area, and at night estimates were made based on the calls of birds flying past. The only previous autumn survey was of the Moroshechnaya Estuary between 2–18 August 1989. Survey locations and periods are shown in Fig. 1, and counts from selected years in Table 1.

Additional information on shorebird migration on Kamchatka was obtained from banded and flagged shorebirds, and satellite tracking of Eastern Curlew *Numenius madagascariensis* (Ueta *et al.* 2002). In the 1990s Dunlin *Calidris alpina* were also banded with plastic colour-rings. A series of papers on different shorebird species have been published from this research (Gerasimov & Gerasimov 2000b, 2001, 2002).

Observations of northward migration on west Kamchatka show that this coast is very important for shorebirds. Species including Dunlin, Red-necked Stint *Calidris ruficollis*, Great Knot *Calidris tenuirostris*, Bar-tailed Godwit *Limosa lapponica*, and Whimbrel *Numenius phaeopus* arrive either at the southwest and western coasts and migrate northwest, or arrive on in the southeast and migrate along the northeast coast. The largest shorebird concentrations were observed in 1990 at the mouth of the Moroshechnaya River on the mid-west coast of the peninsula, although full counts for all species (except for Great Knot) could not be made, and it is probable that total numbers of Dunlin, Red-necked Stint and Bar-tailed Godwit were much higher than counted.

Thousands of Wood Sandpipers *Tringa glareola*, Black-tailed Godwits *Limosa limosa* and Common Greenshanks *Tringa nebularia* were counted in 1999 at Karchinskoe Lake in central Kamchatka, but significant migration of these species

**Fig. 1.** Main locations where shorebird migration studies have been carried out on Kamchatka. Observations at Lopatka Cape were conducted by Lobkov (2003); all other observations were carried out by the author.

was not seen on west coast of the peninsula. So these species may be arriving at Kamchatka at high altitude and flying into the central part of the peninsula only after crossing its eastern mountain range, before dispersing to breed throughout the peninsula. Thousands of Common Snipe *Gallinago gallinago* and Long-toed Stints *Calidris subminuta* pass by Kharchinskoe Lake during the second half of May, but accurate counts could not be made as these species were migrating mainly at night. In contrast to the west coast, surveys in 1991, 1992, 1995 and 2000 found only small number of shorebirds using different parts of the south-east coast of the peninsula (Gerasimov 2001).

The various surveys permit a minimum estimation of the total numbers of different shorebirds using the peninsula during northward migration (Table 2).

There is much less information available for southward (autumn) migration. However, both areas surveyed – the mouth of Penzhina River in north-east Kamchatka and the Moroshechnaya Estuary on its mid-east coast – are important as staging places for shorebirds (Gerasimov & Gerasimov 1997, 1999, Huettmann & Gerasimov 2002, Gerasimov 2003, 2004). However, observations showed that shorebirds generally remain

**Table 1.** Numbers of shorebirds counted in different parts of Kamchatka.

Species	Northward migration (spring)					Southward migration (autumn)

at the Penzhina River mouth in north-east Kamchatka for only one day, as there are no suitable roosting places for species such as Dunlin and Red-necked Stint during high tide. In addition, large numbers of shorebirds overfly the mudflats and so are not included in the mudflat counts.

During recent years shorebird migration studies on Kamchatka have been supported by the Australian Department of Environment and Heritage (DEH). We also sincerely thank all those people who have helped us with data gathering on migration of shorebirds on Kamchatka over the years.

## Conserving migrating shorebirds in the Yellow Sea region

C. Kelin & X. Qiang

Wetlands International, Room 501, Grand Forest Hotel, No. 3A, Bei Sanhuan Zhonglu Road, Beijing 100029, China.  
(email: ckl@wetwonder.org or xq@wetwonder.org)

Kelin, C. & Qiang, X. 2006. Conserving migrating shorebirds in the Yellow Sea region. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 319.

The Yellow Sea Region lies between North and South Korea to the east and China to the west, and covers an area of 458 000 sq km. Biodiversity in the inter-tidal zone of the Yellow Sea Region is high: excellent feeding and roosting areas accommodate many different species of waterbirds, and preliminary records indicate that the coastal zone of the Yellow Sea eco-region supports about 200 breeding, staging and wintering waterbird and seabird species.

The Yellow Sea eco-region is a very important component of the East Asian-Australasian Flyway. It serves as an essential staging site for shorebird migration between the south and north: its position is crucial for shorebird migration as it acts as an energy station due to its large coastal inter-tidal flats. Shorebirds breeding in the Russian Far East, northeast China and northern China can either migrate along the coastline and winter in the middle and lower Chang Jiang and South China, or continue to fly southward to winter in Southeast Asia, Australia or New Zealand. The northern coast of the Yellow Sea is probably the final staging site for many shorebird species flying to their breeding sites.

In order to assess the shorebird resources in the Yellow Sea and to accurately understand the utilization of the region by shorebirds during their northward and southward migration, Wetlands International-China has for the past nine years organized experts to conduct regular field surveys along the most of the coasts of the Yellow Sea.

A total of 54 shorebird species have so far been found in the Yellow Sea during southward or northward migration, of which 34 species occurred in internationally important numbers (more than 1% of its estimated biogeographic population) at one or more sites. This number represents 60% of the migratory shorebird species in the East Asian – Australasian Flyway. It is estimated that at least 2 million shorebirds, approximately 40% of all migratory shorebirds population in the Flyway, use the Yellow Sea Region during northward migration. Large numbers of shorebirds, perhaps exceeding 1 million, also pass through this region during southward migration. A total of 14 sites have been identified in the Yellow Sea-China coast where at least one shorebird species has been recorded in internationally important numbers.

The majority of one globally threatened species, the Spotted Greenshank *Tringa guttifer*, uses the Yellow Sea for both northward and southward migrations, and nine sites have been identified as internationally important for this species. Almost the entire migratory population of five shorebird species uses the

Yellow Sea: Curlew Sandpiper *Calidris ferruginea*, Bar-tailed Godwit *Limosa lapponica*, Eurasian Curlew *Numenius arquata*, Great Knot *Calidris tenuirostris* and Kentish Plover *Charadrius alexandrinus*. Approximately 80% of the estimated population of Eastern Curlew *Numenius madagascariensis* and 40% of Asian Dowitcher *Limnodromus semipalmatus* were represented in the Yellow Sea during northward migration.

Seven species occur in internationally important concentrations in the southern part of the Yellow Sea during the non-breeding season, i.e. the Eurasian Curlew *Numenius arquata*, Spotted Redshank *Tringa erythropus*, Common Greenshank *Tringa nebularia*, Sanderling *Calidris alba*, Eurasian Oystercatcher *Haematopus ostralegus*, Pied Avocet *Recurvirostra avosetta* and Kentish Plover *Charadrius alexandrinus*. The Oriental Pratincole *Glareola maldivarum* breeds in the Yellow Sea in internationally important numbers.

Based on the analysis of the survey results, it is clear that shorebird use of the Yellow Sea Region is very varied. Some species occur at high densities within limited wetland sites, while some species are distributed in many sites but at lower density.

Approximately 600 million people from China, South Korea and North Korea live in the Yellow Sea Region. The rapid growth of the population and economy of China and South Korea has resulted in degradation and a serious loss of wetland habitat along the Yellow Sea and regionally due to environmental pollution, reduced river flows and human disturbance.

Successful shorebird conservation will depend on positive national policies and plans and wise and sustainable development and use of inter-tidal mudflat and coastal resources. Coordination and cooperation between related agencies will be important as a basis for the successful realization of these national policies and plans. In addition to traditional approaches, further efforts should be made to facilitate regional environment improvement and shorebird conservation. These may include:

- regular surveys, assessment and monitoring of wetland and shorebirds in the Yellow Sea;
- initiation of a long-term general and overall protection plan for the Yellow Sea Eco-region;
- define a set of key fields and priorities for conservation in the Yellow Sea Region;
- increase public awareness activities; and
- establish a wetland and shorebird conservation network for the Yellow Sea eco-region.

## The North East Asian Crane Site Network

**Simba Chan**

*Flyway Officer of the North East Asian Crane Site Network, Wild Bird Society of Japan, WING 2-35-2 Minamidaira, Hino, Tokyo 191-0041, Japan. (email: simba@birdlife-asia.org)*

Chan, S. 2006. The North East Asian Crane Site Network. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 320-323.

### ABSTRACT

The North East Asian Crane Site Network was launched in 1997. The main goal of the Network is to conserve crane species and their habitats in north-east Asia. As of October 2003, there are 26 sites important for cranes and storks in the six north-east Asian countries that have joined the Crane Network. Since its launch in 1997, the Crane Network has organized a number of workshops, symposia and training courses with a view to improving site management and promoting public awareness of the need for site conservation. At the workshops and training courses, the Crane Network has provided opportunities for reserve staff, researchers and conservation organizations from the six countries in north-east Asia to share their experiences and to establish closer bonds both within these countries and with countries outside the region.

### BACKGROUND

Cranes have long been regarded as symbols of longevity and happiness in north-east Asia, and there has been a long history of crane protection in the region. In recent decades, cranes have been amongst the first species to be given legal protection and to benefit from the designation of special sanctuaries. Cranes are therefore important flagship species for the conservation of wetland habitats in north-east Asia.

Of the fifteen species of cranes in the world, seven are found in north-east Asia (Mongolia, China, North Korea, South Korea, Japan and the eastern part of Russia). Four of these species are largely or wholly confined to the region and are globally threatened: Siberian Crane *Grus leucogeranus*<sup>1</sup>, Red-crowned Crane *G. japonensis*, White-naped Crane *G. vipio*, and Hooded Crane *G. monacha*. North-east Asia is thus the most important region for crane conservation in the world. As cranes are birds of very high cultural significance, they are also ideal flagship species for wetland conservation in the region.

### HISTORY

In 1990, the Wild Bird Society of Japan (WBSJ), together with the Yamashina Institute for Ornithology and other researchers in the region, began using satellite-tracking to study the migration of cranes in Asia. This work resulted in the identification of many important migration routes and stopover sites for cranes. In 1993, WBSJ organized an international workshop “The Future of Cranes and Wetlands” in Tokyo and Sapporo, Japan, to discuss the next steps in the conservation of cranes in the region. The concept of building a network of important sites was raised at this workshop.

In December 1994, representatives from 16 East Asian and Australasian countries attended a workshop on the conservation of migratory waterbirds in Kushiro, Japan. The meeting was organized under the auspices of the Environment Agency of Japan<sup>2</sup> and the Australian Nature Conservation Agency<sup>3</sup>, with assistance from the Asian Wetland Bureau<sup>4</sup> and the International Waterfowl and Wetlands Research Bureau - Japan Committee<sup>5</sup>. WBSJ was a strong supporter of the workshop. The workshop produced a summary statement known as the “Kushiro Initiative” which called for the following:

- preparation of a conservation strategy for migratory waterbirds in the region;
- development of Action Plans for species groups; and
- development of networks of internationally important sites for species groups.

In 1997, the North East Asian Crane Site Network (hereafter referred to as the Crane Network) was launched at an international conference on wetlands and waterbirds held at Beidaihe, China. The Crane Network is one of three networks that have been established for particular groups of waterbirds under the Asia-Pacific Migratory Waterbird Conservation Strategy, the others being for Anatidae (ducks, geese and swans) and shorebirds. The Working Group of the Crane Network was established in 1997 to give guidance to the activities of the Crane Network. It consists of national representatives from all six countries in the region, researchers and international crane experts. The Crane Flyway Officer implements the activities as discussed and decided upon by the Crane Working Group. Since 2000, the Crane Network has also covered activities relating to the conservation of stork species in north-east Asia, particularly the globally endangered Oriental White Stork *Ciconia boyciana*.

By April 2004, 26 sites of importance for cranes and storks had joined the Crane Network. They include sites from all six north-east Asian countries and some of the most important wetlands in north-east Asia. Twelve of the sites have already been listed as Ramsar sites under the Ramsar Convention on Wetlands, and all 26 sites have been identified as Important Bird Areas under the BirdLife International global programme. A list of the Crane Network Sites is given in Table 1 (see also Fig. 1).

### ACTIVITIES

Since 1997, the Crane Network has organized a number of workshops on research and management, symposia to promote public

<sup>1</sup> There is a very small population of this species in central and western Asia, but more than 99% of the global population occurs in north-east Asia.

<sup>2</sup> Now known as the Ministry of the Environment, Japan.

<sup>3</sup> Now known as the Department of the Environment and Heritage, Australia.

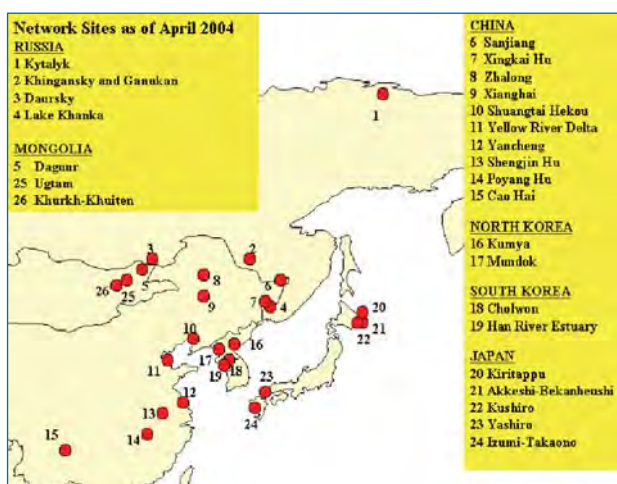

<sup>4</sup> Now part of Wetlands International.

<sup>5</sup> Now known as Wetlands International Japan.

- December	Third issue of the Crane Network Newsletter published

researchers and conservation organizations from the six countries in north-east Asia to share their experiences and to establish closer ties between these countries and with countries outside the region. For example, in 2001, 2002 and 2003, the Crane Network organized workshops and training courses on education and visitor management in China, Japan and Mongolia. At each meeting, there were over 50 participants from various countries. Translation has always been a challenge, but it is a very good

sign that people from countries throughout the region are now interested to know what their foreign counterparts are doing. Good communication within the region has started.

The main focus of the Crane Network is to empower reserve managers in north-east Asia, and to provide opportunities for multinational co-operation in conservation. The 15 principal activities in the Crane Network Action Plan for the period 2001-2005 cover the following major areas: develop-

ment of the Crane Network, improvement of management skills of site managers, promotion of education programmes at the sites, research and monitoring of crane populations, and exchange of information within the region. A chronological list of the main activities of the Crane Network up to March 2004 is given in Table 2. The Working Group of the North East Asian Crane Site Network is currently preparing a new action plan for the period 2006-2010.

## THE FUTURE

There seems to have been some recovery in the numbers of cranes in north-east Asia in recent years as a result of effective protection. There are now at least 10 000 Hooded Cranes, 6 000 White-naped Cranes, 2 000 Red-crowned Cranes and 3 000 Siberian Cranes in the wild. However, the continuing increase in the human population and higher expectations in living standards resulting from rapid economic growth in north-east Asia will no doubt place higher demands on the already limited land resources in this region. More land will be claimed for agriculture, industry and housing, and agriculture in existing farmlands will become more intensive. This is certainly not good news for wildlife, particularly species such as cranes which are adapted to semi-agricultural habitats in their wintering areas.

Cranes are now becoming increasingly concentrated at a few wintering sites. The situation is very serious in Japan and South Korea, and a similar trend has also been noted in China. If we do not save enough sites now, within one or two decades the cranes in north-east Asia will end up having to survive at only a handful of sites. Unlike the situation in the late nineteenth century, the biggest threat to cranes now is not human persecution, but habitat destruction, as it is to most other threatened wildlife. For this reason, we should not think that the cranes are “saved” just because there has been an increase in numbers. In fact, cranes are facing a very serious threat from habitat loss in north-east Asia.

One of the major research topics in the Crane Network Action Plan for 2001-2005 is to study the feasibility of dispersing over-concentrated crane populations, particularly the populations of Hooded Cranes and White-naped Cranes wintering at Izumi in Japan. This is a very difficult task, not only because suitable alternative wintering sites have to be identified, but also because the support and co-operation of local communities is essential. While on the one hand, it is important to disperse the over-concentrated cranes at some sites, on the other, it is important to prevent over-concentration of cranes in other countries, particularly in China.

This is why site conservation and proper management are very important. The Crane Network can play a role in empowering local stakeholders and strengthening co-operation between different sites and different countries. In the coming five years, and certainly in the long term, the Crane Network will work with researchers, conservationists and stakeholders to improve the management of sites important for cranes in north-east Asia, and bring these people together in closer co-operation.

## ACKNOWLEDGEMENTS

The Ministry of the Environment of Japan has been supporting the Crane Network from the outset. Since its launch, the Crane Network has also received support from the State Committee for Environmental Protection of the Russian Federation, the Ministry of Nature and the Environment of Mongolia, the State Forestry Administration of the People's Republic of China, the Nature Conservation Center of the Democratic People's Republic of Korea, and the Forestry Administration and Ministry of Environment of the Republic of Korea. Their support and guidance are essential for the success of crane conservation in north-east Asia.

The International Crane Foundation and other national crane research groups and experts have provided advice and assistance in the formation of the Crane Network. We are particularly grateful to the Amur Chapter of the Socio-ecological Union (Russian Federation), the Muraviovka Park for Sustainable Land Use (Russian Federation), the National Institute of Environmental Research (Republic of Korea), the City Government of Dongying (China), Wetlands International Japan, the City Government of Kushiro (Japan), the Mongolian Academy of Sciences, and the UNDP Eastern Steppe Biodiversity Project (Mongolia) for assistance at meetings, training courses and symposia. Ligue pour la Protection des Oiseaux assisted in raising funds to organize education workshops. Activities of the Crane Network have been generously funded by the Japan Fund For Global Environment, Japan Trust for Global Environment, Keidanren Nature Conservation Fund (Japan), Ministry of Environment (Republic of Korea), City Government of Suncheon (Republic of Korea), Société des Eaux Minérales d'Evian of the Danone Corporate Group (France), French Global Environment Facility, and UNEP/GEF Siberian Crane Wetlands Project.

Education and awareness raising are critical aspects of crane conservation. Dr Evgeny Bragin explaining use of radio telemetry equipment to monitor Siberian Cranes *Grus leucogeranus* in Yakutia as part of the UNEP/GEF Siberian Crane Wetlands project. Photo: Crawford Prentice.

## The role of Asian wetland centres in the conservation of wetlands and migratory waterbirds

Lew Young

Mai Po Nature Reserve, WWF Hong Kong, Mai Po, San Tin, Yuen Long, Hong Kong. (email: lyoung@wwf.org.hk)

Young, L. 2006. The role of Asian wetland centres in the conservation of wetlands and migratory waterbirds. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 324-327.

### ABSTRACT

The establishment of visitor centres to raise awareness of the importance of wetlands and migratory waterbirds probably began in the UK in the 1940s. Since then, a network of similar wetland centres has been developed around the world, and wetland education has become one of the key tools in the conservation of wetlands and their wildlife. These centres are often associated with important wetlands, and may play a significant role in the study and conservation of these sites. Since the early 1980s, interest in the development of wetland centres in Asia has gained considerable momentum. This paper provides a brief history of a few of the wetland centres in Asia and the efforts that have been made to conserve migratory shorebirds through education programmes and management of the wetland habitats associated with the centres. Special attention is given to the work of the education centres associated with the Mai Po Inner Deep Bay Ramsar site in Hong Kong, P.R. China.

### INTRODUCTION

The concept of establishing education centres to raise awareness of the importance of wetlands and their wildlife probably began with the opening of the centre at Slimbridge (UK) in 1946 by Sir Peter Scott. Since then, a network of similar centres has been built around the world, and wetland education has become one of the key tools in the conservation of wetlands and their wildlife.

However, these centres do not just focus on wetland education and public awareness. They are often carefully located on the edge of an important wetland so that the centre may also play an important role in the management of the wetland, conducting monitoring and research, working with local communities and lobbying government to ensure the “wise use” of the wetland and its long-term protection.

Over the past decade, wetland centres around the world have been working together more closely through the Wetland Link International (WLI) initiative in order to share resources and ideas for programmes, and to carry out co-operative projects. This has been particularly true in Asia, where a number of established wetland centres have played important roles in providing support for the establishment of new protected wetland sites and associated centres in other countries. These centres have recently decided to form an Asian Chapter of WLI to help promote greater co-operation between Asian wetland centres.

### THE ROLE OF WETLAND CENTRES AND WETLAND NATURE RESERVES

#### Education and awareness

One of the advantages of having an education centre built adjacent to a wetland is that the wetland can be used as an educational tool where students and other visitors can be guided and shown first-hand the variety of wildlife that wetlands support

and the ecological stories that they can reveal.

To facilitate the visitors’ appreciation and understanding of the wetland, facilities such as an exhibition room, nature trails, notice boards, bird-watching hides and boardwalks are often available. Educational material such as books and leaflets are usually produced to explain the various aspects of the ecology of the wetland and its wildlife. A range of special (e.g. guided) education and public awareness programmes are also often offered, targeting the general public (including the disabled), students, decision makers and others. There may also be programmes for volunteers to help with the daily management of the reserve and centre.

#### Conserving and managing habitats for wetland wildlife, including waterbirds

Wetland centres may, or may not, also be responsible for the management of the adjacent wetland. If so, then the work will involve maintaining the ecological value of the site. This may include providing habitat for the various species of wildlife for which the wetland is important, and balancing the need to conserve the site with maximizing opportunities for visitors to enter and learn about the site, and value its importance.

#### Monitoring and research

In order to manage a wetland in a manner that can maximize its ecological value, regular baseline ecological monitoring needs to be conducted. This will ensure that any adverse changes are detected quickly, and allow action to be taken immediately to resolve the problem. Such monitoring may include the quality of water in the wetland and changes in the diversity and abundance of waterbirds for which the site is important.

Research projects may be carried out by staff of the wetland centre or, alternatively, co-operative links may be established with local colleges or universities and projects conducted by students or academic staff. Examples of such projects may include investigating the optimum means of managing certain habitats in the reserve in order to maximize its value for key wildlife species. It is important that the data and reports from such monitoring and research projects are published and made available to the reserve staff who can then take appropriate management action.

#### Training

Wetland centres can often provide training for overseas site managers and decision makers on topics such as habitat management, waterbird identification and survey techniques, waterbird catching and banding, and environmental education techniques. This training can be achieved by inviting participants to the centre, by staff from the centre visiting overseas sites, remotely via e-mail (such as the Shorebird Sister Schools Programme), or by twinning sites.

Mai Po Wildlife Education Centre, Hong Kong. Photo: Lew Young.

### WETLAND CENTRES IN ASIA

The development of wetland centres in Asia originally lagged behind that in “western” countries, but since the early 1980s, interest in providing such centres has gained momentum. This is especially so in those Asian countries whose economies have been growing rapidly in recent decades. The following section provides a brief history of a few of these centres in Asia, their importance for shorebirds, and the work that has been carried out to conserve these birds through education programmes and management of the wetland habitats associated with the centres.

#### Wetland Centres around Deep Bay, P.R. China

##### Mai Po Marshes Wildlife Education Centre and Nature Reserve, Hong Kong

The Mai Po Marshes form part of the complex of wetlands around Deep Bay in the north-western corner of Hong Kong, and have been well known as a site for wetland wildlife since the end of the 1800s. At present, some 54 000 waterbirds winter in these wetlands, and an additional 20 000-30 000 shorebirds pass through the area during the spring and autumn migration. At least 177 species of waterbirds have been recorded in Deep Bay. Forty of these (almost 23%) are of special importance either because they are threatened species, or because they occur in numbers that exceed 1% of the flyway population (Carey & Young 1999).

Due primarily to the importance of the area for migratory waterbirds, in 1995 the Hong Kong government designated an area of 1 500 ha of wetlands around Deep Bay as a Wetland of International Importance under the Ramsar Convention on Wetlands. This Ramsar site includes the Deep Bay mudflats, the Mai Po Marshes Nature Reserve, and an area of commercial fishponds on the land-ward edge of the site.

In 1984, WWF Hong Kong took over the management of the 380 ha Mai Po Marshes Wildlife Education Centre and Nature Reserve (MPNR) with a view to promoting education and conservation in collaboration with the Hong Kong government. The MPNR is made up of 24 traditionally operated shrimp ponds (locally known as “*gei wai*”), each of about 10 ha in size and supporting a mixture of mangroves, reed-beds and areas of open water. Shorebirds feed on the inter-tidal mudflats in Deep Bay, but at high tide, they fly into the reserve and roost in a number of specially managed “*gei wai*” that provide areas of shallow water during spring or autumn passage and throughout the winter period. In summer, however, the water level in these ponds is kept high to prevent the encroachment of reeds from the edges of the pond into the areas of open water. The height of the vegetation around the roost sites is also kept low so as not to obstruct the flight lines of the shorebirds; this also allows the shorebirds to see the approach of aerial predators (Lawler 1995).

MPNR staff also carry out some management of the shorebirds’ feeding areas on the adjacent mudflat. This is necessary because the mangroves that fringe the mudflat are slowly advancing out over the mud. Each autumn, the mangrove seedlings in an area of approximately 30 ha in front of the bird-watching hides on the edge of the mudflat are removed manually. This not only keeps the view from the hides unobstructed, but also maintains an open area of mudflat for feeding shorebirds and other waterbirds.

Through a programme of specially guided visits to the reserve, students and the general public can get a first-hand understanding of the importance of wetlands and waterbirds, and the need for their conservation. However, due to the small size of the reserve, visitor numbers have to be controlled so as to minimize disturbance to the wildlife. As a result, only around

40 000 people visit MPNR each year. These include about 400 groups of primary and secondary school students on specially guided programmes sponsored by the government's Education Department. Teams of volunteers also help with reserve management at various times of the year.

### Wetland Park, Hong Kong

In 1987, reclamation work began on an area of 300 ha of fishponds in the south-western corner of the Deep Bay wetlands for the construction of a new town (Tin Shui Wai) that would eventually house some 135 000 people. However, with increasing awareness of the importance of wetlands, the government proposed in 1995 to set aside an area of 64 ha at the development site as mitigation for the loss of wetlands caused by the construction of the new town. This area would also act as a buffer between the new town and the Mai Po Inner Deep Bay Ramsar site.

After further discussions, the government decided in 1999 to expand the ecological mitigation area into a Wetland Park for both local residents and overseas visitors. This was partly in response to the increasing demand from people wishing to visit Deep Bay and obtain a greater understanding of the wetlands, but unable to do so because of a lack of space on the guided tours at MPNR. The facility will have a modern wetland education centre as well as a range of demonstration wetland habitats, including a high-tide roosting site for shorebirds and other waterbirds. Work began on the Tin Shui Wai Wetland Park in 2000, and the park was finally opened in May 2006. The Wetland Park is managed by the Agriculture, Fisheries and Conservation Department of the Hong Kong SAR government.

Being less ecologically sensitive than MPNR, this new wetland centre will have a capacity of up to 400 000 visitors per year. It will therefore be able to bring the message of the importance of the Deep Bay wetlands and waterbirds to a much larger and wider audience.

### Futian National Nature Reserve, Shenzhen

A range of wetlands, such as mudflats, mangroves, shrimp ponds and fishponds, is also found along the northern, Mainland China side of Deep Bay. Some protection was afforded to these wetlands in 1984, and in 1988, the area was upgraded to a National Nature Reserve (NNR). The boundaries of the Futian National Nature Reserve were confirmed in 1998, and enclose an area of 368 ha; the reserve is managed by the Department of Agriculture and Forestry, Shenzhen SEZ.

Many of the shorebirds that use Deep Bay feed on the mudflats on both the Hong Kong and Shenzhen sides of the bay. However, at high tide, the majority of these birds fly to MPNR to roost on the shallow ponds there, because of the lack of suitable high-tide roosts at Futian NNR.

In the late 1990s, the reserve began to develop a range of visitor facilities, such as a floating boardwalk and a tower hide for bird-watching that overlooks the mudflats. In December 2003, the reserve launched its education programme with the opening of a wetland education centre which works with local school teachers to promote environmental education in Shenzhen's schools. This provides a good opportunity to spread the message of the importance of the Deep Bay wetlands to the community on the Shenzhen side of the bay and, hopefully, will lead to co-ordinated conservation management of the whole Deep Bay catchment.

### Guandu Nature Park, Taipei

The coastal wetlands at Guandu in northern Taiwan have always been an important site for bird-watching, and so in 1986 the Taipei government agreed to establish the Guandu Nature Park. A committee was formed to investigate the ecology of the site and plan its management. In 1988, the committee published its report, and the government began acquiring land for management. Finally in 1993, the government announced that an area would be set aside for the Guandu Nature Park. By 1996, an area of 57 ha had been taken over, and this was granted to the Wild Bird Society of Taipei (WBST) for management.

Some 23 species of shorebirds have been recorded on the coastal mudflats, with the commonest being Pacific Golden Plover *Pluvialis fulva*, Common Greenshank *Tringa nebularia*, Wood Sandpiper *T. glareola* and Common Snipe *Gallinago gallinago*. A further three species of shorebirds have been recorded within the Nature Park, namely Greater Painted-Snipe *Rostratula benghalensis*, Black-winged Stilt *Himantopus himantopus* and Little Ringed Plover *Charadrius dubius*.

At present, the peak numbers of shorebirds are about 500, but prior to 1997, there were over 2 000 Kentish Plover *Charadrius alexandrinus* and Dunlin *Calidris alpina* alone. The decline in shorebird numbers is thought to have been due to a decline in the area of mudflat adjacent to the Nature Park as a result of encroachment by mangroves. However, the WBST has recently created a high-tide roost site within the Nature Park, and a group of 60 Dunlin was recorded there in November 2003.

The Nature Park has an active wetland education programme attended by some 120 000 visitors annually. This programme includes many types of activities:

- Teachers organize special activities for school students on themes selected by the teachers themselves. These activities are mainly for primary school students;
- During weekends and holidays, a variety of activities are offered for the public and for family groups. Depending on the season, these activities may include courses on wetland ecology, such as studying the local birds, aquatic plants and frogs. Other educational activities which further increase wetland awareness include creating models of waterbirds and dragonflies from folded paper, and pressing flowers. Other topics may also be offered, such as watching the stars at night;

- Teachers also help to lead volunteers into the Nature Park to carry out various types of work that not only promote greater appreciation amongst the volunteers of how to maintain the ecological value of wetlands, but also help to improve the environment of the Nature Park; and
- Special annual events are organized, such as an annual International Bird Fair in November.

### Sungei Buloh Wetland Reserve, Singapore

This coastal wetland dominated by mangroves is located on the northern shore of Singapore. Historically, local fishermen had impounded the area for shrimp farming using inter-tidal ponds, but in 1989 an area of 87 ha was designated as a Nature Park, and this was opened to the public in 1993. In 2001, its status was upgraded to Nature Reserve and it was listed as a Shorebird Network Site. The size was expanded to 130 ha in 2003.

Some 35 species of shorebirds have been recorded at Sungei Buloh, with peak numbers of between 1 500 and 2 500 birds being recorded at any one time. These shorebirds feed mainly on the nearby mudflat but roost inside the reserve. There is an active shorebird banding programme, with some 500 shorebirds being banded each year and recoveries coming from as far afield as Russian Yakutia. A colour-flagging programme was initiated in 2003.

One of the problems that the reserve faces is from mangrove encroachment both over the mudflat and around the shorebird roosting sites within the reserve. Whilst mangrove seedlings are removed from the mudflat on an annual basis, a programme to control mangroves inside the reserve has yet to begin.

The Sungei Buloh Wetland Reserve has an active programme of wetland education for the 100 000 local and overseas visitors that it receives annually. With assistance from Hong Kong and Shanghai Banking Corporation (HSBC), a Sungei Buloh Education Fund was established in 1997 to support a series of nature outreach programmes at the reserve. These programmes range from self-guided walks to specialized thematic trails such as “Heron Watch” and “Prawn Watch”. For walk-in visitors, volunteer guides are available on Saturdays at specific times to explain the ecology of the reserve. For organized groups, a series of “Nature Hunts” has been developed to allow these visitors to explore and learn more about the reserve. In 1999, the reserve began a programme with local schools whereby a school can adopt a particular part of the reserve and be responsible for its maintenance.

### DISCUSSION

From the early 1980s, there has been a growing awareness in Asia of the importance of wetland conservation and the need to communicate this message to the public through the establishment of wetland education centres. These wetland centres now play a very important role in promoting wetland education and public awareness, and in many cases, their staff are also involved in the active management and conservation of the wetland of which they are a part.

With the growing economic affluence in many Asian countries, more and more education centres are being built, many of which are the first centres of their kind in the countries concerned. As a result, the message of wetland conservation will

continue to spread across the continent. This is now especially the case, as many of the wetland centres are beginning to network amongst themselves to share resources and experience so as to make their work more effective.

### ABSTRACT

Large-scale wader studies, revolving around ringing and wader counts, started in the early 1980s and have progressed to co-operative studies over much of Australia, New Zealand and the Asia-Pacific region. Despite extensive ringing and colour-flagging programmes and counting programmes over an increasing area of the East Asian-Australasian Flyway, research is hardly keeping pace with the loss of wader habitats and declines in many of the wader populations of this flyway. Plans to extend a network of researchers and volunteers across the three flyways of the Asia-Pacific region are underway with collaborative studies and the establishment of a multi-lingual wader studies newsletter.

### INTRODUCTION

This paper seeks to highlight some of the achievements towards our understanding of migratory waterbirds in the Asia-Pacific region, and some of the issues that need to be addressed in the future, if we are to effectively protect migratory and non-migratory waterbirds and their habitats. The views are from an Australian perspective and focus on waders, but essentially cover significant events in the move towards conservation of migratory waterbirds in the Asia-Pacific region.

The Asia-Pacific region is made up of three recognized wader flyways, the Central Asian-South Asian Flyway, the East Asian-Australasian Flyway and the Western (or Central) Pacific Flyway (Fig. 1). The best known is undoubtedly the East Asian-Australasian Flyway due to the extensive research carried out there in recent years. The East Asian-Australasian Flyway alone is home to at least five million migratory waders and an untold number of non-migratory waders. Migratory species fly along the three identified flyways crossing 57 countries and territories in the region. During their migration, these birds depend on strategically located staging areas where birds stop to rest and “refuel”, by building up fat deposits, before continuing their migration. Many of these birds pass through heavily populated regions that encompass more than 45% of the world human population who compete for resources and space with the waders.

Over the past twenty-five years, a number of wader studies have been carried out in the East Asian-Australasian Flyway. These studies have identified the range, migration routes, staging areas and breeding grounds of many species. A result of these studies has also clearly illustrated the worrying decline in available habitat, critical for the long-term survival of many species.

At a recent International Wader Study Group Conference in Cadiz, Spain, wader experts found that the majority of wader populations are in decline. However, the Asia-Pacific region is of special concern as it has the largest number of populations under

**Fig. 1.** The Central Asian-South Asian, East Asian-Australasian and Western Pacific Flyways (Wetlands International image).

threat or least understood. These concerns are not restricted to waders; other waterbirds such as cranes and Anatidae are also under threat or in decline. For migratory species to survive, they must have secure breeding, staging and non-breeding areas where there are sufficient food resources and minimal disturbance. At this stage, it is not known to what extent the loss of inter-tidal habitat in the Yellow Sea (the most important staging area for a large proportion of migratory waders in the East Asian-Australasian Flyway) has had an effect on migratory waders, an area of research obviously needing further investigation.

### RESEARCH

Research on migratory species in the Asia-Pacific region has slowly gained momentum over the past twenty-five years. Prior to this, large-scale research had been carried out only in New Zealand where shorebird researchers have been active since the 1960s.

Serious research on populations and migration in Australia was not initiated until 1981 after the formation of the Australasian Wader Study Group (AWSG), a Special Interest Group of the Royal Australasian Ornithologists' Union (Curry 1981). Prior to this, little was known about the wader populations over much of the Australian continent and even less about those of the rest of the Asia-Pacific flyways.

In 1981, the AWSG conducted its first national wader counts at known key non-breeding (overwintering) sites in an effort to understand changes in numbers of various migratory species, as well as providing information on wader movements (Martindale 1981). During these early surveys, 303 volunteers surveyed accessible sites over a single weekend, counting a total of about 400 000 waders. Some of the more remote areas of Australia, such as the Gulf of Carpentaria and the north-west coastline, were surveyed during the same season from the air using small, fixed-winged aircraft. These surveys revealed large concentrations of waders and highlighted the need to explore these areas in more detail.

The first major ground expedition to the north-west of Australia was carried out in 1981 with financial and logistic support from the Western Australia Government. This, and subsequent surveys, revealed internationally significant numbers of about 20 species of migratory waders, including most of the world's population of Great Knot *Calidris tenuirostris*. Even now, new discoveries are being made about wader populations in these sparsely populated areas of Australia. It was not until the 1990s that the Northern Territory coastline was investigated. Counts in this region were due to the efforts of a single individual who deviated from standard aerial fauna surveys to discover over two million waders of 40 species along this coastline. An example of an even more recent discovery is the occurrence of an estimated 2.9 million Oriental Pratincoles *Glareola maldivarum* along 80 Mile Beach in northern Western Australia in February 2004. Prior to this, the previous population estimate for this species in Australia was 60 000 (Sitters *et al.* 2004).

Despite the amount of work carried out so far in Australia, there is no long-standing tradition of focussed wader research in Australian universities or other research institutes, as there is, for example, in Europe. Most wader research in Australia has been carried out by volunteers. A great deal has been learned through their efforts, but volunteers working in their own time are not well placed to carry out ecological studies that require long periods of continuous fieldwork, prolonged analysis, or expensive field equipment. Such studies, for example of foraging ecology or precise roosting requirements, are often needed for science-based management of wader sites. The need for professional studies in Australia, and the Asia-Pacific region as a whole, is likely to increase as human development encroaches further into wader sites.

### Bird ringing as a research tool

Although wader ringing has been carried out in New Zealand, and to some extent in Australia, since the 1960s, large-scale ringing did not start until the late 1970s with the introduction of cannon-netting by ringers from the UK. Since then, over 320 000 migratory waders have been ringed in Australia by various wader study groups, though mainly in the north-west and south-east of the country. Ringing recoveries have played a major role in plotting migration routes and identifying major staging areas throughout the East Asian-Australasian Flyway. Recoveries come from retrapped birds, hunters, or rings returned by members of the public from birds found dead. By far the most numerous recoveries have been from hunters and, to some extent, ringing recoveries were a measure of the density of hunters and hunting activity, rather than large concentrations of birds as may have previously been thought. Nevertheless, ringing provided useful information locating important wader sites and these have been

**Fig. 2.** Great Knot *Calidris tenuirostris* with alpha-numeric colour flag visible in the field. Photo: Adrian Boyle.

supported by ground surveys. The situation was vastly improved with the introduction of colour-flagging in Australia in 1990 (Minton 2005). Colour flags are basically coloured plastic (darvic) rings that are shaped so that a tab extends from the ring providing a much larger viewable surface area than conventional colour rings. The results of introducing flagging have been impressive. Many bird-watchers, armed with binoculars or a spotting scope, are now able to see the various combinations of colour flags which identify the locality where the birds were marked. The reporting rate from flags has far outstripped the recovery rate from conventional ringing (Minton 2005). Flag sightings are now regularly reported from Arctic Russia and Alaska, either of birds observed at the nest or, in the case of Bar-tailed Godwits *Limosa lapponica* in Alaska, of birds congregating before departing on their southward migration.

There are now 20 different locations throughout the East Asian-Australasian Flyway where colour flagging is taking place. With new ringing sites being established in the flyway, new discoveries are made each season, such as a Dunlin *Calidris alpina* caught while overwintering in the Yangtze River estuary, China, and then observed nesting on Barrow Island, Alaska. This is the first known connection of this species between China and the USA. Some individuals of species such as the Great Knot have been observed in successive years on their nesting grounds in Siberia and at their non-breeding grounds in north-western Australia. Even when only small numbers of birds are colour-flagged at their breeding grounds, as in the case of the endangered Spoon-billed Sandpiper *Eurynorhynchus pygmeus*, very useful “recoveries” have been made along their migration routes and in the non-breeding grounds, providing invaluable information for their long-term conservation.

It has been possible, for some time, to identify individual birds in the field by placing a combination of colour bands on their legs. However, this relies on accurate observations to determine the position of a number of bands, and wrongly reported combinations can be a problem, especially as some colours tend to fade over time. In 2004, a trial using alpha-numeric engraved colour flags was undertaken in Australia with a high degree of success. This system is now used increasingly throughout the East Asian-Australasian Flyway with very rewarding results, especially with the advent of digital cameras and “digiscoping” enabling photographs to be taken of flagged birds through a telescope (see Fig. 2).

Recent moves to train people in ringing and survey techniques have resulted on some large-scale ringing and flagging in mainland China with some spectacular results. Birds ringed in Asia that migrate to Australia and New Zealand have a high probability of being observed by bird-watchers and interested members of the public; they are also observed in other regions with high numbers of bird-watchers, such as Japan and parts of China (Taiwan and Hong Kong), Russia (study sites on the breeding grounds) and Alaska.

Bird ringing and colour-flagging have provided a lot of information on movements of birds between breeding and non-breeding areas and on longevity, while the data collected at the time of capture (morphometrics, weights, etc.) have provided invaluable information on the timing of moult and weight gains, which in turn provide an indication of distance travelled between one site and another. In an attempt to understand recruitment and mortality rates, recent emphasis has been on the determination of the proportion of first-year birds (identified by plumage differences) at a range of sites in south-eastern Australia, particularly Victoria and South Australia. These are correlated with observations made of breeding conditions in the Arctic (Minton *et al.* 2005).

### Radio and satellite tracking

Radio and satellite tracking have been carried out by a number of researchers in Australia to determine the movements of shorebirds locally or globally. The advantage of radio tracking is the small nature of the transmitters involved enabling them to be used on the smallest waders without causing significant inconvenience to the birds. The downside of radio transmitters is the short range of operation. Despite this, useful information has been gained using this equipment tracking birds between foraging habitats and roost sites, especially at night when visual observations are virtually impossible. Such studies have played important roles in providing information for wildlife and land managers, including local and state government agencies. Examples include Rohweder (2000) and Todd (2000) whose studies located previously unknown nocturnal roost sites and foraging habitat.

Satellite tracking holds no geographic bounds and is providing invaluable data about the precise migration routes taken by migrating shorebirds and the time spent at staging areas and time taken to fly between sites. The first successful attempt to track migratory shorebirds in this flyway was worked carried out by the Queensland Wader Study Group, in association with the Wild Bird Society of Japan, between 1997 and 1999 when Far Eastern Curlews *Numenius madagascariensis* were fitted with transmitters using custom-made harnesses to attach the transmitter. Although the project tracked a number of birds between their non-breeding grounds in Australia and breeding grounds in Russia and northern China, the majority of birds abandoned their migration and returned to the sites at which they were trapped. It would appear that the weight and/or wind drag of the transmitters were too great. More recently, work carried out in Alaska on Bar-tailed Godwits that migrate between Alaska and eastern Australia and New Zealand has demonstrated that this species is able to carry satellite transmitters during this apparent 11 000 km non-stop flight (Gill 2006). In this study, new technology was available, enabling relatively small transmitters to be surgically implanted in the abdominal cavity of the bird. Although the transmitters failed to function, the birds, marked with individually

numbered leg flags, were observed after their arrival in Australia and New Zealand. Without doubt it is only a matter of time before such flights will be tracked accurately, providing much needed data for shorebird management in the Asia-Pacific region.

### Population monitoring

An ongoing population monitoring programme (PMP) of Australian waders has been carried out since a pilot study in 1981. The purpose of the programme is to monitor year to year changes in populations of migratory and non-migratory waders at selected sites across the continent. Counts are made twice each year: in February, when migratory species have finished any southward movement, enabling counts to be carried out at many sites without fear of double counting; and again in late June to early July, when all migratory species that breed in the Northern Hemisphere are on their breeding grounds, leaving only non-breeding (largely immature birds) behind. Twenty-three key sites were among those counted in 1981, and additional important sites have been added since as a result of increased knowledge of site use by key species. Regular monitoring has shown alarming declines in some wader populations, such as the Curlew Sandpiper *Calidris ferruginea*. More subtle or slow changes in Australian wader populations cannot be detected easily with the existing array of count sites, and it has been stressed that the PMP needs to be expanded (Wilson 2001). In 2004, the AWSG, in conjunction with the Australian Government (Department of Environment and Heritage), commenced a programme in Australia aimed at monitoring waders that utilize the Yellow Sea as a stopover en route to/from Australia, to determine any short-term trends in the populations of species likely to be impacted by the significant inter-tidal land claim in this region, particularly at Saemangeum in South Korea. This programme also has an objective of testing methodological approaches that could improve the sensitivity of population monitoring on the non-breeding grounds.

Fluctuations in population sizes detected in Australia are thought to be as a result of the influence of some impact along the flyway rather than in Australia. There do not seem to be major impacts in the way of habitat loss or disturbance of waders, other than at some local sites, in Australia, or obvious changes in the Arctic breeding grounds. Concerns about the impacts of habitat loss on migratory species have led to a programme of surveys in East Asia, especially the Yellow Sea area (Barter 2002). Surveys conducted since 1996 in China and Korea show that the extensive inter-tidal areas and near-coastal wetlands of the Yellow Sea support very large numbers of migratory waders during both northward and southward migrations.

In the Asia-Pacific region, the Asian Waterbird Census (AWC) was initiated in 1987 as an integral part of the International Waterbird Census co-ordinated by Wetlands International. The AWC provides the most comprehensive waterbird count programme in the region. The census is undertaken in January each year, and is carried out primarily by a volunteer-based network to monitor the populations and distribution of waterbirds and the status of wetland habitats, while at the same time enhancing public awareness about waterbird and wetland conservation. Since the establishment of the AWC, more than 5 700 sites across 25 countries have been counted at least once by thousands of volunteers. This project is linked to the shorebird monitoring programme in Australia, Anatidae and shorebird censuses in Japan and waterbird counts in Hong Kong.

## LOOKING TO THE FUTURE

We are very fortunate in having several long-term counting programmes in Australia, New Zealand and parts of Asia (through the AWC), as well as long-term ringing programmes in northern Western Australia, south-eastern Australia, New Zealand and Japan. We also have long-term productivity data from measurements of the percentage of juvenile birds in catches each year. Studies in New Zealand have provided some of the essential foundations for conservation actions as a result of long-term research programmes, providing knowledge of populations and changes to populations over time. Such studies should continue and be extended into other countries in the region.

As a result of the efforts put in by many people over the past 25 years, we are now able to identify some of the major issues that need to be addressed if we are to ensure the conservation of waterbird populations and their habitats in the Asia-Pacific region. A network of important sites for migratory waders has been identified and supported by the governments of many of the countries in the East Asian-Australasian Flyway through the efforts of Wetlands International, with support from the Australian, Dutch, Japanese and U.S. Governments.

Future counts of waterbird populations, including migratory waders, and wetland surveys will need to include a network of a large number of people on the ground, more than the membership/staff of any single group. This will take the collaborative efforts of international, national and local bird groups and conservationists, as well as the establishment of an effective communication network in a region with a high diversity of languages.

It has recently been proposed that an Asia-Pacific wader specialist group, or network, be formed, working in close association with other international groups, such as Wetlands International, WWF, BirdLife International and special interest groups (e.g. International Wader Study Group), regional groups, such as the AWSG, and national and local bird and conservation groups in all of the countries within the Asia-Pacific region.

A major challenge for this new group will be to establish a network of university researchers in the Asia-Pacific region. To some extent, this has started to happen through co-operative work co-ordinated by Wetlands International with major input from members of the AWSG and New Zealand Wader Study Group. Researchers from Fudan University and the East China Normal University in Shanghai, Beijing Normal University in Beijing, and Tunghai University in Taiwan, have been involved in collaborative ringing and flagging projects and wader surveys along the east coast of China and the Yellow Sea for the past ten years, as well as conducting research projects in shorebird ecology. While it is likely that research is being carried out at universities in other countries in the Asia-Pacific region, communication has been difficult. To a large extent, this is being addressed by the translation of a newsletter for the East Asian-Australasian Flyway (The Tattler) into Chinese and Indonesian and an increased circulation now covering countries in all of the flyways in the Asia-Pacific region.

International concerns publicized during recent wetland reclamation projects have helped to focus attention on the tragic loss of essential wetland habitats in Japan, China and Korea. However, it is essential to have rigorous scientific data to back up arguments for protection against future losses, rather than

solely depending on the emotional side of wildlife conservation. Hopefully the lessons learned from the losses in Japan and the impending loss of more than 40 sq. km of inter-tidal habitat at Saemangeum in South Korea will help to prevent similar disasters in the future. An international research project is planned, starting in 2006, to monitor the effects of the loss of wader feeding habitat at Saemangeum on waders in the Yellow Sea as well as in Australia and New Zealand.

Planning for the future would include improved monitoring of waders over a wide range of wetlands, increasing the networking of researchers and conservationists, and extending training programmes to provide expertise in bird identification, ecology and survey techniques as well as the effective management of wetlands.

### ABSTRACT

This paper outlines three priority-setting projects conducted by the BirdLife International Asia Partnership which are relevant to threatened waterbirds in the East Asia-Pacific Flyway, all of which are designed to collect the best available information on these birds, their habitats and key sites, and to use this to define the most appropriate actions for their conservation. Many projects are already underway to implement the recommendations resulting from these priority-setting analyses. The development of a network for the conservation of the endangered Black-faced Spoonbill *Platalea minor* is given as an example of an approach that could be used more widely in the region.

### INTRODUCTION

Asia is immensely rich in waterbirds, but these birds and their wetland habitats are under great pressure, linked to a combination of rapid economic development and increasing human population. As a consequence, many Asian waterbird species are globally threatened. This paper presents an overview of three projects of the BirdLife Asia Partnership<sup>1</sup>, conducted in collaboration with Wetlands International and other organizations, which are relevant to the conservation of threatened waterbirds in eastern and southern Asia.

### The Asia Red Data Book

BirdLife International (formerly ICBP) has been identifying and documenting globally threatened bird species since the 1960s. In addition to global checklists of threatened birds (e.g. Collar *et al.* 1994, BirdLife International 2000), regional bird Red Data Books have been published for Africa (Collar & Stuart 1985), the Americas (Collar *et al.* 1992) and, most recently, a large part of Asia (BirdLife International 2001). The publication of *Threatened birds of Asia: the BirdLife International Red Data Book* in 2001 was the culmination of a six-year project involving well over 1 000 compilers and data contributors. This book covers the whole of eastern and southern Asia from the Pacific west as far as the valley of the Yenisey in the north and Pakistan in the south (hereafter referred to as “the Asia region”). It documents in great detail the 323 globally threatened bird species that regularly occur in this region, in two volumes totalling over 3 000 pages of text and maps. The Red Data Book has been produced on CD-ROM, and the species accounts can be viewed and downloaded on the Internet (www.rdb.or.id). There is a facility on the web-site to add new data on threatened birds to the species accounts, which will make it possible to keep these accounts up to date. Thousands of copies of the book, CD-ROM and species accounts have been distributed and are being widely used within the Asia region.

### Saving Asia's threatened birds

Although the Asian Red Data Book is a valuable resource for many in the conservation community, it is not suitable for some target audiences, for example government officials with responsibility for land-use planning but without any specialist knowledge of birds. A follow-up to the Red Data Book was therefore produced, *Saving Asia's threatened birds: a guide for government and civil society* (BirdLife International 2003). This was designed as an advocacy document to present the main conclusions of the Red Data Book to decision-makers in a clear and highly visual format. It is based upon a synthesis of the detailed information from the Red Data Book, with a particular focus on recommendations for the conservation of birds and their key sites and habitats. In addition to its technical content, *Saving Asia's threatened birds* includes approximately 200 photographs of birds, habitats and conservation issues designed to illustrate that Asia's threatened birds and their habitats are a beautiful and spectacular part of Asia's heritage that must be saved. Over 1 000 copies of the book have been distributed to government and civil society in the Asia region.

### Important Bird Areas in Asia

BirdLife's Important Bird Area (IBA) Programme is a world-wide initiative aimed at identifying, documenting and working towards the conservation and sustainable management of a network of critical sites for the world's birds. These sites are selected through the application of standard, internationally recognized criteria, based upon the most up-to-date information available on bird distributions and populations. The IBA approach is particularly appropriate for waterbird conservation because many species have a tendency to congregate at particular wetland sites. This means that many of their conservation needs can be addressed by actions focussed on certain key sites. Two of the four standard global selection categories used to identify IBAs are relevant to waterbirds. One of these is used to select sites that support significant numbers of one or more globally threatened species, while the other is used to select sites because they support internationally important congregations of one or more waterbird species. The Asian IBA Programme was launched in 1996, and has so far resulted in the publication of *Important Bird Areas in Asia: key sites for conservation* (BirdLife International 2004) and directories of IBAs in Cambodia (Seng Kim Hout *et al.* 2003), India (Islam & Rahmani 2004), several regions of Indonesia (Rombang & Rudyanto 1999, Holmes & Rombang 2001, Holmes *et al.* 2001, Rombang *et al.* 2002), Laos (Ounekham & Inthapatha 2003), the Philippines (Mallari *et al.* 2001), Taiwan (Wild Bird Federation

<sup>1</sup> BirdLife International is a world-wide partnership of organizations working to conserve all bird species and their habitats. In Asia, BirdLife has Partner and Affiliate organizations or Country Programmes in 17 countries and territories, and works with research contacts in all of the other countries and territories in the region.

**Table 1.** Globally threatened waterbird species in eastern and southern Asia. The table includes the threatened categories allocated to waterbird species in Collar *et al.* (1994), BirdLife International (2001) and BirdLife International (2004). If the 1994 or 2001 columns are blank, the threatened category is the same as that given in the 2004 column.

Taiwan 2001), Thailand (Bird Conservation Society of Thailand 2004) and Vietnam (Tordoff 2002). Several other national directories are in preparation.

The Asian IBA Programme has five long-term objectives: (i) to provide a basis for the development of national conservation strategies and protected areas programmes; (ii) to highlight areas that should be safeguarded through wise land-use planning, national policies and regulations, and the grant-giving and lending programmes of international banks and development agencies; (iii) to provide a focus for the conservation efforts of civil society, including national and regional NGO networks; (iv) to highlight sites that are threatened or inadequately protected, so that urgent remedial measures can be taken; and (v) to guide the implementation of global conservation conventions and migratory bird agreements.

## RESULTS

BirdLife International (2001) documented a total of 323 globally threatened bird species that regularly occur in the Asia region. These include 54 waterbird species (of which six also range into Europe), a higher total than for any other region of the world (Table 1, Fig. 1). This high total reflects both the richness of Asia in waterbird species, and the great pressures on the region's wetlands and their birds.

Many of the threatened waterbird species in Australasia, Africa and the Americas are island endemics or continental species with restricted ranges. When these restricted-range species are excluded from the regional totals, a more dramatic picture is apparent (Fig. 2). Eastern and southern Asia have a much higher total of widespread threatened waterbirds than any other region of the world. These include northern migrants such as Swan Goose *Anser cygnoides*, Siberian Crane *Grus leucogeranus* and Spoon-billed Sandpiper *Eurynorhynchus pygmeus*, some of which disperse very widely outside the breeding season. They also include tropical waterbirds such as Spot-billed Pelican *Pelecanus philippensis*, Lesser Adjutant *Leptoptilos javanicus* and Indian Skimmer *Rynchops albicollis*, which were formerly found throughout much of south and south-east Asia. The protection of these widespread threatened waterbirds is a particularly difficult conservation challenge, because they are often shared between several countries and occur at many sites.

BirdLife International (2001) illustrated the major declines and localized extinctions suffered by many of Asia's threatened waterbirds. For example, the Indian Skimmer has virtually disappeared from south-east Asia, and the species is now largely restricted to the northern Indian subcontinent (Fig. 3).

Many of the 323 threatened species in the Asia region overlap in range and habitat requirements, and a single conservation action can often benefit several species. In BirdLife International (2003), these threatened species were subdivided into groups according to their distributions and the habitats that they occupy. This analysis identified nine major forest regions, three grassland regions and twenty wetlands regions. The twenty wetland regions (Fig. 4) together cover all significant breeding, passage and wintering habitats for threatened waterbirds in the Asia region. Fifteen of these wetland regions lie within the East Asia-Pacific Flyway. BirdLife International (2003) included a standard account for all of the forest, grassland and wetland regions. This documented the threatened species that occur in the region and the key habitats and IBAs for their conservation, with an analysis

Fig. 1. Numbers of globally threatened waterbirds by region of the world.

Key: VU = Vulnerable; EN = Endangered; CR = Critically Endangered. Columns represent Regions of the world: 1 = Asia and Europe; 2 = Australasia and the Pacific; 3 = Africa and the Middle East; 4 = The Americas.

The totals for "Asia and Europe" (column 1) include the Critically Endangered Slender-billed Curlew *Numenius tenuirostris*, which occurs in Europe and western Asia outside the region covered in BirdLife International (2001) and is therefore not listed in Table 1. The Sarus Crane *Grus antigone* and Red-legged Kittiwake *Rissa brevirostris* occur outside the Asia region, in Australasia and the Americas, respectively, but are included in the total for "Asia and Europe" (column 1) because substantial proportions of their ranges lie within Asia. Six species, Dalmatian Pelican *Pelecanus crispus*, Lesser White-fronted Goose *Anser erythropus*, Marbled Teal *Marmaronetta angustirostris*, White-headed Duck *Oxyura leucocephala*, Sociable Lapwing *Vanellus gregarius* and Slender-billed Curlew, have most of their ranges in Europe and Asia and are therefore included in the totals for "Asia and Europe" (column 1), but they also range into the Middle East and/or Africa. The Bristle-thighed Curlew *Numenius tahitiensis* occurs in the Asia region and was documented in BirdLife International (2001), but most of its range is in the Pacific and North America, and it is included in the totals for "Australasia and the Pacific" (column 2). Note that the Socotra Cormorant *Phalacrocorax nigrogularis* and Northern Bald Ibis *Geronticus eremita*, which are included in the totals for "Africa and the Middle East" (column 3), range into south-west Asia.

Fig. 2. Numbers of "widespread" globally threatened waterbirds by region of the world.

Key: VU = Vulnerable; EN = Endangered; CR = Critically Endangered. Regions of the world: 1 = Asia and Europe; 2 = Australasia and the Pacific; 3 = Africa and the Middle East; 4 = The Americas.

of the threats to birds and their habitats, and the conservation measures required to address these threats. The main conservation issues (and proposed conservation measures) in each region

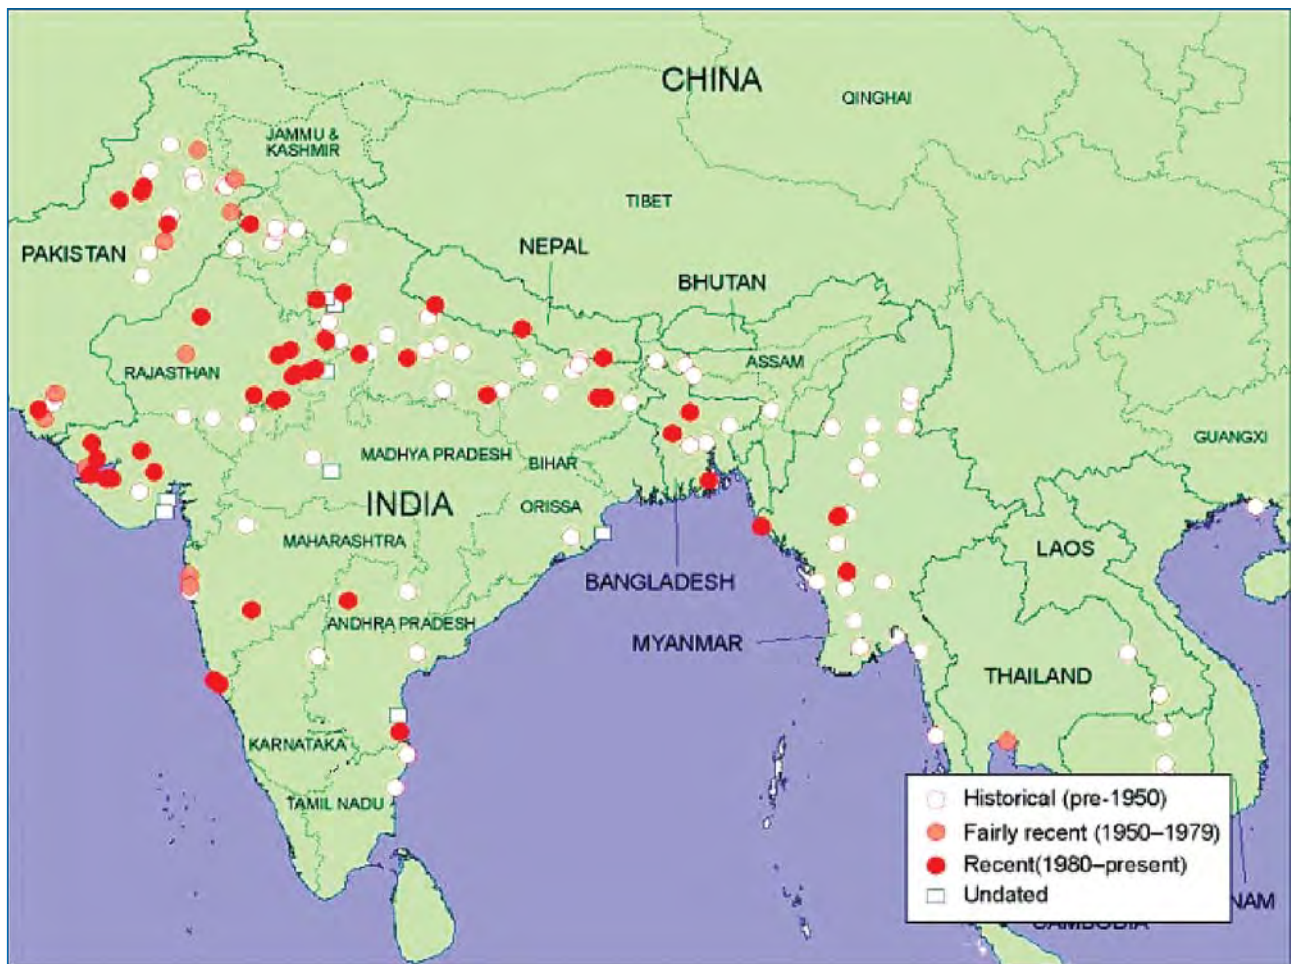

Fig. 3. The decline in the range of Indian Skimmer *Rynchops albicollis*.

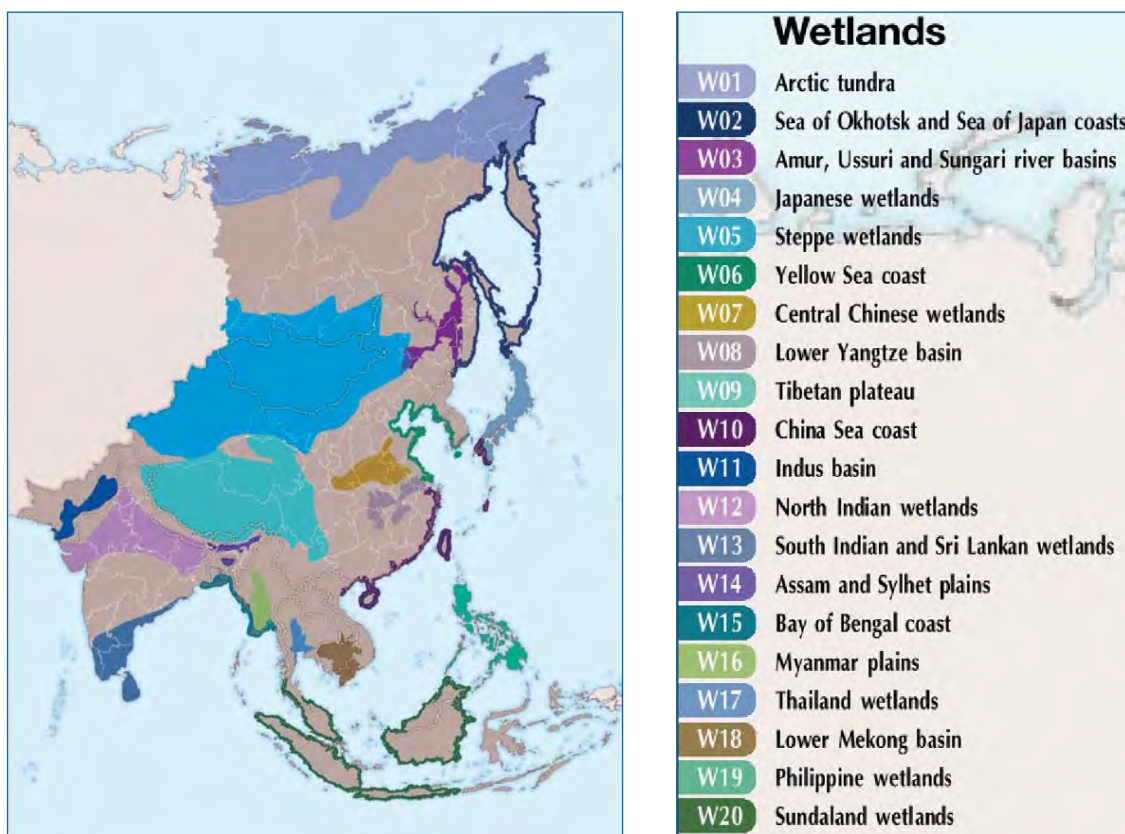

Fig. 4. Key wetland regions for threatened birds in the Asia region.

are grouped under four main headings: (i) habitat loss and degradation; (ii) protected areas coverage and management; (iii) exploitation of birds; and (iv) gaps in knowledge.

BirdLife International (2004) documented a total of 2 293 IBAs in the 28 countries and territories in the Asia region (Fig. 5). These sites cover a total area of 2 331 560 sq.km, equivalent to 7.6% of the region's land area. Eighty-two percent of the IBAs were identified because of their significance for globally threatened bird species, including the 54 threatened waterbird species that occur in the Asia region. Forty-one percent of the IBAs were identified because they hold globally significant congregations of waterbirds, seabirds and/or migratory raptors or cranes.

## DISCUSSION

The projects outlined above have compiled comprehensive, up-to-date information on threatened waterbirds in eastern and southern Asia. They have identified the wetland regions where these threatened waterbirds are concentrated and the Important Bird Areas that are critical for their long-term survival. A large number of measures have been proposed for the conservation of these waterbirds, and their habitats and key sites. These projects therefore provide a sound basis for waterbird and wetland conservation in eastern and southern Asia. However, there are still many gaps in knowledge of Asia's waterbirds, and our perceptions of the priority actions required for their conservation are likely to change in the light of new information and as new threats affect Asia's birds and their habitats.

The main threats to Asia's waterbirds include conversion of wetlands to agricultural land and for development, and unsustainable levels of exploitation. Conservation NGOs can carry out some of the measures recommended in BirdLife International (2001, 2003) to help address these threats; for example, through projects to improve the protection and management of key IBAs, by raising awareness of waterbirds and the threats that they face, and through surveys and monitoring. However, there are many actions that can only be taken by governments or the corporate sector. For example, the governments of China, North Korea and South Korea have plans to reclaim almost half of the remaining inter-tidal wetlands around the Yellow Sea, which would have a devastating impact on coastal ecosystems and east Asian endemic shorebirds such as Spotted Greenshank *Tringa guttifer*. The conservation community needs to persuade governments to review and revise potentially damaging plans of this type, and should seek to be involved in the processes to assess the environmental impact of new projects. Large numbers of copies of *Threatened Birds of Asia*, *Saving Asia's threatened birds* and *Important Bird Areas in Asia* have been distributed to government and civil society with the aim of raising awareness and motivation for the conservation of threatened birds throughout the Asia region.

The BirdLife Partnership is currently developing two mechanisms for the protection and management of IBAs, the "Site Support Group" (SSG) concept and IBA monitoring. SSG is a generic term used to describe groups of local stakeholders who share a common commitment to the conservation of an IBA. SSG activities vary according to local circumstances and priorities, but often include monitoring of biodiversity and threats, implementing education and awareness programmes, and developing eco-tourism or other income-generating activities with benefits for local livelihoods and biodiversity. At formally

protected IBAs, SSGs can complement the work of protected area management staff; where appropriate, this relationship can be formalized to allow the SSG to participate in protected area management. At IBAs that are not designated as formal protected areas, SSGs can support local authorities, local people and/or private land owners to conserve biodiversity, or even take responsibility for site management themselves. In addition to supporting site management, SSGs are frequently well positioned to campaign against immediate threats to biodiversity or to lobby for change in policies that undermine IBA conservation.

A prerequisite for effective conservation action for the IBA network is accurate, up-to-date information on the nature and severity of threats to biodiversity, the status of bird populations and habitats, and the type and effectiveness of conservation action at IBAs. To this end, a region-wide monitoring system needs to be established, comprising site-based monitoring at individual IBAs linked to national and regional mechanisms to manage data on the IBA network as a whole. Such a system could generate information to guide policy development at the national and regional levels, as well as supporting site safeguard policies, by providing early warnings about threats to biodiversity at sites. Furthermore, an IBA monitoring system could facilitate adaptive management of individual IBAs, by identifying priority conservation actions and evaluating their effectiveness. Given the scale of the IBA network and the finite resources available for its conservation, the monitoring system needs to be cost effective and engage as broad a spectrum of stakeholders as possible.

There is a much higher number of widespread threatened waterbird species in the Asia region than in any other region of the world, and many of these require conservation action in several of their range states. An international network established for the endangered Black-faced Spoonbill *Platalea minor* provides a good example of a mechanism to stimulate and co-ordinate conservation actions for a widespread threatened waterbird. The Black-faced Spoonbill is a rare waterbird which breeds on islets in the Yellow Sea off the coasts of Korea and China, and winters in several east Asian countries. Kennerley (1990) published a review that showed that the known population of the species at that time was only 288 individuals, leading to increased concern for its conservation. In 1995, an international workshop was held for the species in Taipei, and this led to the production of a Black-faced Spoonbill Action Plan (Severinghaus *et al.* 1995). Follow-up workshops, also involving experts from all range states, were held in Beijing in 1996 and Tokyo in 1997, and a regional network for the conservation of the species has been developed.

Many of the recommendations from the Black-faced Spoonbill Action Plan and from the workshops have been implemented, including the production of education leaflets and posters on the conservation of the species in the national languages of all range states, and co-operation on satellite tracking to study its migration. An international census of Black-faced Spoonbills has been carried out every January since 1997. This census has recorded increasing numbers of birds since it began in 1997, but it is unclear whether this is the result of a real increase in numbers or can be entirely accounted for by improved coverage of the species' wintering sites. The increased interest in the species has led to effective conservation action in many parts of its range, including improved protection of

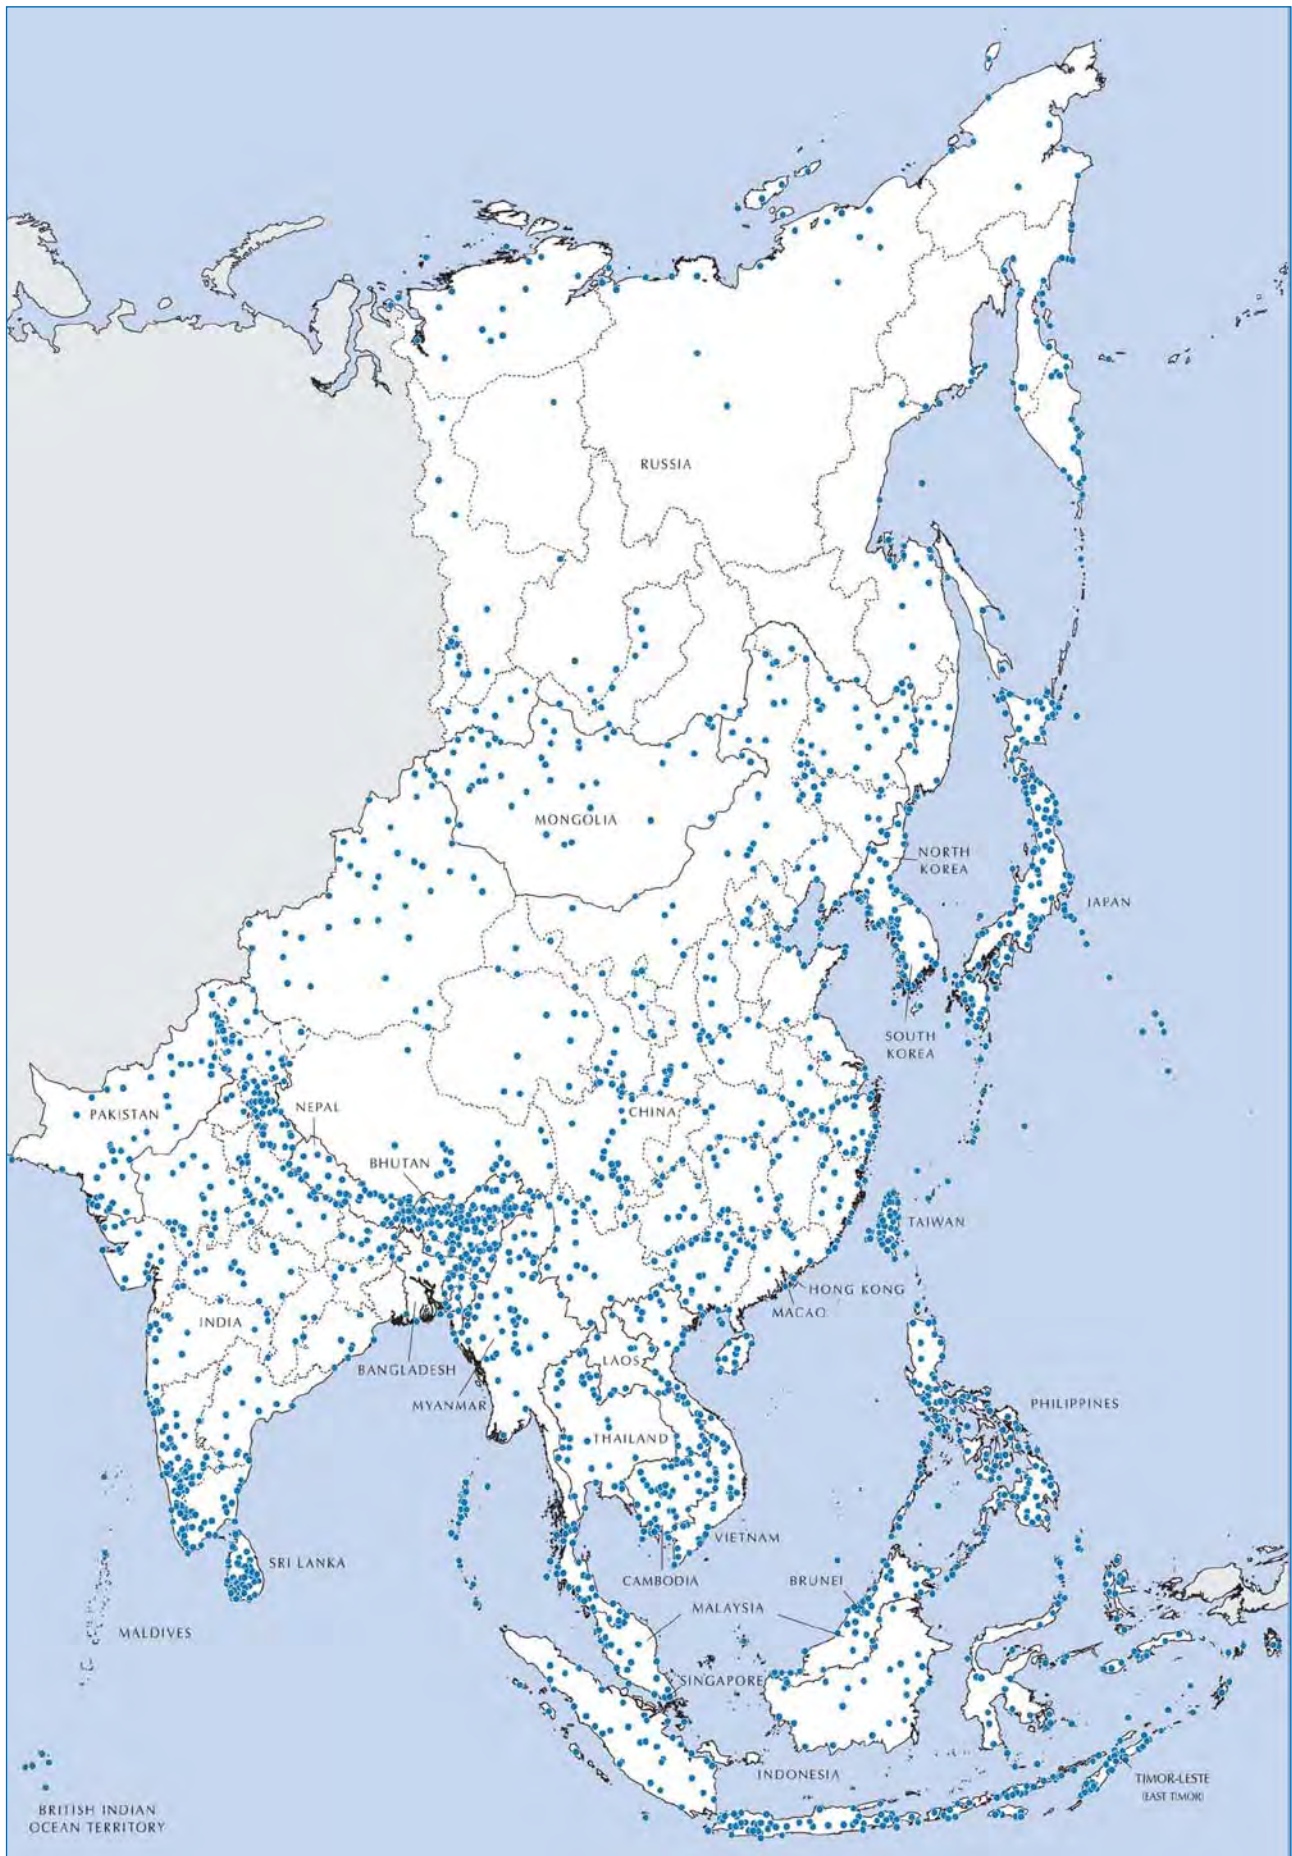

Fig. 5. The location of Important Bird Areas in the Asia region. Source: BirdLife International 2004.

wintering sites in several range states through the establishment of new protected areas and designation of new Ramsar sites. For example, the most important wintering site for Black-faced Spoonbills in the world is on the west coast of Taiwan. This site is under considerable pressure from development, but increased concern for the conservation of the spoonbill has resulted in the site being designated as a new protected area. Several spoonbills were shot in this area in the early 1990s, apparently by local people frustrated that the presence of this threatened species was preventing the reclamation of the mudflats for development, but a round-the-clock watch by local bird clubs prevented any further shooting.

Other networks are being developed for the benefit of threatened waterbirds in eastern and southern Asia under the co-ordination of Wetlands International. Three networks of sites of international importance have been established under the Asia-Pacific Migratory Waterbird Conservation Strategy: the Anatidae Site Network in the East Asian Flyway; the East Asian-Australasian Shorebird Site Network; and the North East Asian Crane Site Network. Numerous activities have been undertaken at network sites, including public awareness and education, surveys and training courses in wetland management, while international and national meetings have been held to share information and skills relevant to wetland management. The annual Asian Waterbird Census involves large numbers of people in counting waterbirds at thousands of wetlands in the region, and the project therefore plays an important role in monitoring waterbird numbers. However, there is potential for the Asian Waterbird Census to be broadened to monitor the sites themselves and the pressures that they face. There is also potential for participants in the three flyway networks and the Asian Waterbird Census to become involved in IBA Site Support Groups.

## ACKNOWLEDGEMENTS

We are grateful for the input of the many people who contributed to, and are acknowledged in, *Threatened Birds of Asia*, *Saving Asia's threatened birds* and *Important Bird Areas in Asia*. Taej Mundkur provided valuable guidance during the preparation of this paper, and the manuscript was improved by comments received from an anonymous reviewer.

### ABSTRACT

The Asian Waterbird Census (AWC) provides the most comprehensive monitoring programme for waterbirds in the Asia-Pacific region. It was initiated in 1987 as an integral part of the International Waterbird Census, and is co-ordinated by Wetlands International. Since the establishment of the AWC, more than 5 700 sites across 26 countries have been counted at least once, and this has involved the active participation of thousands of volunteers. This regional census has close links with a number of comprehensive national schemes that are undertaken in January and at other times of the year. These include the long-running shorebird monitoring programme in Australia, the censuses of Anatidae and shorebirds in Japan, and waterbird counts in Hong Kong. The AWC also has close links with the international monitoring programme for the Black-faced Spoonbill *Platalea minor*. Countries within the Asia-Pacific region have occasionally organized censuses of waterbirds at site level, and the Arctic breeding grounds of many migratory waterbirds are being monitored through an extensive annual International Breeding Conditions Survey. This paper provides an overview of the ongoing monitoring schemes; it identifies present weaknesses, and recommends various measures that should be taken to improve the monitoring of waterbirds throughout the region.

### INTRODUCTION

Migratory waterbirds are one of the most remarkable components of global biodiversity. Their long migrations and tendency to concentrate in large numbers on particular wetlands make them both visible and charismatic. They are important indicators of the ecological condition and productivity of wetland

ecosystems, and their presence is widely valued by numerous stakeholders including local human populations, tourists, associated enterprises and research biologists throughout the world. They also offer many opportunities for using wetlands on a sustainable basis, particularly through eco-tourism.

Many species of waterbirds are relatively easy to count because at certain times of the year they occur in conspicuous concentrations. No other group of birds has been so comprehensively and frequently surveyed. There is a strong tradition in Europe and North America, and a growing tradition in other parts of the world, of using long-term waterbird census data as a basis for estimating the sizes and trends of waterbird populations.

This paper provides a brief overview of waterbird monitoring programmes in the Asia-Pacific region. It identifies gaps in coverage of the existing programmes, and recommends a number of ways in which these programmes could be improved to achieve more effective monitoring of migratory waterbirds throughout the Asia-Pacific flyways.

### ASIAN WATERBIRD CENSUS

#### Introduction

The Asian Waterbird Census (AWC) was initiated in 1987 and runs in parallel with other waterbird censuses carried out in Africa, Europe, central and western Asia, and Latin America under the umbrella of the International Waterbird Census (IWC), which is co-ordinated by Wetlands International. The IWC is the largest and longest-running international monitoring programme of animals in the world (although some national programmes are older).

The IWC (and thus the AWC) aims to contribute to the conservation of waterbirds and their habitats by:

- providing the basis for estimates of waterbird populations;
- monitoring changes in waterbird numbers and distribution by regular, standardized counts at representative wetlands;
- improving knowledge of little-known waterbird species and wetland sites;
- identifying and monitoring networks of sites that are important for waterbirds and, in particular, identifying and monitoring sites that qualify as Wetlands of International Importance under the Ramsar Convention on Wetlands;
- providing information on the conservation status of waterbird species for use by international agreements; and
- increasing awareness of the importance of waterbirds and their wetland habitats at local, national and international levels.

The AWC also aims to build and strengthen national networks of enthusiastic volunteers and facilitate their training. It takes place once a year, during the second and third weeks of January. The census was initiated in 1987 on the Indian subcontinent, and has grown rapidly to cover most countries in southern and eastern Asia,

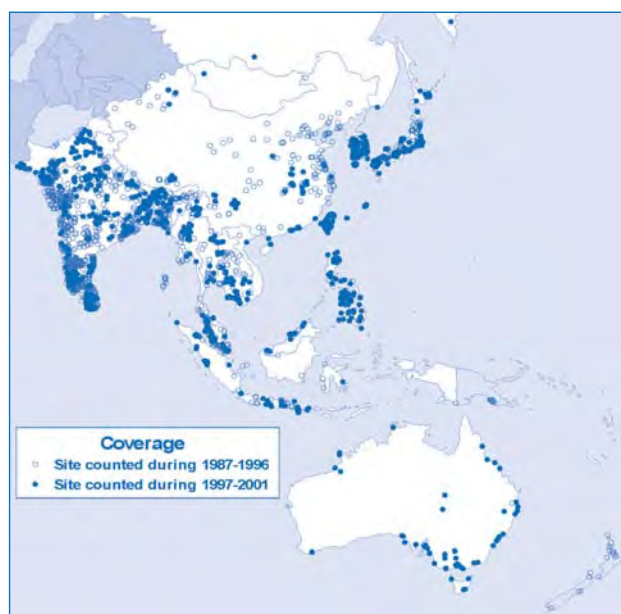

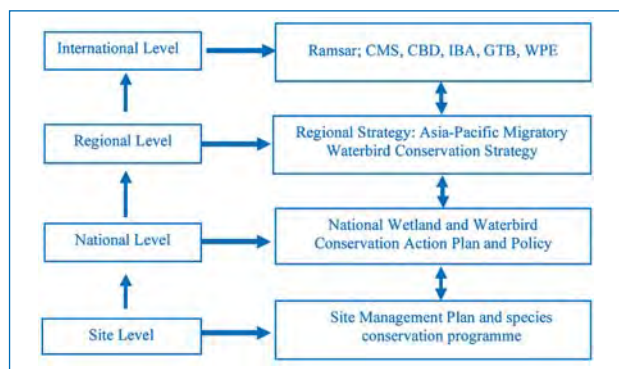

Fig. 1. Regional coverage of the Asian Waterbird Census (AWC).

**Fig. 2.** The contribution of the Asian Waterbird Census to national and international conservation frameworks.

**Key:** Ramsar – Convention on Wetlands; CMS – Convention on Migratory Species; CBD – Convention on Biological Diversity; IBA – BirdLife International’s *Important Bird Areas* programme; GTB – IUCN/BirdLife International’s *Globally Threatened Birds Update* programme; WPE – Wetlands International’s *Waterbird Population Estimates* programme.

as well as Australasia (Fig. 1). A total of 5 700 sites in 26 countries have been counted at least once since 1987. The data collected by the AWC have been used in various reports and contribute to a range of conservation activities from local to global level (Fig. 2).

### Results of AWC: 1997-2001

The results of the AWC from 1997 to 2001 have been summarized by Li & Mundkur (2004) as follows:

- A total of 1 392 sites in 22 countries were covered at least once, including a total of 61 internationally important wetlands listed under the Ramsar Convention, 32 Migratory Waterbird Network Sites in the East Asian–Australasian Flyway, and 43 Important Bird Areas (IBAs) in Cambodia, Lao PDR, the Philippines, Taiwan and Vietnam (as at 31 December 2003). The highest count was in 2001, when 4 571 522 birds were recorded at a total of 770 sites;
- Eighty-two sites in 10 countries (about 6% of the total number of sites counted) were reported to support more than 20 000 birds;
- In total, 291 species of waterbirds and 15 species of wetland-dependent raptors (birds of prey) were recorded. Thirty-seven of these species are listed as globally threatened by BirdLife International (2004). They include three Critically Endangered, 12 Endangered and 23 Vulnerable species. Thirty-one of the globally threatened species are restricted to the region covered by the AWC. In addition, 16 Near Threatened species were recorded; and
- One hundred and forty-five species recorded during the census are listed in the Appendices to the Convention on Migratory Species; 26 species are listed by the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES).

Li & Mundkur (2004) found, however, that it was still difficult to determine population sizes and trends for most species of waterbirds in the Asia-Pacific region on the basis of data available from the AWC, because of inconsistent coverage of sites in some countries.

### Future development of the AWC: a strategy for 2004-2006

In order to improve the AWC to meet the needs of waterbird and wetland conservation, a strategy has been developed to guide the development of the AWC during the period 2004-2006 (Wetlands International 2003). The objectives of the strategy include the following:

- enhance geographic and site coverage of the AWC;
- improve the quality of AWC data to achieve the aim of monitoring of waterbird populations;
- enhance communication amongst AWC co-ordinators and the networks of counters;
- develop training, communication and public awareness programmes for the AWC;
- develop a fundraising strategy for the AWC, and to seek funding opportunities to support its development;
- support improved decision making and policy development on waterbird and wetland conservation at international and national levels through enhanced use of AWC data; and
- develop a co-ordination mechanism for the AWC.

### INTERNATIONAL BLACK-FACED SPOONBILL CENSUS

In 1993, Tom Dahmer initiated an international census of the Black-faced Spoonbill *Platalea minor*, a globally threatened species confined to eastern Asia and listed as Endangered by BirdLife International (2004). This is the only single-species monitoring programme for a waterbird in the Asia-Pacific region. The Hong Kong Bird Watching Society has taken over responsibility for the International Black-faced Spoonbill Census since 2003. The results of the census show an apparent increase in numbers from only 294 birds during a preliminary survey in January 1989 to at least 1 206 birds in January 2004 (Yu 2004; see Fig. 3).

**Fig. 3.** Total counts of wintering Black-faced Spoonbills *Platalea minor*: 1989-2004.

### INTERNATIONAL ARCTIC BIRDS BREEDING CONDITIONS SURVEY (ABBCS)

The International Arctic Birds Breeding Conditions Survey (ABBCS) is a joint project of the International Wader Study Group and the Goose and Swan Specialist Groups of Wetlands International. The project aims at collating information on

environmental conditions on the breeding grounds of birds nesting in the Arctic. Data on bird numbers and breeding performance during the Arctic summer are analyzed in relation to climatic factors and predation levels. Information is available online on waterbird breeding success, rodent abundance and certain weather characteristics in the Arctic for the summers of 1992 to 2003 inclusive. Information is available for 83 sites in the summer of 2002 (Soloviev & Tomkovich 2003).

## NATIONAL AND SUB-NATIONAL MONITORING PROGRAMMES

### Shorebird monitoring programme in Australia

In 1981, the Australasian Wader Studies Group began regular counts of shorebirds (waders) at a selection of 23 sites in February and June (Gosbell 2003). The results of the counts have been used in estimating population trends in shorebirds. Cannon-netting is providing data from re-traps and information on the proportion of juveniles in the populations to supplement the counting programme. Additional information is being obtained from the re-sighting of birds marked with flags.

### Waterbird counts in Hong Kong

Regular waterbird censuses in Hong Kong include monthly waterbird counts, heron and egret counts, and shorebird counts. The synchronized monthly waterbird counts are undertaken throughout the year by voluntary waterbird counters at assigned sites; the January count coincides with the AWC. Counts of herons and egrets are carried out every year at the breeding colonies, where the numbers of nests are also counted. Shorebird counts are carried out throughout the year by professional counters, the main aim of this programme being to monitor the usage of the Mai Po Ramsar site by shorebirds.

### Anatidae and shorebird censuses in Japan

An Anatidae monitoring programme was initiated in Japan in 1971. A nation-wide census is undertaken in mid-January every year, and covers all species of Anatidae. The counts are co-ordinated by Prefecture governments, and the annual national reports are compiled by the Ministry of Environment. Since 1989, the data have been digitized and stored in the Japan Integrated Biodiversity Information System (J-IBIS).

The shorebird monitoring programme started in 2000. Three surveys are conducted each year: during the northward migration, during the southward migration, and in winter. The censuses are undertaken by WWF-Japan with financial support from the Ministry of Environment. The results of the shorebird censuses have been published in a range of survey reports.

## OTHER WATERBIRD SURVEYS

Other waterbird surveys in the Asia-Pacific region have included the following:

- surveys undertaken by governments at national and local level;
- surveys conducted at regional, national and local level as part of various on-going wetland and waterbird projects;
- surveys conducted by specialist groups in the implementation of the three Actions Plans for the conservation of Anatidae, cranes and shorebirds, respectively, in the East Asian-Australasian Flyway; and

- surveys conducted by groups or individuals with an interest in a particular species or group of species.

## DISCUSSION

The monitoring of waterbirds in the Asia-Pacific region continues to suffer from a number of deficiencies:

- the AWC is unable to fulfil its role in monitoring the population sizes and trends of waterbirds during the non-breeding season for several reasons. Site coverage is poor and inconsistent in some countries, and the data received from some counters are of poor quality. Important sites that are not popular for counters, or are difficult to access, are often omitted, while some of the commoner waterbird species, as well as some little-known species, are often not well monitored. Furthermore, there is often a lack of financial support for activities at national level;
- comprehensive national waterbird monitoring programmes are not being undertaken by developing countries due to funding constraints and limited capacity;
- the ABBCS programme covers only a limited part of the breeding grounds of migratory waterbirds, and information on the breeding populations of waterbirds breeding outside the Arctic is not being collected in a comprehensive and co-ordinated manner;
- there are no regular ongoing monitoring programmes at most of the important staging areas, and comprehensive information on these sites is lacking; and
- surveys at national and site level are conducted irregularly. The results of many surveys are not readily accessible as the data are often published only in the local language, or are not published at all and remain widely dispersed.

## RECOMMENDATIONS

The following measures should be taken to improve the effectiveness of monitoring programmes for waterbirds in the Asia-Pacific region:

- 1 promote the application of the Asian Waterbird Census as a flagship programme for monitoring waterbird populations and trends;
- 2 implement the AWC Strategy 2004-2006 to enhance coverage of the census, build local capacity and improve data quality;
- 3 extend the AWC to cover the island nations of the Pacific;
- 4 promote the Black-faced Spoonbill Census as one tool to enhance coverage of the AWC in countries throughout the range of this species;
- 5 complement the coverage of the ABBCS to monitor populations of migratory waterbirds in all breeding areas in the region;
- 6 encourage the establishment of comprehensive monitoring programmes for migratory waterbirds at important staging areas in the flyway;
- 7 identify sites of international and national importance (Important Bird Areas, Ramsar sites, network sites, national parks, etc.) that should be given high priority in monitoring programmes;
- 8 strengthen co-operation between institutions and organizations to promote greater sharing of information on water-

birds and wetlands, and establish appropriate co-ordination mechanisms to facilitate comprehensive monitoring of waterbirds throughout the region;

- 9 improve current monitoring programmes to assess the status of wetlands and waterbirds at different times of the year;
- 10 produce and regularly update flyway atlases for waterbird groups to promote awareness of the importance of sites for conservation;
- 11 increase the resources available for local, national and regional waterbird monitoring networks to improve the collection and collation of information and effective dissemination and use of outputs; and
- 12 ensure that land-use and management decisions are being based on the best information available.

## Shorebird abundance and diversity in Sungei Buloh Wetland Reserve, Singapore

James T.W.M. Gan & R.K. Ramakrishnan

National Parks Board, Sungei Buloh Wetland Reserve, 301 Neo Tiew Crescent, Singapore 71892.

(email: James\_Gan@NParks.gov.sg)

Gan, J.T.W.M. & Ramakrishnan, R.K. 2006. Shorebird abundance and diversity in Sungei Buloh Wetland Reserve, Singapore. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 343-344.

The Sungei Buloh Wetland Reserve of Singapore hosts appreciable numbers of migratory shorebirds during the northern winter. Shorebirds have been counted regularly at the wetland since 1990 providing information on the abundance, species composition and population trends. The information indicates those shorebird species and numbers that might be expected in similar wetland sites in the vicinity and on scores of, as yet, ornithologically unsurveyed islands south of Singapore.

Sungei Buloh Wetland Reserve (SBWR) is a gazetted nature reserve and wetland of 131 hectares comprising habitats such as mangrove forest, coastal mudflats and brackish water ponds (National Parks Board 2003). Counts have been done at various sites in Singapore since the 1980s, notably by the former organisation INTERWADER and the Asian Waterfowl Census. However, regular weekly long-term shorebird counting programmes have only been done in SBWR.

The census area was within SBWR and counts were made at least once a month using binoculars and telescopes during daylight hours, at both high and low tide, along a prescribed route, although counts prior to 1993 sought to capture a snapshot of the numbers of shorebirds in the area and did not necessarily adhere to this route. The maximum shorebird count for a session in each month is shown in Table 1. The daily peak counts highlight some clear patterns. The southward migration period, September to December, consistently tends to see larger numbers

of shorebirds (c. 2 000 birds), compared to the northward migration, February to May (c. 1 000 birds). Numbers typically start to build up from July reaching a peak in September with a second peak in November before declining in December. Numbers then start to increase again, with evidence of spring peaks with lesser peaks between February and April before declining very rapidly in May. Very small numbers of shorebirds remain in the wetland between May to July these being largely Common Redshank *Tringa totanus* and Whimbrel *Numenius phaeopus*.

In terms of species diversity and abundance, seven species of shorebirds dominate. Their maximum and minimum numbers recorded from 2001 to 2003 for each month are provided in Table 2. The most numerous species at the wetland is the Pacific Golden Plover *Pluvialis fulva* whose numbers tend to peak in November with a mean monthly maximum of 1 086. A limitation of the data in Table 2 is that a substantial influx of passage shorebirds may be missed since count sessions are from one to almost four weeks apart. Closer spaced counts would help refine and clarify the magnitude and timing of passage peaks. However, these data do give an overall picture of the seasonal abundance of shorebirds at SBWR.

## Using predictive modelling to investigate large-scale shorebird migration in the Russian Far East for Great Knot *Calidris tenuirostris*, Red Knot *Calidris canutus* and Bar-tailed Godwit *Limosa lapponica*

Kyle Kusch<sup>1</sup> & Falk Huettmann<sup>2</sup>

<sup>1</sup>University of Calgary, Geography Dept, Calgary T2N 1N4 Canada.

<sup>2</sup>University of Alaska-Fairbanks -EWHALE lab- Institute of Arctic Biology, Biology and Wildlife Department, Fairbanks, Alaska, 99775-7000 USA. (email: fffh@uaf.edu)

Kusch, K. & Huettmann, F. 2006. Using predictive modelling to investigate large-scale shorebird migration in the Russian Far East for Great Knot *Calidris tenuirostris*, Red Knot *Calidris canutus* and Bar-tailed Godwit *Limosa lapponica*. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 345.

Predictive modelling allows the presentation of relative probabilities of occurrence for species of interest. This approach is particularly useful for large areas which have only been poorly studied. The Sea of Okhotsk in the Russian Far East is such an area with a huge coastline along the East Asian-Australasian (EAA) Flyway. It comprises large mudflats, estuaries and wetlands; some of them never inventoried. Detailed shorebird survey data are missing or only locally known for this region. We used “presence only” and “confirmed absence” information from an extensive review of Russian literature (Huettmann 2003) as the basis for predicting the occurrence of shorebirds in this large region. In addition, the predictive model used six years of data from an international field research project that investigated shorebird migration in spring and autumn based on identified, representative mudflats and estuaries in eastern and southern Kamchatka, Magadan region, Sakhalin Island and southern Kurile Islands (Antonov & Huettmann 2004). These compiled sources in a GIS (ArcView) format represent the best available digital data set on shorebirds in the region. For data transparency reasons they are described with FGDC NBII meta-data in XML format, available for public review, quality review and further extension.

A progressive modelling approach was used (Manly *et al.*, 2002, Scott *et al.* 2002) using GIS, modified S-PLUS code (Huettmann and Linke 2003) and statistical linear and non-linear modelling algorithms (Huettmann & Diamond 2001, Yen *et al.* 2004) in order to predict where Great Knot *Calidris tenuirostris*, Red Knot *Calidris canutus* and Bar-tailed Godwit *Limosa lapponica* occur during autumn and spring migration on the shores of the Sea of Okhotsk. Significant model predictors such as tidal range, river type and size, substrate type and mudflat size were derived from Remote Sensing layers, software tools, hard-copy maps and others.

From the compiled locations with known shorebird occurrences, it appeared that the three species prefer tidal saltwater locations with organic matter and freshwater inflow. The model showed a difference between spring and autumn migration, suggesting different migration strategies.

The models indicated a good agreement with known shorebird migration “hotspots”. This is important for obtaining population estimates and quantifying turn-over rates. However, more field work is needed to further improve these quantitative prediction accuracies and to learn more about the migration strategies. This predictive shorebird GIS model is the first of its kind, and

can contribute greatly to conservation decisions and advanced field research. Together with other it can support development and implementation of conservation strategies for shorebird species along the EAA Flyway. Eventually, it could be used in a spatial Population Viability Analysis (PVA) framework and for environmental impact studies. These modelling applications should become further recognized and improved, and eventually be used to support international conservation management policy decisions such as through the Ramsar and Bonn Conventions.

Bellio, M.G., Bayliss, P., Morton, S. & Chatto R. 2006. Status and conservation of the Little Curlew *Numenius minutus* on its over-wintering grounds in Australia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 346-348.

### ABSTRACT

The Little Curlew *Numenius minutus*, the smallest member of the genus *Numenius*, is strongly migratory with a restricted breeding range in eastern Siberia and wintering grounds in Australia and elsewhere in the South Pacific region (Marchant & Higgins 1996, van Gils & Wiersma 1996). Since Gould's discovery of the Little Curlew in Australia in 1840 and the collection of the first specimens from their breeding area in northern Siberia, further studies, both on their breeding and wintering grounds, have added to our knowledge of this bird (Labutin *et al.* 1982, Marchant & Higgins 1996, Watkins 1993, van Gils & Wiersma 1996).

Nevertheless, the species has received little attention in terms of detailed studies of its distribution and biology and it is probably one of the least known waders that migrate from Siberia to Australia.

This paper reviews the literature on this species, in particular that available on its wintering-grounds in Australia, and highlights further research which could assist the species' conservation.

### WINTERING DISTRIBUTION IN AUSTRALIA

Movements of Little Curlew *Numenius minutus* in Australia are poorly understood and information is highly biased toward months when wetlands are most accessible. Little Curlews are nomadic and very mobile across Australia and while their occurrence can be predictable at certain sites, at other locations their distribution is highly unpredictable and variable between years. Some sites are used only for short periods, or not at all in some years. The triggers that drive movements are likely to be a combination of availability and accessibility to suitable roosting and feeding habitat (Collins & Jessop 2001). No quantitative studies have been attempted to investigate the cause/effect of these movements. Each year individuals stage in large numbers across the Top End of Northern Australia, including Darwin, from their arrival from their breeding grounds till the onset of the wet season (Crawford 1972, 1978; Garnett & Minton 1985; Mc Kean *et al.* 1986, Lane 1987, Bamford 1988, 1990, Jaensch 1994, Collins & Jessop 2001, Barter 2002, Bellio 2004). By the end of February, they disappear from the sub-coastal floodplains of northern Australia and disperse inland. The role of ephemeral wetlands, such as the systems of intermittent lakes (e.g. Lake Woods, Sylvester, Corella) of inland Australia need to be investigated in more detail, and the patterns of northward migration are still subject to debate.

Northern Australia wetlands, such as those of the Alligator Rivers Region, seem unsuitable during northward migration periods, with large areas still inundated. Nevertheless, there are occasional records (usually in small numbers) of Little Curlews

in April for Darwin and the Alligator Rivers Region (Morton *et al.* 1991, Niven McCrie & David Donato pers comm.). These observations coincide with El Niño years or with exceptional cyclone events in the Gulf of Carpentaria in Queensland. In the context of climate change scenarios, climatic events at a local (rainfall patterns) and large scale (cyclones, El Niño/La Niña events) need to be investigated. Investigating movements with radio-telemetry and using remote sensing techniques to map habitat availability at varying scales could be used to relate movements to habitats and climatic conditions.

### DIET AND HABITAT USAGE

In Australia, Little Curlews are closely associated with grasslands, including dry floodplains such as those of Kakadu National Park (Northern Territory) and the black-soil plains of the northern interior (Bamford 1988, 1990). They are one of the few migratory birds to utilise urban grassed areas, such as lawns, ovals and airstrips (Collins & Jessop 2001). Little Curlews are omnivorous, feeding on a wide range of plant and animal material, and seem to respond opportunistically to peaks of one type or other food resource. During a pilot study at Darwin airport, between October 2003 and January 2004, the stomach contents of six Little Curlews were analysed. Termites (*alatae*) represented 90% of stomach items, the remaining 10% comprised stones and plant parts (of genera *Scleria* and *Eleocharis*). The stomach content of one individual collected in Kakadu National Park comprised entirely seeds of wild rice (*Oryza* sp.) (Bellio 2004).

Few quantitative studies have been carried out on diet, foraging behaviour, and on physical structure of habitats (vegetation and water depth) and how this influences suitability. The ecological conditions posed by the highly variable environment of Australia and the relative suite of behavioural and physiological adaptations of the species remain largely unknown. Some of the questions that remain to be answered include:

- how they harvest their food resources?
- their foraging niche in relation to other species?
- conspecific relationships with respect to habitat, time of the year and kind of resources available?

Understanding mechanisms of habitat selection is central to addressing how vulnerable this long-distance migrant may be to rapidly changing conditions.

### POPULATION ESTIMATES AND BANDING STUDIES

The minimum population estimate for Little Curlew in the East-Asian-Australasian Flyway is 200 000 individuals (Barter 2002).

Several studies have been published on the distribution, abundance, and areas of significance on Australian wintering grounds (Garnett & Minton 1985, McKean *et al.* 1986, Lane 1987, Bamford 1988, 1990, Morton *et al.* 1991, Jaensch 1994). Banding studies have been carried out in the Northern Territory (Kakadu National Park), and Western Australia (Anna Plains) by the Australian Wader Study Group (AWSG), but only a few have been caught. Biometrics suggest the existence of possible distinct populations, but this hypothesis has not been tested (Bamford 1988, 1990, Barter 1992c). The AWSG has collected much data on Little Curlew moulting strategies, with results soon to be published. Nevertheless, more banding studies are required in order to estimate survival between years, and to provide information on population dynamics and trends. Further banding studies will also increase our knowledge on movements in Australia and elsewhere along the East-Asian-Australasian Flyway. Targeted surveys aimed at reassessing population estimates should also be planned, as the population estimates for their wintering ground are based on surveys more than 20 years old (Morton *et al.* 1991, Barter 2002).

### THREATS TO HABITAT

As for many other migratory shorebirds, the Little Curlew faces threats due to habitat loss and/or habitat modification. The extent of these threats are difficult to evaluate, due to a lack of long term monitoring data, but they are likely to include the species' breeding sites, stop-over sites along flyway, and wintering grounds. As an example, the Alligator Rivers Region in Northern Australia, and Kakadu National Park in particular, have been long recognised as important for Little Curlew during southward migration (Morton *et al.* 1991, Bamford 1988, 1990, Barter 2002). The wetlands of Alligator Rivers Region are considered pristine in comparison to those elsewhere in Australia.

Nevertheless, over the past two decades many pressures have been identified that are or will adversely affect the ecological condition of these wetlands (Storrs & Finlayson 1997, Finlayson *et al.* 1988), including: loss of extent and diversity of habitat due to weeds such as *Mimosa pigra* (Walden & Bayliss 2003, Walden *et al.* 2004), and introduced grasses such as Olive Hymenachne *Hymenachne amplexicaulis* and Para Grass *Brachiaria mutica* (Finlayson *et al.* 1997), consequences of rising sea levels including saltwater intrusion (Bayliss *et al.* 1997; Eliot *et al.* 1999; Waterman *et al.* 2000) and damage to micro and macro-scale habitat caused by feral animals such as pigs and buffalos (Skeat *et al.* 1996, East 1996). Without quantitative studies on species-habitat relationships, sound predictions on the consequences of these pressures on Little Curlew habitat are difficult.

### CHALLENGES FOR THE FUTURE

The Little Curlew differs from its relatives within the genus *Numenius* both in terms of morphological and behavioural characters and it seems to be a close relative of the almost extinct Eskimo Curlew *Numenius borealis* (Labutin *et al.* 1982). Habitat loss and hunting have been recognised as the major factors responsible for the disappearance of the Eskimo Curlew. In order to save its Asian-Australian counterpart, the following key data and information is needed:

- ecological studies;
- quantitative studies on species-habitat relationships;
- population dynamics and trends in population established by banding studies (proportional survival of juveniles and adults);
- cause/effect mechanisms of movements in relation to climatic events at local and broad scales;
- mapping of habitat suitability at landscape-scale using GIS and remote sensing;
- patterns of movements using radiotelemetry; and
- identification of areas of importance and significance, across its breeding grounds, along the flyway and on its wintering areas.

### ACKNOWLEDGMENTS

The information summarised here would not have been possible to collate without much valuable data and comments provided by Australian scientists, bird-watchers and public who have undertaken research and made field observations for many years and were happy to share their knowledge for the benefit of the species. As such we would like to thank and acknowledge the following people/organisations: Alan Anderson (CSIRO – Darwin), Birds Australia, Jared Archibald (NT Museum), Walter Boles (Australian Museum, Sydney), Pete Collins (AWSG), Ian Cowie (NT Herbarium), David Donato (NT Field Naturalist Group), Peter Dostine (DIPE, NT), Lunar Eclipse (Darwin Airport), Roger Jaensch (WI), Wayne Longmore (Museum Victoria), Niven McCrie (NT Field Naturalist Group), Clive Minton (AWSG), Robert Palmer (ANWC CSIRO), Danny Roger (AWSG), Pavel Tomkovich (Zoological Museum Moscow) and Doug Watkins (WI).

### 3.7 Sustainable use of natural resources in the African-Eurasian Flyway. Workshop Introduction

**Bert Lenten**

*Executive Secretary of AEWA, UN Campus, Hermann Ehlers-Str. 10, Bonn 53113, Germany. (email: blenten@unep.de)*

Lenten, B. 2006. Sustainable use of natural resources in the African-Eurasian Flyway. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 349.

The widespread Mallard *Anas platyrhynchos* is one of the commonest duck species in many countries and makes up a large proportion of the annual harvest of waterbirds across Eurasia. Photo: Paul Marshall.

Conservation of migratory waterbirds can only be achieved by connecting the protection of migratory waterbird populations and the conservation of their habitats to the sustainable use of their populations themselves and the natural resources they depend upon.

However, in African-(West) Eurasian Flyways, the generally good knowledge of waterbirds is not being effectively transferred into necessary national and local actions. Nor have conservation efforts led to maintaining or restoring the health of many waterbird populations, including globally threatened species (see Davidson & Stroud, this volume).

There are urgent needs to integrate waterbird conservation as part of sustainable development, to the greater benefit of local communities and other stakeholders dependent on wetlands as well as benefiting biodiversity. The African-Eurasian Waterbird Agreement (UNEP/AEWA) provides a good basis to achieve this.

Traditional knowledge in the use of these resources by local human communities is more and more in danger of being lost and should be safe-guarded: it should be taken into account when developing action and management plans. The impact of intensive and/or detrimental use of natural resources, be it

marine fisheries or hunting, has to be reduced and controlled in order not to interfere with traditional sustainable use. However, there are some highly-unsustainable practises that need to be stopped (such as the use of lead gunshot in wetlands).

The Agreement on the Conservation of African-Eurasian migratory waterbirds entered into force in 1999. Since then, 57 out of 119 potential Range States have ratified the Agreement to become Contracting Parties. The Preamble to the Agreement stresses that any taking of waterbirds must be undertaken sustainably, taking account of the conservation status of the specie concerned. A number of projects in the Agreement's International Implementation Priorities have addressed the sustainable use of natural resources. Accordingly, the Agreement provides a valuable framework within which to consider these issues.

A major African-Eurasian-Flyway GEF Project was approved in November 2003 and will start to be implemented in mid 2006. This project, which will be executed by Wetlands International in close cooperation with BirdLife International, will especially focusing on: capacity building, cooperative research and monitoring and communication activities.

## The Agreement on the Conservation of African-Eurasian Migratory Waterbirds

**Bert Lenten**

*Executive Secretary of AEWA, UN Campus, Hermann-Ehlers Str. 10, Bonn 53113, Germany. (email: blenten@unep.de)*

Lenten, B. 2006. The Agreement on the Conservation of African-Eurasian Migratory Waterbirds. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 350-353.

### ABSTRACT

The Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA) – an agreement developed under the aegis of the Convention on the Conservation of Migratory Species of Wild Animals – was concluded in The Netherlands in June 1995 and entered into force in November 1999. The geographical coverage of the Agreement extends from north-eastern Canada and Arctic Siberia to the southernmost tip of Africa, and includes 119 countries. The Agreement adopts a flyway approach, and provides for co-ordinated conservation action to be taken by the Range States throughout the migration systems of the 235 species of waterbirds to which it applies. By the end of 2006, 58 countries had joined the Agreement. This paper gives a brief history of the Agreement and reviews the progress that has been made in its implementation. Recent

activities relating to sustainable hunting, the African waterbird ringing scheme, climate change and avian influenza are discussed. The paper concludes by looking at some of the future challenges for the AEWA and emphasizing the need to strengthen co-operation with other multinational environmental agreements and organizations.

### INTRODUCTION

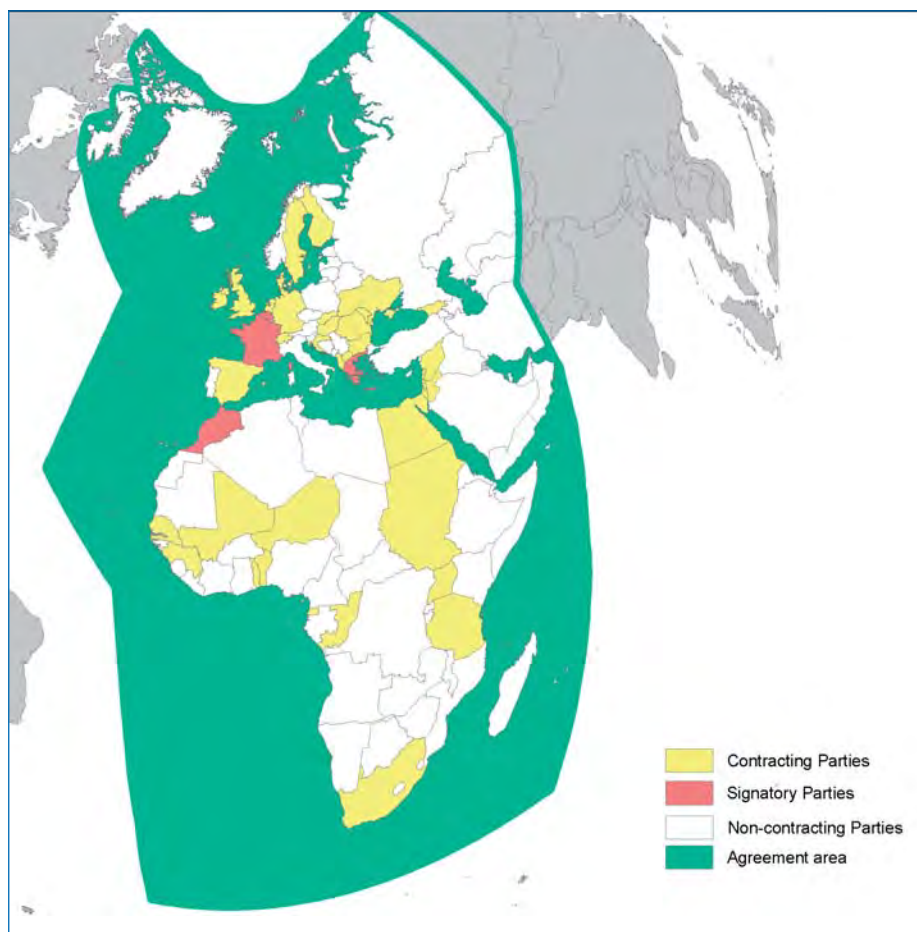

The Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA) is the largest of its kind hitherto developed under the Convention on the Conservation of Migratory Species of Wild Animals (CMS). It was concluded on 16 June 1995 in The Hague, The Netherlands, and entered into force on 1 November 1999 after the required number of at least fourteen Range States, comprising seven from Africa and seven

from Eurasia, had ratified. Since then, the Agreement has been an independent international treaty.

The AEWA covers 235 species of birds ecologically dependent on wetlands for at least part of their annual cycle, including many species of divers, grebes, pelicans, cormorants, herons, storks, rails, ibises, spoonbills, flamingos, ducks, swans,

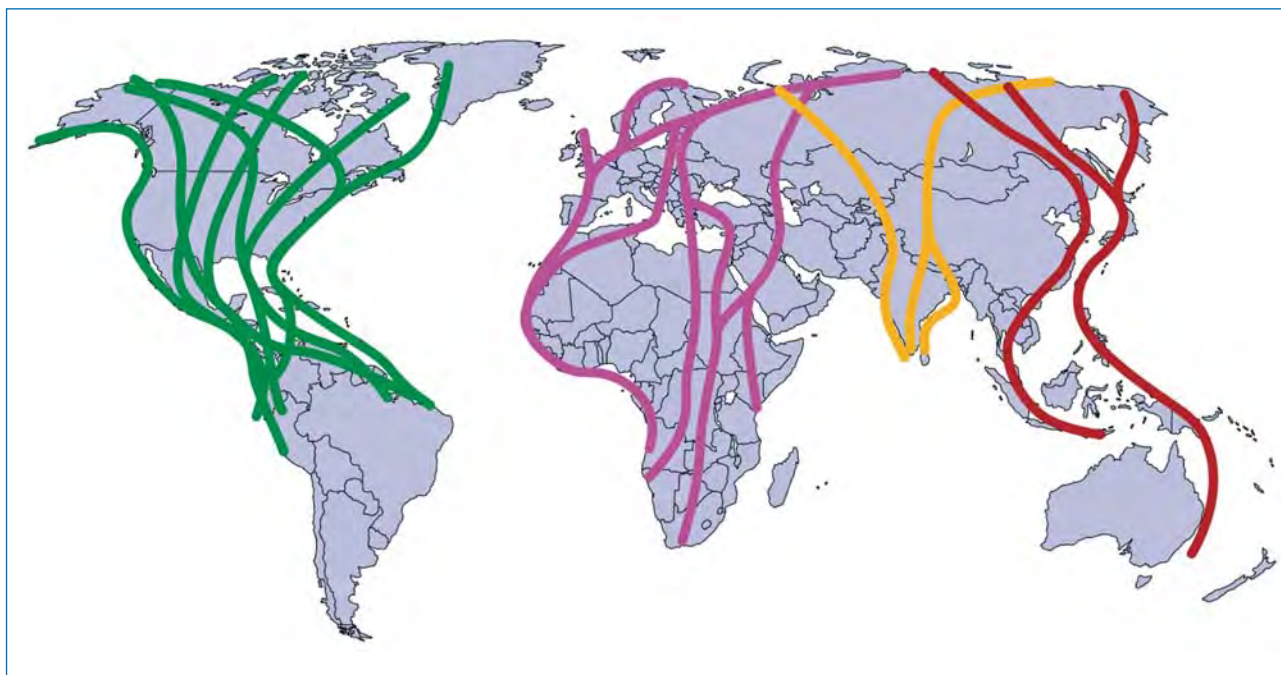

**Fig. 3.** Tenth anniversary celebration and opening ceremony of the AEWA exhibition "Impressions of travelling birds" by the Federal Minister for the Environment, Nature Conservation and Nuclear Safety, Mr. Jürgen Trittin, at the Museum Alexander Koenig in Bonn, Germany, on 4 July 2005. **Fig. 2.** Subsidiary bodies of the African-Eurasian Migratory Waterbird Agreement (AEWA).

geese, cranes, waders, gulls, terns and even the African Penguin *Spheniscus demersus*.

The Agreement covers 119 countries in Europe, parts of Asia and Canada, the Middle East and Africa. In fact, the geographical area of AEWA stretches from the northern reaches of Canada and the Russian Federation to the southernmost tip of Africa. The Agreement provides for co-ordinated and concerted action to be taken by the Range States throughout the migration system of the waterbirds to which it applies. Of the 119 Range States, 58 coun-

**Fig. 4.** The principal flyways of migratory waterbirds breeding in the Northern Hemisphere. (Note that many waterbirds migrate in directions other than those indicated here (Boere & Stroud, this volume, p. 40)).

tries have joined the AEWA, Guinea-Bissau being the latest Contracting Party as of 1 November 2006 (see Fig. 1 and Table 1).

Parties to the Agreement are called upon to engage in a wide range of conservation actions which are described in a comprehensive Action Plan (2006-2008). This detailed plan addresses such key issues as: species and habitat conservation, management of human activities, research and monitoring, education and information, and implementation.

After the conclusion of the Agreement on 16 June 1995, an Interim Secretariat was established. The first Meeting of the Parties (Cape Town, South Africa, November 1999) decided to establish a permanent Secretariat integrated in the United Nations Environment Programme (UNEP) and co-located with the Secretariat of the CMS in Bonn, Germany. This materialized in mid-2000.

To support and oversee the implementation of the Agreement, two subsidiary bodies have been established, namely the Technical Committee and, after the Second Meeting of the Parties (Bonn, Germany, September 2002), also a Standing Committee (Fig. 2). The latter took over all matters relating to policy, governance, administration and finance.

In 2005, AEWA celebrated its 10th Anniversary (Fig. 3). Although the Agreement is still relatively young, it has already proven to be quite successful. Thanks to support given by the European Union, Denmark, France, Germany, Switzerland, the Netherlands, Sweden and the United Kingdom, good progress has been made with the implementation of the Agreement. Much more could, of course, be done, but as always, lack of resources is the main bottleneck in this respect.

A welcome development will be the implementation of the African-Eurasian Flyways GEF (Global Environment Facility) project, which began in late 2006. This project has been designed by Wetlands International in close co-operation with BirdLife International and in consultation with the Ramsar Bureau and the AEWA Secretariat, and will be implemented by

Wetlands International and BirdLife International within the next five years. The main focus of the project will be on capacity building, co-operative research and monitoring, and communication activities.

#### FLYWAY APPROACH

In the mid-1980s, the Ministry of Agriculture, Nature Management and Fisheries (LNV) in The Netherlands decided to take the lead in drafting the Agreement on the Conservation of African-Eurasian Migratory Waterbirds. Being a Contracting Party to the CMS, The Netherlands felt that it was one of their obligations to support the CMS in developing such a regional agreement for migratory waterbirds. Waterbirds are of extreme interest for The Netherlands which, being located more or less in the middle of the East Atlantic Flyway, provide breeding grounds for several species of waders that overwinter in West Africa, as well as wintering areas for geese that breed in the high Arctic. Furthermore, LNV was convinced that conservation of migratory species is only possible through international co-operation and therefore strongly promoted the “flyway approach”.

As noted above, implementation of the AEWA is well underway. One of the success stories is that the “flyway approach” (Fig. 4) has been widely accepted not only by experts, but also by decision makers and policy makers. It is clear that for the conservation of migratory birds, international co-operation is needed. Without co-operation, all efforts made to conserve a species in country A could be in vain if, for example, unsustainable taking is accepted in country B. The flyway approach means that all the threats that a particular species encounters during its migrations between its breeding grounds and its wintering areas are identified and tackled, or at least mitigated, through international co-operation of the countries along the flyway. This concept is easy to understand even for non-experts, which is the reason why the AEWA Secretariat has been able to raise more awareness and to convince many countries to join the Agreement.

The AEWA is the first multilateral environmental agreement dealing with the conservation of migratory waterbirds. It is seen as a model that could be replicated within the CMS framework in other regions of the world.

### AEWA ACTIVITIES SINCE THE EDINBURGH CONFERENCE

Since the Waterbirds around the world conference, the AEWA has been active on a range of issues addressed in Edinburgh. The Third Meeting of the Parties took place in October 2005 in Dakar, Senegal, and adopted 20 Resolutions – thus paving the way for further development of the Agreement. The Parties strongly endorsed the concluding statement of the Waterbirds around the world conference, and committed themselves to the implementation of the Edinburgh Declaration (this volume).

#### Sustainable hunting

In order to raise awareness among hunters and the relevant authorities on the issue of lead poisoning, the AEWA Secretariat planned several workshops on this subject, one of which took place in Senegal in October 2004. This workshop was organized in close co-operation with ONCFS, Wetlands International, CIC, OMPO, FNC and the Government of Senegal, and adopted 11 recommendations dealing with topics such as improving waterbird surveys and the setting of quotas for the number of birds that may be harvested. Two more workshops are planned for 2006 and 2007. These will be jointly organized with BirdLife International and will take place in Lebanon and Tunisia.

#### African Waterbird Ringing Scheme

Ringing studies in Europe have contributed greatly to our current understanding of waterbird migration and ecology. In order to develop an African Ringing Scheme (AFRING) which, it is hoped, will provide long-term international co-ordination between the various ringing schemes in Africa, the AEWA Secretariat supported the first AFRING waterbird ringing course, which was held in September 2004 in East Africa (Kenya). The next course is planned for Ghana in 2006.

#### Waterbirds and climate change

The impacts of climate change on migratory waterbirds are an important and complex issue that the AEWA will have to deal with in future in order to develop policies that adapt waterbird conservation to changes in climate. A desk study was suggested at the Third Meeting of the Parties; this will summarize understanding of the current and future responses of migratory waterbirds to actual and predicted climate change, and practical means of adaptation.

#### Avian influenza

The Third Meeting of the Parties also responded to the recent spread of the Asian lineage of highly pathogenic avian influenza (HPAI) subtype H5N1, and emphasized the need for national surveillance and monitoring mechanisms, especially in African countries, as well as for international co-operation in order to identify and eliminate HPAI H5N1. The Parties stressed the key role of the AEWA as a member of the International Scientific Taskforce on Avian Influenza, which has been set up under the auspices of the CMS, in disseminating information and scientific assessments related to the developing situation.

### FUTURE OF THE AEWA

According to the United Nations, there are 191 sovereign states world-wide. Taking into account that 119 Range States are located in the AEWA region, it is clear that we have to deal with a very complex situation. Nowhere else on the globe do birds have to cross so many political borders. These borders make no sense for the birds, but could have an impact on their chances of survival. One of the challenges for the Secretariat is to convince more Range States to join the Agreement in the near future. The number of Contracting Parties is 58 (as of November 2006), and several more Range States are in the process of joining. However, this means that approximately 60 Range States still have to be convinced of the benefits of joining the Agreement.

Another issue is the question of whether the scope of the Agreement should be broadened in the sense of geographical and species coverage. Both options have been in discussion in the subsidiary bodies of the Agreement for several years, and will be a major issue for the next decade.

Last but not least, a challenge will be to increase the implementation of the Agreement. A great deal has already been achieved, but much more remains to be done. The recent Third Meeting of the Parties has shown that a major challenge for the AEWA is to strengthen co-operation with other multilateral environmental agreements and organizations. Current incidents such as the spread of highly pathogenic avian influenza H5N1 require prompt reaction. This implies close co-operation with other organizations, particularly non-governmental organizations which have the means and mechanisms to implement short-term projects. Moreover, the discussions on the impacts of climate change have made it clear that waterbird conservation needs to be dealt with as one aspect of nature conservation in general, rather than in isolation, and that adaptive policies have to be developed in close co-operation with other agreements and key partners. The AEWA is ready to contribute to the 2010 target as set by the World Summit on Sustainable Development (Johannesburg, South Africa, 2002) to reduce the current rate of loss of biodiversity by 2010. This can, of course, only be achieved by putting all our efforts together.

## Conservation problems of migratory waterfowl and shorebirds and their habitats in the Kaliningrad region of Russia

Dimitri Grishanov

Kaliningrad State University, Universitetskaya str., 2, Kaliningrad 236040, Russia. (email: grishanov@email.albertina.ru)

Grishanov, D. 2006. Conservation problems of migratory waterfowl and shorebirds and their habitats in the Kaliningrad region of Russia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 354.

The Kaliningrad region is an important area for migrating waterfowl, but is threatened by changes in agricultural practice and oil pollution. Current and potential threats to wildfowl and habitat in the area are described as well as their present status.

The Kaliningrad region of Russia is situated on the south-east coast of the Baltic Sea, and is part of the Belomoro-Baltiyskiy migratory flyway; it provides many sites for short- and long-term stop-over by large numbers of migratory waterfowl and shorebirds. Particularly numerous migrants are the White-fronted Goose *Anser albifrons*, Bean Goose *A. fabalis*, Greylag Goose *A. anser*, Mallard *Anas platyrhynchos*, Wigeon *A. penelope*, Pintail *A. acuta*, Tufted Duck *Aythya fuligula*, Long-tailed Duck *Clangula hyemalis*, Goosander *Mergus merganser*, Coot *Fulica atra*, Ringed Plover *Charadrius hiaticula*, Lapwing *Vanellus vanellus*, Ruff *Philomachus pugnax*, Dunlin *Calidris alpina*, Common Snipe *Gallinago gallinago* and many others. Some rare and threatened species (e.g. Bewick's Swan *Cygnus columbarius bewickii*, Lesser White-fronted Goose *Anser erythropus*, Ferruginous Duck *Aythya nyroca* and others) have also been recorded in the region.

The main migratory stop-over sites in the Kaliningrad region are the coastal waters of the Baltic Sea, shores of the Curonian and Vistula lagoons and reservoirs, peat-bogs, marshes and river valleys. The current state of the main long-term migratory stop-over sites for waterfowl and shorebirds is relatively favourable. However, there are many negative factors affecting habitat quality, the most important in the Kaliningrad region being the following.

**Petroleum pollution of the coastal waters of the Baltic Sea.** Sources of land-based petroleum pollution are badly equipped petroleum terminals, numerous storehouses of mineral oil, industrial, agricultural and transport agencies, boilers, poor drainage from industrial enterprises and municipal services, and storm drains of cities and vehicles. From official data, pollution by mineral oil and sewage is estimated to be from 50 to 90 tons per year. Potential threats of petroleum pollution are oil recovery operations on land and sea, and oil pipelines and large oil storage depots. However, the basic sources of shoreline pollution by mineral oil in the Kaliningrad region are from the sea – probably from large petroleum terminals abroad. In the last decade, pollution of mineral oil in coastal areas was estimated (for example in 1996) at hundreds kilograms up to more than 100 tons. Sources of pollution in all cases were outside the territorial waters of Russia. Cases of mass destruction of a waterfowl population from petroleum pollution on the Kaliningrad coast are rare, but each year high mortality of Long-tailed Ducks is very noticeable.

**Drainage.** As a result of land drainage for use by agriculture and extraction of peat, many ecosystems including wetlands are being destroyed. Drainage of swamps, flooded meadows and raised bogs round the borders of lagoons and in the valleys of the larger rivers results not only fewer sites being available to migratory birds, but also in the reduction of the value of the habitat for use during migration. It is noticeable that in such cases the migration of many waterbirds has become transitory.

**Overgrowing of the low-grass meadows by shrubs and tall grass.** The change in use of meadows from mowing and moderate grazing has resulted in low-grass meadows becoming high-grass meadows, frequently overgrown by shrubs and reeds. This type of habitat change dominated the Kaliningrad region at the end of the twentieth century, and as a result, the quality of coastal meadow habitats of birds has declined, with many sites becoming unsuitable as migratory stop-over sites for geese and shorebirds.

**Peat-extraction.** Recently, five raised bogs where many migratory species of geese, ducks and shorebirds stopped, have been destroyed in full or in part. Modern legislation and the strategy of nature management in the region do not provide adequate protection of marsh habitats. As a result, only three large raised bogs remain in a condition thought to be suitable for migratory waterfowl and shorebirds to utilize as stop-over sites.

**Burning and mowing of reeds on the shores of the lagoons and in the mouths of rivers.** In winter and early spring a large quantities of reeds are mowed, contrary to recommended practice, with the result that total area of mowed sites is increasing. From the middle of March, reeds in many places are set on fire. Sites of partly mowed and partly burned reeds become unattractive for birds and lose their value as migratory stop-over sites.

**Spring and illegal hunting.** Legal hunting for waterfowl opens in April (in 2004, for example, from April 3 to April 22), causing stress to the birds and compelling them to leave traditional migratory stop-over sites prematurely. In addition to a high level of legal hunting there is also a very high level of poaching, even in protected areas.

In conclusion, the basic problems of protection are the following:

- many valuable stop-over sites for migratory birds are not protected, and there are no areas protected under the Ramsar Convention;
- in those reserves that are protected, habitat conservation for birds is lacking or ineffective; and
- management plans for the major migratory stop-over sites are not yet developed in any detail.

## The state and conservation problems of key stop-over sites of migratory Common Snipe *Gallinago gallinago* in the Kaliningrad region of Russia

Julia Yarovikova

Kaliningrad State University, Universitetskaya str., 2, Kaliningrad 236040, Russia.  
(email: grishanov@email.albertina.ru)

Yarovikova, J. 2006. The state and conservation problems of key stop-over sites of migratory Common Snipe *Gallinago gallinago* in the Kaliningrad region of Russia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 355.

In the Kaliningrad region, Common Snipe *Gallinago gallinago* migrate in large numbers during both spring and autumn. Their migration route covers all areas of the region, but mostly they move along the large rivers Neman and Pregolia, and along the coasts of the Curonian and Vistula lagoons.

Abundance and availability of food resources are the major factors determining their distribution. Results of field research show that the optimal conditions for foraging migratory Common Snipe are soil humidity being wet to very wet, vegetation height being from 10 to 25 cm, and vegetation cover from 40 to 60%.

The key stopover sites in this region are seasonally flooded meadows and swamp meadows, located in the Neman River delta, and the eastern and southern coasts of the Curonian lagoon. In some years, favorable conditions in some meadows leads to densities of more than 500 resting and feeding Common Snipe per 10 ha. However, the location and suitability of these habitats changes each year according to water levels during a migration season, and from the levels and types of agricultural use.

The hydrological regime of these areas fluctuates as a result of water management works and to a large extent the weather conditions of the season. During the last decade management works have been irregular and at a local scale. At some sites, especially if there was no agricultural usage, meadows were flooded, and have become boggy and overgrown by shrubs. Currently, within the framework of the Federal target program in the Kaliningrad region, major work on the restoration of water management systems is being undertaken. This has led to

increased drainage of floodplains and the loss of suitable staging habitats for migratory Common Snipe.

The location, intensity and type of agricultural use, such as haymaking and grazing, determine the structure of vegetative cover and thus the abundance of food resources. Late mowing and moderate grazing (80-90 cows on 100 ha) promotes favorable vegetative characteristics for Common Snipe foraging. However, excessive grazing results in the degradation of vegetation cover, which in turn negatively influences the abundance of food resources. In the Kaliningrad region agricultural use depends upon the economic situation of individual farms. For the last decade, grazing and hay making in the region has become erratic owing to the sharp reduction in numbers of live-stock, from 468 000 in 1990 to 240 000 in 2000. As a result, some meadows are now completely trodden down due to high levels of grazing, while others are overgrown with high grass and shrubs due to no agricultural usage. In both situations these habitats thus have become unsuitable for migratory Common Snipe. Due to lack of haymaking, vegetation is burnt on some sites. Early spring fires in some areas improve the state of stopover sites during spring migration.

The stopover sites of migratory Common Snipe situated in the Important Bird Area of the Neman river Delta and Curonian Lagoon coast, also includes three state nature zoological reserves, Diunniy, Gromovskiy and Zapovedny with a total area of 57 000 ha. These reserves are managed by the Kaliningrad Regional Hunting Department, but there is no special conservation strategy for migratory Common Snipe and their key stopover sites.

## The Neman River Delta: a potential Ramsar site in Kaliningrad, Russia

Gennady Grishanov<sup>1</sup> & Dimitri Grishanov<sup>2</sup>

<sup>1</sup> Chair of Ecology and Zoology, Kaliningrad State University, Universitetskaya str., 2, Kaliningrad 236040, Russia.

<sup>2</sup> Kaliningrad State University, Universitetskaya str., 2, Kaliningrad 236040, Russia.

(email: grishanov@email.albertina.ru)

Grishanov, G. & Grishanov, D. 2006. The Neman River Delta: a potential Ramsar site in Kaliningrad, Russia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 356.

The delta of the Neman River and the adjacent eastern coast of the Curonian Lagoon is the main stop-over site of migratory waterbirds in the Kaliningrad region. It is a complex mosaic of wetland and forest habitats, with rivers, canals, marshes, meadows and forests. These unique, pristine wetlands are the largest such area in the south Baltic region and play a key role in maintaining the biodiversity of the region.

The northern part of the Neman River delta is located in Lithuania and was designated as a Ramsar site in December 1993. The southern part of the delta is Russian territory and despite its huge significance for migratory birds still does not have Ramsar status although it meets the Ramsar criteria for identifying wetlands of international importance in the following respects:

- the site is a representative and unique example of a coastal wetland complex, characteristic of the Eastern Baltic Region (Criterion 1);
- the site is very important for the conservation of biological diversity and for the natural hydrological regime of the region (Criterion 3);
- the site supports significant numbers of rare, vulnerable or endangered species of birds, mammals and plants. Among these are numerous species of fauna and flora of European conservation concern (Criterion 2);
- the site regularly supports more than 20 000 waterbirds (Criterion 5).

There are 16 priority habitat types in the delta which are included on Annex 1 of the EU Habitats Directive. Approximately 250 bird species occur in the delta, including 156 breeding species and up to 50 species with special conservation status. The wetlands are important as a stop-over site for migratory waterbirds such as Greylag Goose *Anser anser*, White-fronted Goose *A. albifrons*, Bean Goose *A. fabalis*, Tufted Duck *Aythya fuligula*, Pochard *A. ferina*, Wigeon *Anas penelope*, Pintail *A. acuta* and Mallard *A. platyrhynchos* which form large concentrations of more than 20 000 individuals in the autumn.

Thirteen species of birds have been recorded breeding in the Neman River delta which are listed in The Red Data Book for the Russian Federation: Spotted Eagle *Aquila clanga*, Lesser Spotted Eagle *A. pomarina*, White-tailed Eagle *Haliaeetus albicilla*, Osprey *Pandion haliaetus*, Eagle Owl *Bubo bubo*,

Little Tern *Sterna albifrons*, Curlew *Numenius arquata*, Oystercatcher *Haematopus ostralegus*, Avocet *Recurvirostra avosetta*, Great Grey Shrike *Lanius excubitor*, Middle Spotted Woodpecker *Dendrocopos medius*, Black Stork *Ciconia nigra* and Golden Plover *Pluvialis apricaria*. The following Russian Red Data Book listed species are regularly recorded on migration in the delta: Black-throated Diver *Gavia arctica*, Red Kite *Milvus milvus*, Golden Eagle *Aquila chrysaetos*, Peregrine *Falco peregrinus*, Dunlin *Calidris alpina*, Caspian Tern *Sterna caspia*; and the globally threatened Lesser White-fronted Goose *Anser erythropus*, Ferruginous Duck *Aythya nyroca*, Spotted Eagle, Corncrake *Crex crex*, Great Snipe *Gallinago media*, Aquatic Warbler *Acrocephalus paludicola*. The delta also hosts the largest density of breeding Bittern *Botaurus stellaris*, Montagu's Harrier *Circus pygargus*, White-tailed Eagle, Spotted Crake *Porzana porzana*, Corncrake, Crane *Grus grus*, Little Tern and Black Tern *Chlidonias niger* in the region.

Two State Zoological Nature Reserves, Diunny and Zapovedny are located in the wetlands. However, they provide insufficient protection to maintain ecological and biological diversity or the hydrological regime of the area. Economic development projects are a threat to conservation of the key habitats. Urgent measures are required to regulate certain kinds of human economic activities such as the proposed works for deepening part of the Neman river and the coastal part of the Curonian lagoon which are of particular concern for this region.

Increasing human disturbance, such as the unregulated development of water-based tourism, threaten this unique natural complex. Frequent spring fires in large areas of reed thickets, peat bogs and woods, regular fires on the embankments of dams and increased poaching are also cause for concern.

The long term plan for nature conservation in the Kaliningrad region includes the establishment of a State Nature Complex (landscape) Reserve with zonation plans for differing uses and levels of protection. Designating the wetlands of the Neman River delta as a Ramsar site would be an important step towards conserving these valuable habitats for waterbirds. Their unique landscape and biodiversity value is significant for the whole Baltic region and should provide the basis for further protection and conservation status, such as working with Lithuania to establish a possible transfrontier protected area of European significance. Such transfrontier sites are especially encouraged by the Ramsar Convention.

## The migration routes of waterfowl and their protection in Baikal Siberia

Yuri I. Mel'nikov

State Nature Reserve 'Baikalo-Lenskiy', Irkutsk, 291 B Baikalskaja St. a/b 3580, 664050, Russia. (email: zapoved@irk.ru)

Mel'nikov, Yu.I. 2006. The migration routes of waterfowl and their protection in Baikal Siberia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 357-362.

### ABSTRACT

Long-term studies have been used to determine features of the migration of waterfowl (ducks, geese and swans) in Baikal Siberia. For the first time, the major and minor migratory routes have been identified, and the way in which these have developed in relation to the mountainous areas and plains of the region has been revealed. Important staging areas, supporting at least 20 000 individuals during the migration seasons, are identified. It is estimated that at least 10-12 million waterfowl pass through Baikal Siberia in autumn. However, there is a poor level of protection for waterfowl in the region. The existing specially protected areas, primarily hunting reserves, do not provide adequate protection for waterbirds, and a decrease in the numbers has been observed in recent years. There is now an urgent need for the creation of a special system of protected areas for the protection and rational use of waterfowl in the region.

### INTRODUCTION

The waterfowl and shorebirds of Baikal Siberia migrate along the East Asian-Australasian Flyway. An analysis of the recoveries from about 170 000 ringed birds (Pizhjanov 1998) has shown that the western limits of the wintering range of waterbirds from Baikal Siberia are in central and eastern India (Mel'nikov 1999), while the majority of birds winter in Japan, China, South-east Asia, the Philippines, New Guinea and Australia (Skryabin *et al.* 1978, 1981, Pizhjanov 1998, Mel'nikov 1999). The migration routes of waterfowl in the East Asian-Australasian Flyway are poorly known. In Baikal Siberia, investigations have been carried out only at the most important staging areas and along the main migration routes. Little information is available on the numbers of waterfowl present, and details of the migration routes through the highlands of this region are practically unknown.

### STUDY AREA, MATERIALS AND METHODS

The extensive territory in the south of eastern Siberia, located around Lake Baikal, is referred to as Baikal Siberia (Peshkova 1972). It lies at the centre of the Asian continent on the boundary between the steppe and forest zones, and is an important ecological barrier in the distribution of many species of animals and plants. The Sajon-Baikal plateau, with its uplifted and strongly shattered ranges (2 500-3 500 m), divides the south of the region into two parts: Prebaikalia and Transbaikalia. Land to the north and south of the plateau has low- and mid-mountainous relief (800-1 800 m), with numerous depressions in the south (Florensov & Oljunin 1965). The Angara valley in the central Sajon-Baikal plateau is open to a southerly air-stream from the valley of the Selenga River to the south, and this warm air supports steppe and forest-steppe zones along the Angara River and lower portions of its tributaries, on Olkhon Island and in Priolkhonje (Peshkova 1972).

Baikal Siberia is characterized by continental climatic conditions. This is especially marked in inter-montane depressions (Zhukov 1965). There is relatively little precipitation, and there are few large lake systems. Coniferous taiga forest dominates everywhere, and there are only small areas of forest-steppe and steppe in the relatively warm, inter-montane basins. Permafrost is widely distributed almost throughout the territory.

This paper is based on the results of 40 years of personal research, and makes use of the published literature and interviews with the local population, waterfowl hunters and forestry experts. Over 15 000 km were covered on foot or by boat during the course of the research, and about 2 000 hours were spent making observations from fixed observation posts. Fieldwork was carried out in most of the large wetland systems in the region. The migration of waterfowl was studied in detail at fixed observation posts at the mouth of the Irkut River, in the Selenga River delta, and in the basins of rivers in East Sajon (Oka, Goloustnaja, Uda, Zima, Malyi Tagul and Toisik). The results of some of these studies have already been published (Mel'nikov 2000a, 2000b, 2001). On the basis of the published material and personal research, migration routes of waterfowl in the region have been mapped.

### RESULTS

#### Spring migration

Two major migration routes (flyways) pass through southern Transbaikalia: the Selenga and the Khingan. They are formed in Mongolia and China (Mel'nikov 1999, 2000b). In early spring, the Selenga flyway reaches the delta of this river, and then divides into several smaller flyways. The Khingan flyway divides into two in the region of Dalay-nor Lake, with one branch following the Argun River (Khingon-Argun) and the other proceeding to the Torej lakes (Khingon-Torej). The first of these soon leaves the limits of Baikal Siberia in the basin of the Aldan River (Gavrin & Rakov 1960). The second divides into three smaller flyways: the Torej-Olekma, Torej-Kirenga-Tunguska and Torej-Baikal-Angara.

Migrating waterfowl first appear in southern Transbaikalia (in the region of Kyakhta and the Torej basin) in the second half of March (Molleson 1897, Gavrin & Rakov 1959). In years with an early spring, small groups of Ruddy Shelduck *Tadorna ferruginea*, and sometimes Mallard *Anas platyrhynchos*, have already appeared in the Selenga River delta and at Verchnee Priangarie (Irkutsk and Ust-Orda) by the end of March. The first large wave of migrating waterfowl appears in southern Transbaikalia as soon as the average daily air temperature exceeds 0°C (Gavrin & Rakov 1959, Shinkarenko 1988). This usually occurs with a significant intrusion of warm air from Mongolia and China at the beginning of April. Waterfowl arriving at this time include early-breeding dabbling ducks, such as Mallard, Common Teal *Anas crecca*, Northern Pintail *A. acuta*

Female Mallard *Anas platyrhynchos* and young. Photo: Paul Marshall.

and Eurasian Wigeon *A. penelope*, and Common Goldeneye *Bucephala clangula*. The north-south orientation of the basins in Transbaikalia promotes rapid penetration of warm air to the north, and the wave of migrants quickly reaches the northernmost areas of forest-steppe, although the numbers are much lower in the north.

The movement of birds far to the north in the first stages of the spring migration is facilitated by a gap in the mountain ranges in the area of the Selenga River delta and a tributary of the Angara River, and also the large areas of steppe on the Irkutsk-Cheremchovo plain and on the edge of the Prebaikalia lowlands. There is already, in the early stages of spring migration in southern Baikal, a well-defined flyway (Baikal-Angara-Yenisei) that leaves in a north-westerly direction to the Yenisei via the extensive Irkutsk-Cheremchovo plain and southern edge of the Leno-Angara plateau.

From this major flyway, smaller flyways diverge to the north and north-east, passing through Verkholeniy (Kachug settlement) and Ust-Kut in the Lena valley, where there are small areas of steppe and agricultural land. Around Irkutsk, the Baikal-Angara-Yenisei flyway divides into two branches. The main branch continues on in a north-westerly direction, while the other (the Baikal-Angara-Tunguska flyway) turns north and follows the valley of the Nizhnijaya Tunguska River to Erbogachen plain, where it joins up with the Torej-Kirenga-Tunguska flyway. Birds reaching the basin of the Lena River follow this valley in a north-easterly direction. Other flyways formed in the Selenga River delta are insignificant in size, and are used by birds moving to breeding areas within Baikal Siberia.

In this first period of the spring migration, the birds migrate exclusively along river valleys, as the land between the valleys

remains under snow and presents a serious barrier to the birds. Both north-easterly and south-westerly movements of birds have been observed along the eastern edge of Lake Baikal at this time of year (Skryabin 1975), and it has not been possible to identify separate migration routes in this area. Groups of ducks that breed locally are already arriving on their breeding grounds in southern Prebaikalia in the middle of April, often before the first major wave of spring migrants (Mel'nikov 1998).

The appearance of the first migrants in early spring always occurs during short warm spells, which are usually followed by cold periods (of three to four days), with air temperatures of  $-5$  to  $-7^{\circ}\text{C}$ . The mass migration of waterfowl begins when the average daily air temperatures rises above  $0^{\circ}\text{C}$  throughout much of the territory (Shinkarenko 1988). This usually occurs at the end of April or the beginning of May, although there may still be short cold spells. However, snow cover in the low mountain ranges between the rivers disappears and conditions for migration improve considerably. Migration occurs on a much broader front, with birds beginning to appear on the southern slopes of high mountainous areas. At this time, birds begin to fly through some of the lower passes in the mountain ranges of East Sajan to reach the Uda river valley, which they follow in a northerly or north-westerly direction. However, the main Yenisei flyway, which includes birds from the East Tuva staging area (Emeljanov & Savchenko 2000), is rather poorly represented in Baikal Siberia.

In other mountain ranges in East Sajan, there are minor flyways of birds from the Khangai flyway which originates in Mongolia. These minor flyways, having passed around the high, snow-covered mountain ranges, enter large river valleys with favourable conditions for further migration. However, the number of birds involved is small. Also during this period, a rather small flyway (Vitim-Paton) is formed in the large lake system in the Vitim Mountains (Ivano-Arahley, Eravna and Baunt lakes), and this has several minor branches in the highlands of the Vitim, Severo-Baikal and Patom plateaux (Mel'nikov 2000a).

In the second half of May, waterfowl migration in southern Baikal Siberia comes to an end, while in northern areas, the mass migration begins. At this time of year, migration occurs everywhere on a broad front, and large concentrations of birds can be found at staging areas at large lake systems. The location of these staging areas determines the directions of the minor flyways. Concentrations of birds elsewhere along the flyways are observed only at certain strategically important locations and, in high mountains, in certain mountain passes. At present, there is a well-defined flyway through the Baikal Mountains leading to the Nizhnijaya Tunguska river valley.

### Moult migration

A return migration of the drakes of some waterfowl species is observed at moulting areas even before the end of the spring migration. The timing of the moult migration is closely linked to the breeding phenology of the birds. Even within southern Baikal Siberia, there is a two-week difference in dates of first egg-laying between the earliest breeders in southern areas and those in northern areas. Differences in the main egg-laying period are more indicative in this respect. The difference between breeders in northern Baikal Siberia (Nizhnijaya Tunguska river valley) and those in the south (Selenga River

delta) is three weeks. In years with an early spring, drake Mallard and Northern Pintail begin to pursue females in the first few days of May. Some 10-15 days after disintegration of the pair bond, the drakes form small flocks (Mel'nikov 1998), and start to undertake local movements to good feeding areas. The number of drakes involved in these movements rapidly builds up, and by early June, drakes greatly outnumber nesting birds at the important moulting sites. By the beginning of July, the moulting drakes have been joined by many females (sometimes 30-35%), presumably birds that have had an unsuccessful breeding season.

The first species to begin their moult migration are those that nest earliest, e.g. Mallard, Common Teal, Garganey *Anas querquedula* and Northern Pintail. Moulting migrations occur on a broad front and under very favourable conditions, with moulting flocks of drakes occurring on practically all wetlands in Baikal Siberia. The direction of the moult migrations basically coincides with the spring and autumn flyways (Mel'nikov 2000b). The long duration of the moult migrations (ranging from 2.0 to 3.5-4.0 months according to species) is a result of the length of the breeding season. Even in mid-July, some ducks remain paired and are still breeding. This late nesting is due to the laying of one or even two replacement clutches, being most common in Gadwall *Anas strepera*, Tufted Duck *Aythya fuligula*, Common Pochard *A. ferina*, Common Goldeneye and Smew *Mergellus albellus*. The moult migration of these late breeders may be delayed until the end of August. Furthermore, birds from northern breeding areas migrate to southern areas to moult, and having nested later than southern breeders, also undertake their moult later. This further extends the duration of the moulting period.

In Baikal Siberia, mass moulting of waterfowl occurs only in the south of the region, in the Selenga River delta and Torej lakes. Depending on water levels, there are between several hundred and up to 30 000-50 000 moulting drakes in these areas. However, throughout Baikal Siberia, some of the drakes moult in their breeding areas, and do not undertake long-distance moult migrations. Usually these are late breeders which gather in groups of five to ten individuals in secure areas with optimum feeding conditions. Only on those lakes with the best conditions are there moulting concentrations of up to some hundreds (but no more than 1 000) individuals. The scarcity of important moulting areas in Baikal Siberia, particularly for diving ducks and dabbling ducks that feed on invertebrates, such as the Northern Shoveler *Anas clypeata*, is thought to be due to the small number of reservoirs in the region, and their low productivity. Even in the northern limits of the forest-steppe zone, conditions are still very poor for moulting birds, although there are some fairly large concentrations of moulting drakes in this area.

### Autumn migration

The autumn migration begins under favourable conditions in the middle or at the end of August. Large concentrations of birds that have bred locally gather on the largest lake systems in the region, and the first dabbling ducks begin to depart. Formerly there were appreciable movements of Baikal Teal *Anas formosa* at this time, but this is now an extremely rare species in Baikal Siberia. The last birds to depart are the diving ducks, sawbills, geese and swans.

The main directions of the movements in spring and autumn almost exactly coincide. Migration occurs on a broad front, with some funnelling along flyways in certain areas. The minor flyways are used by only small numbers of birds, mostly on their way to the main staging areas where they congregate in larger flocks. The number of birds migrating through high mountainous areas, even in favourable conditions, is insignificant, although almost all species migrate in small numbers along flyways at low and middle elevations in the mountains.

Migration through mountain passes is far from uniform. During some seasons, it can occur on a large scale. It is clearly related to weather conditions, with birds not flying through some passes if there is a deterioration in the local weather. In periods of very severe weather, when most or all of the passes are closed, the birds congregate on lakes in the river valleys where they remain until the weather improves.

Three or four waves of migration are observed during autumn, each producing a big increase in the numbers of birds at the main staging areas. The species composition of each wave differs, but Mallard, Common Teal, Northern Pintail, Eurasian Wigeon, Tufted Duck and Common Goldeneye dominate in all waves. The first consists mainly of dabbling ducks, and the last, mainly diving ducks, geese and swans. The total number of birds seen migrating along the main flyways varies considerably from year to year (by as much as eight fold), and obviously depends on conditions along the migration route. Observations made from the ground take into account only those birds flying at low level, while non-stop migration at high altitude (true migration) goes unrecorded.

With the onset of heavy snowfall in the high mountains in the first half of September, migration through these areas almost stops, although there are occasional flocks of geese and Whooper Swans *Cygnus cygnus*. Discrete flyways begin to appear in the valleys, and these are well pronounced by late autumn, when the shallow lakes become covered in ice. In Prebaikalia, the last of the migrants gather on the reservoirs of Ust-Ilym, Bratsk and Irkutsk, and the large lakes of Irkutsk-Cheremhovo plain and Prebaikala plain (Ochaul, Berikul, Kondakov and others). The last wave of the autumn migration appears in the second ten days of November, and passes through the Verkhnee Priangorye, Primorskyi ridge, Selenga River delta and Torej lakes on the way to Mongolia and China.

### Staging areas

The most important staging areas during the spring, moult and autumn migrations are the large lake systems along the major flyways. The largest of these are located on the border of the forest-steppe and steppe zones, the most significant being the Torej lakes and Selenga River delta. Staging areas in the Baikal basin (Barguzin river valley, Arangatujsy lakes, Verkhnjaja Angara and Kichera river mouths, and Verkhneangarsk expansion) are less important. The chain of Angarsk reservoirs is an important staging area, as also are the Irkutsk, Bratsk and Ust-Ilym reservoirs. One of the most important staging areas in northern Baikal Siberia is Erbogachen plain, in the Nizhnjaja Tunguska valley. Many other smaller sites support up to about 20 000 waterfowl during the migration seasons. The location of these staging areas determines the direction of many of the minor flyways, as birds move from one staging area to another.

The total number of a waterfowl using the staging areas in Baikal Siberia is considerable. Unfortunately, it is very difficult

to provide a reliable estimate of numbers on the basis of the available data. However, counts of the large concentrations of waterfowl during autumn migration at the two most important staging areas in Baikal Siberia (Selenga River delta and Torej lakes) allow us to make a tentative estimate of total numbers. It should be noted that there are few areas of mass concentration of waterfowl near the southern borders of Baikal Siberia, and most of these are much less important than the Selenga River delta and Torej lakes. An exception is the Argun River along which migrate at least half of the waterfowl entering Russian territory via the Khingan flyway. However, waterfowl following the Khingan-Argun flyway soon leave Baikal Siberia via the Aldan valley. There has been no accurate estimation of numbers in this flyway for many years, and as the flyway lies largely outside Baikal Siberia, it has not been considered here.

At the end of twentieth century, some research was carried out on the migration of waterfowl in the Selenga River delta and Torej lakes, and this included an estimation of numbers. This work has shown that, depending on the year, between two million and five million waterfowl stop off in the Selenga River delta during the autumn migration (Skryabin 1995), while between three million and five million waterfowl stop off in the Torej lakes (Goroshko 1998). It has been estimated that a further two million birds occur at the many other, less important sites, including sites that hold less than 20 000 individuals. Hence, the total number of waterfowl occurring at staging areas in Baikal Siberia during the autumn migration is estimated at 10-12 million individuals. This is a minimum estimate for the number

Rare waterbirds to Baikal Siberia such as the Bewick's Swan *Cygnus columbianus bewickii* sometimes occur at important staging areas in the north of the region. Photo: Paul Marshall.

Moulting flocks of drake Mallards *Anas platyrhynchos* as well as other ducks occur in autumn on practically all wetlands in Baikal Siberia. Photo: Crawford Prentice.

of waterfowl passing through Baikal Siberia, as an unknown proportion passes through southern Baikal Siberia without stopping to rest. Significant annual fluctuations in the numbers of waterfowl recorded at staging areas are related to the condition of the wetlands. In years with high water levels, the numbers of birds increase sharply, while in years with low water levels, numbers are greatly reduced.

### Protection of waterfowl

Sites of importance for the protection of waterfowl are poorly represented in the current network of specially protected natural territories (SPNT), which includes various categories of protected area. Indeed, most of the internationally important wetlands are unprotected. Furthermore, the fact that a site of high importance as a breeding or staging area for waterfowl has been designated as a SPNT at local level (territorial hunting reserve) does not mean that it is well protected. Infringement of the regulations concerning the exploitation of wildlife resources in territorial hunting reserves is now the usual situation. Only twelve of the 30 most important areas for waterfowl are formally protected; in two reserves (Dauria and Olekma), two national parks (Prebaikalian and Transbaikalian) and eight hunting reserves. All of these are sites of international importance.

With a few exceptions, important staging areas for waterfowl on the main flyways in Baikal Siberia are not specially protected, and this is the main deficiency in waterfowl protection in the region. Many of these staging areas are unique wetlands and support a high diversity of waterfowl. The southern lake systems are especially interesting in this respect, as they often support a number of specially protected species such as Greylag Goose *Anser anser*, Swan Goose *A. cygnoides*, Baer's Pochard *Aythya baeri* and Baikal Teal. Important staging areas in the north of the region support rare species such as Bewick's Swan *Cygnus columbianus bewickii*, Middendorff's Bean Goose *Anser fabalis middendorffi*, Lesser White-fronted Goose *A. erythropus*, Harlequin Duck *Histrionicus histrionicus* and White-winged Scoter *Melanitta (fusca) deglandi*, and also require more protection.

The extreme importance of the Selenga River delta for waterfowl was recognized in the 1980s, and yet this site remains unprotected. The establishment of a protected area in the delta is a high priority, as also is the establishment of an ornithological reserve to protect the Inarigda lake complex in the Nizhnaja Tunguska valley (Nizhnetungusskiy). All other important sites require, if not full protection, then at least regulations concerning the economic exploitation of waterfowl resources. In the creation of the SPNT network, no consideration was given to the special protection of waterfowl, although this group of birds includes many species that require special attention. Special approaches are required in the planning of a system of protection and management for waterfowl, as well as for various other groups of birds.

### DISCUSSION

Hitherto, the waterfowl flyways of Baikal Siberia have been poorly investigated. The information collected by us and the general information available in the literature have enabled us to present the first overview of the main directions and character of movements of waterfowl within the limits of this extensive territory. The main flyways along which birds reach Baikal Siberia during the spring migration converge on the important staging

areas in the Selenga River delta and Torej basin, and then divide into a series of smaller flyways. A significant proportion of the birds finish their migration in Baikal Siberia, and settle down to breed here and in adjoining regions. During the autumn migration, birds use a wide network of minor flyways to reach the main staging areas in Baikal Siberia, whence they continue along the major flyways to their wintering areas.

The large and well-defined flyways reflect the main directions of the migrations of long-distance migrants: north-west in spring and south-east in autumn. In spring, these flyways appear much earlier in southern Baikal Siberia than flyways in other directions, and in autumn, continue until the middle of November, when migration on other flyways has ceased. Many of the birds in these major flyways breed in central and eastern Taymyr, where there are very high breeding densities of many species of waterfowl.

The formation of well-pronounced flyways in Baikal Siberia is principally caused by the natural features and climatic conditions of the region. The Sajon-Baikal plateau is relatively low in elevation, and has gaps through which southerly air streams can penetrate in early spring, bringing warm air to the Selenga and Angara valleys. This is reflected in the presence of large areas of steppe vegetation. Other, less well-pronounced flyways are formed later in the spring, and are connected with the movement of birds through high mountain ranges (2 500-3 000 m). It has been demonstrated that orographic features and the latitudinal distribution of vegetation zones have a big influence on the direction and intensity of the migration routes of waterfowl.

Despite the scarcity of large lake systems in Baikal Siberia, very large concentrations of waterfowl occur at staging areas during the spring and autumn migration seasons. There would appear to be abundant food resources for the migrating birds, as the quality of the wetlands in Baikal Siberia has essentially not changed in recent decades. However, the numbers of migrating waterfowl are now much lower than they were in the middle of twentieth century.

The wetlands of southern Baikal Siberia are of great importance for migratory waterfowl, providing staging areas where the birds can build up their fat reserves before continuing their migration. However, the present system of state protected territories is obviously insufficient to provide adequate protection for waterfowl and maintain species diversity. The main reason for this is that, until now, the creation of a system of protected areas has focused exclusively on the preservation of fur-bearing animals because of their high economic value. The development of a special system of protected territories is therefore required for the protection of breeding and migrating waterfowl.

## Enigmas about Whimbrel *Numenius phaeopus* in the East Atlantic Flyway

Bertrand Trollet

Office National de la Chasse et de la Faune Sauvage, Chanteloup-85340, Ile d'Olonne, France.  
(email: bertrand.trollet@oncfs.gouv.fr)

Trollet, B. 2006. Enigmas about Whimbrel *Numenius phaeopus* in the East Atlantic Flyway. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 363.

Current estimates of the number of Whimbrel *Numenius phaeopus* breeding in Europe are between 322 000 to 369 000 pairs, of which 250 000 are in Iceland (Thorup 2006). However, surveys in (northern) summer in Guinea and the Banc d'Arguin have shown that around 50% of the numbers in winter do not migrate north in spring. Thus, taking into account that a proportion of birds do not return to breeding grounds but overwinter in their wintering areas, the number of breeding pairs should be multiplied by four to estimate the wintering numbers, which would thus amount to 1.3 to 1.5 million individuals.

These birds are thought to winter along the West African coast, with small numbers wintering in Europe, which is confirmed by ring recoveries. The total number of wintering birds, counted or estimated, in Europe and West Africa (from Morocco to Gabon), is approximately 111 000 individuals (Trollet & Fouquet 2004), i.e. 7.5 to 8.5% of the estimated breeding population. This implies that more than one million individuals could be wintering in areas that have not been surveyed, possibly mangrove areas. These figures also would imply that Whimbrel is the most abundant coastal wader in Africa. There is no data showing that European-breeding Whimbrel winter further south in Africa (where, anyway, known numbers are small).

Between Africa and the breeding grounds in Iceland and north continental Europe, only a few areas are known where Whimbrel stopover during their spring migration. The total peak numbers (which occur almost simultaneously) on these known stopover places does not exceed 70 000 individuals.

One of these stopover sites is Chanteloup, Vendée, in western France. Counts made at this roosting site, biometric analysis of more than 2 100 Whimbrels captured there in spring, and estimates of energy requirements, indicate that the birds staging on these known stopover places represent at most 1.1 million days x individuals, corresponding to less than 220 000 individuals. Birds must stage for an average of more than five days to deposit enough energy reserves to reach their breeding areas. This would mean that well in excess of 424 000 Whimbrels stopover in known staging areas in spring.

This implies that either these birds:

- stopover elsewhere, although it seems unlikely that such large numbers have been missed; or,
- they fly directly from Africa to their breeding areas.

To fly direct, birds breeding in continental Europe would need to cover at least 6 000 km. However, studies in Mauritania are not compatible with the departure from there of hundreds of thousands of Whimbrel going direct to their breeding areas. This suggests that the great majority of Icelandic Whimbrel would have to depart from more southerly areas, situated at least 5 800 km from Iceland. Estimates of energy expenditures

suggest that such long nonstop flights are probably impossible. However, metabolism rates and the energy costs of flight under the actual conditions of migratory flights over long distances are insufficiently known and may differ considerably from predictions of theoretical models.

Thus we have to conclude that breeding numbers are over-estimated, particularly in Iceland. However, this over estimation is probably not so excessive, and enigmas remain about populations sizes, winter distribution and migrations of European Whimbrels.

To answer these questions, it is suggested that studies begin, or continue, on:

- numbers breeding in Iceland;
- numbers wintering in West Africa's mangroves, notably in Nigeria;
- the birds' movements, ecology and physiology in West Africa in April, and
- surveys to locate other spring migratory stopover places in Europe.

## The European Non-Estuarine Coastal Waterbird Survey

Steve J. Holloway, Niall H.K. Burton & Mark M. Rehfishch

British Trust for Ornithology, The Nunnery, Thetford, Norfolk, IP24 2PU, UK. (email: niall.burton@bto.org)

Holloway, S.J., Burton, N.H.K. & Rehfishch, M.M. 2006. The European Non-Estuarine Coastal Waterbird Survey. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 364-365.

This paper provides a brief overview of the background and results of the European Non-Estuarine Coastal Waterbird Survey (NEWS), which reported on the wader populations wintering on the non-estuarine coasts of 12 European countries.

NEWS was the first co-ordinated survey of waders wintering on the continent's non-estuarine coasts. The survey aimed to provide population estimates for waterbirds using the non-estuarine habitats in different participant countries, which would complement information from better-monitored estuarine sites.

In total 12 different countries participated in the survey, covering non-estuarine shores from Sweden to Croatia (Table 1). Most counts took place in the winter of 1997/98, with some in 1999/2000.

The survey's results will be published in an International Wader Studies volume (Burton *et al.* in prep.). For each country, papers report on the numbers of waders recorded during the survey and provide population estimates for their non-estuarine coasts. Numbers of other waterbirds recorded are also summarised.

In total, 25 wader species were recorded during the survey. Most widespread were Oystercatcher *Haematopus ostralegus*, Grey Plover *Pluvialis squatarola*, Sanderling *Calidris alba*, Purple Sandpiper *C. maritima*, Dunlin *C. alpina*, Redshank *Tringa totanus* and Turnstone *Arenaria interpres* (Table 1).

The United Kingdom held most non-estuarine waders, with a total estimated population of 380 100 birds (Rehfishch *et al.* 2003). The non-estuarine coasts of the countries surveyed support large proportions (>20%) of the biogeographic populations of Ringed Plover *Charadrius hiaticula*, Sanderling,

Purple Sandpiper, Curlew *Numenius arquata*, Redshank and Turnstone.

### ACKNOWLEDGEMENTS

Thanks are due to all those who participated in the survey and particularly the national organisers and authors: K. Devos (Belgium), D. Radović, V. Sčetarić Legan, J. Kralj, D. Blažina (Croatia), O. Thorup, H. Ehrup, N. Burton (Denmark), B. Deceuninck, R. Mahéo, F. Gabillard, (France), J. Blew, K. Günther, J.-J. Kieckbusch, H.-W. Nehls (Germany), J. Cortes (Gibraltar), K. Colhoun, G. Austin, S. ## The evaluation of some key wetlands for waterfowl in Central Anatolia, Turkey

Utku Perktas, Atıl Barış Albayrak & Zafer Ayaş

Hacettepe University, Faculty of Science, Department of Biology (Zoology Section), Beytepe, Ankara, Turkey.  
(email: perktas@hacettepe.edu.tr)

Perktas, U., Albayrak, A.B. & Ayaş, Z. 2006. The evaluation of some key wetlands for waterfowl in Central Anatolia, Turkey. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 366-367.

This paper presents the results of waterfowl population surveys carried out in five areas in the Central Anatolia region of Turkey between 1998 and 2001.

Turkey contains a significant number of wetlands important on a continental scale within Europe. Although these wetlands are known to be important for breeding and wintering waterfowl populations, little quantitative information is known about the population status of the bird species that use them (Tucker & Heath 1994, Scott & Rose 1996, Tucker & Evans 1997). However, because of the loss or degradation of wetlands across Turkey, wetland dependent species are at high risk, and we therefore examined the number of breeding and wintering waterfowl and looked at the importance of the selected wetlands for some protected waterfowl species.

Our study was conducted from 1998 to 2001 across five different wetlands in the Central Anatolia region of Turkey (Fig. 1): Nallihan Bird Paradise (900 ha); Balıkdami on the Sakarya River; Seyfe Lake (max. 9 350 ha); Palas Lake (saline, 2 330 ha); and Sultansazlığı in the Develi closed basin. The wetland includes a series of salt, brackish and freshwater lakes, and extensive marshes. *Salicornia* steppe encloses the salt-lakes environs, and southern marshes include large *Phragmites* reedbeds.

Between 1998 and 1999, we worked in the Seyfe Lake, Palas Lake and Sultansazlığı areas, and in 2000 and 2001 in Nallihan Bird Paradise and Balıkdami. We used the survey methodology suggested by Bibby *et al.* (1992) to determine the individual numbers of wintering and breeding waterfowl. European Threat Status (ETS) suggested by Tucker & Heath (1994) was also used to evaluate waterfowl conservation status.

A total of 41 waterfowl species were recorded in the five study sites between 1998 and 2001 (Table 1), and many waterfowl

species were recorded in both wintering and breeding seasons. A total of 17 species were of unfavourable conservation status. Twelve of these species were recorded in Sultansazlığı. Turkey has rich and diverse bird habitats that are vulnerable to the habitat destruction that has been continuing for about 30 years (Özesmi 1989).

In conclusion, the status of bird populations in Turkey appears to be different from that of the rest of Europe. However further population work will be necessary to clarify the changes in species numbers over time and their relationship to habitat change.

### ACKNOWLEDGEMENTS

We are especially grateful to Hacettepe University Research Foundation, ENCON Com. Ltd., Assoc. Prof. Dr. Levent Turan, Çağatay Tavşanoğlu, and Kadir Yiğit US for their great support.

## Changes in abundance and diversity of waders and wintering waterfowl on the southern coast of the Caspian Sea

Ahmad Barati<sup>1</sup> & Olia Gholi Khalilipoor<sup>2</sup>

<sup>2</sup> Department of Environmental Sciences, University of Khorramshahr, Iran.

Barati, A. & Khalilipoor, O.G. 2006. Changes in abundance and diversity of waders and wintering waterfowl on the southern coast of the Caspian Sea. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 368-369.

Changes in the abundance and diversity of waterbirds on the southern coast of the Caspian Sea were studied using mid-winter census data collected by Department of Environment of Iran during 1999-2003. We investigated changes in the size and diversity of waterbird populations in the southern coastal zones of the Caspian Sea. In this paper, population trends and species distribution of waders and wintering waterfowl in different years and regions are presented.

Iran has about 105 important wetland bird habitats hosting about 502 species (Firouz 1974). Due to their geographic and ecological situation, Iranian wetlands are used as wintering sites by many wader and waterfowl populations (Rabiee 2002). A census has been conducted since 1982 by the Department of Environment of Iran in the main wetlands from Makhtum Gholi bay to Astarain. These wetlands lie in the three northern provinces of Iran, Golestan, Mazandaran and Gilan, from where we have utilised data from 15, 17 and 25 water bodies/wintering sites respectively. The census carried out total counts every year in early January till February. Population trends in each region were assessed and summarized for the period 1999-2003.

Fig. 1. Location of Gilan, Mazandaran and Golestan in Iran.

The number of all wintering species varied from 87 in 2001 and 2003 to 80 in 2000, with waders varying from 61 in 2003 to 53 in 2000, and waterfowl from 27 in 2001 to 22 in 1999 (Figs. 2-4, Table 1). In all regions the highest number of species belonged to the Anatidae family and the lowest to the Threskiornithidae, Dromadidae, Gruidae, Phoenicopteridae, Haematopodidae, and Burhinidae.

The waterfowl population in the southern coastal zones of Caspian Sea reached a maximum of 2 835 800 birds in 2003 and a minimum in 1999. The largest and smallest populations waders in 2003 and 2002 was about 166 990 and 16 600 birds respectively.

<i>Calidris minuta</i>	Little Stint
<i>Calidris ferruginea</i>	Curlew Sandpiper
<i>Calidris alpina</i>	Dunlin
<i>Limicola falcinellus</i>	Broad-billed Sandpiper
<i>Philomachus pugnax</i>	Ruff
<i>Phalaropus lobatus</i>	Red-necked Phalarope
<i>Stercorarius parasiticus</i>	Arctic Skua
<i>Stercorarius pomarinus</i>	Pomarine Skua
<i>Larus canus</i>	Common Gull
<i>Larus argentatus</i>	Herring Gull
<i>Larus fuscus</i>	Lesser Black-backed Gull
<i>Larus ichthyæus</i>	Great Black-headed Gull
<i>Larus ridibundus</i>	Black-headed Gull
<i>Larus genei</i>	Slender-billed Gull
<i>Larus minutus</i>	Little Gull
<i>Sterna caspia</i>	Caspian Tern
<i>Sterna sandvicensis</i>	Sandwich Tern
<i>Sterna hirundo</i>	Common Tern
<i>Sterna albifrons</i>	Little Tern
<i>Chlidonias hybridus</i>	Whiskered Tern
<i>Chlidonias leucopterus</i>	White-winged Tern

Population estimates of waterfowl, waders and waterbirds in the three provinces are presented in Figs. 5-7 below.

**Fig. 5.** Waterfowl populations in southern coastal zones of Caspian Sea.**Fig. 6.** Waders population in southern coastal zones of Caspian Sea.**Fig. 7.** Waterbirds population in southern coastal zones of Caspian Sea.

Within the last five years some significant changes in populations and diversity have taken place. There was a rapid increase of waterbirds and waders in Gilan while in other regions we did not find spectacular fluctuations. In total, the mean size of waterbird populations was greater in Mazandaran than in other regions.

In general, there has been an increasing trend in the size of waterbird populations in the southern coastal zones of Caspian Sea. Mazandaran was the most abundant and diverse region in northern Iran as Mazandaran wetland seems to have food resources and large-scale water bodies.

Sultanov, E. 2006. Results of eight years of monitoring wintering and nesting waterbirds in Azerbaijan. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 370-371.

This paper discusses counts of waterbirds in Azerbaijan between 1993-2005. Most counts were conducted in winter and some have already been reported (Paynter *et al.* 1996, Sultanov & Haddow 1997, Sultanov *et al.* 1998, 1999, 2000, Sultanov *et al.* 2004).

Azerbaijan has about 1.25 million wintering waterbirds that use the Caspian-West Siberian-East African Flyway (Sultanov &

Mustafayev 1994, Sultanov 1997), and it is estimated that along the shores of Azerbaijan there are no fewer than 250 000 breeding waterbirds of which over 40 000 winter on islands and old oil platforms (Sultanov & Kerimov 1999). We estimate the number of migratory birds to be 8-10 times higher than wintering birds. During winter, the major species are ducks

**Table 1. Main waterbird sites in Azerbaijan.**

Sites	Months XI-II	III-IV IX-X (for one day counts)	V-VI	Importance
Lake Agzybir	Up to 30 000	Up to 20 000	Up to 10 000	II

(more than 1 000 000), coot (nearly 200 000), geese (40 000), many swans (up to 30 000 in extremely cold winters) and pelicans (up to 3 000). During the breeding period, herons, ibises, terns, gulls, cormorants and moorhens are present, while waders occur during migration.

The sharp increase in Caspian Sea oil production represents an escalation of an already severe risk of oil pollution, and it is therefore essential to conduct regular monitoring. During the period of monitoring, bird populations fluctuated on the sites along the Caspian Sea coast from a low of 70 000 (April 1997, 10-12% of the maximum number in winter) to a high of 1 076 000 in winter 2002-2003 (Sultanov 2004). In inland wetlands where there is less migration, there is a sharp increase in the number of birds in the beginning-middle of December and then a decrease during February.

We can distinguish sites by their importance in terms of the number of birds: the most important have congregations of more than 30 000 waterbirds during at least one season of year, while other sites have fewer than 30 000 birds.

Thirteen threatened species were observed in the survey area, the most important wintering species being White-headed Duck *Oxyura leucocephala*, Lesser White-fronted Goose *Anser erythropus* and Dalmatian Pelican *Pelecanus crispus*, and the most important resident species Pygmy Cormorant *Phalacrocorax pygmeus*.

Lakes Aggyol, Sarysu, Mahmudchala, Agzybir, Hajigabul, Kura river Delta Varvara water reservoir and Gyzylagach State reserve have large mixed colonies of pelicans and storks that can include up to 11 species numbering from two to 60 thousand for Gyzylagach State reserve (Konovalova 1979).

In most important inland wintering areas, diving and surface-feeding ducks are in equal proportion. For example at Aggyol and Mahmudchala lakes and Sarysu (about 90% of all waterbirds are Red-crested Pochard *Netta rufina*, Pochard *Aythya ferina* and Tufted Duck *Aythya fuligula*). Surface-feeding ducks predominate in Lake Hajigabul (Mallard *Anas platyrhynchos* and Shoveler *Anas clypeata*). In total, 108 species of waterbirds have been identified.

## Evolution of freshwater lagoons in Daghestan and their importance for waterbirds on the west Caspian coast

E.V. Vilkov

Russian Academy of Sciences, Daghestan Scientific Centre, Republican Ecologico-Biological Centre of Pupils, Pr. Gamidova (Kirova), 367003 Makhachkala, Daghestan, Russia. (email: [evberkut@mail.ru](mailto:evberkut@mail.ru); [eberkut@xtreem.ru](mailto:eberkut@xtreem.ru))

Vilkov, E.V. 2006. Evolution of freshwater lagoons in Daghestan and their importance for waterbirds on the west Caspian coast. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 372.

The Caspian Sea is important for migrating and wintering waterfowl. In 1979 there was a significant rise in sea level of approximately 3 m which lasted until 1996; during this time, a group of brackish lagoons free from surface vegetation appeared on the west coast. These 52 km - long lagoons are located along the routes of migratory birds flying along the western side of the Caspian. This paper considers the effects these lagoons have had on waterbird populations.

The narrowing of a migration corridor towards the plain of the Caspian coast has created a “bottleneck” effect resulting in a mixture of terrestrial and waterbird populations. Since their initial formation, the lagoons have become naturally desalinated and have developed freshwater wetland flora. This makes them especially attractive for a variety of waterfowl with reeds serving as natural protection, and algal meadows occupied by 13 fish species. What is most surprising is that this adjoins a lifeless semi-desert-steppe landscape.

Lagoons that do not freeze during winters have become increasingly used for over-wintering by coots, ducks, swans, gulls and cormorants that previously used to migrate to more remote areas of the southern Caspian Coast and to southeast Africa. The lagoons have therefore increased the biodiversity of the western Caspian Coast not only during migration periods, but also during winter. During one migration season, >12 million birds flew through this area, with many stopping for rest on the lagoons. Over 40 000 Tufted Duck *Aythya fuligula* have been sighted in four hours during peak migration.

Surveys have identified 283 species of birds, amounting to 79.2% of the total recorded in the Republic of Daghestan. Of those, 46 are listed in the Red Book, including the Pygmy Cormorant *Phalacrocorax pygmeus*, Dalmatian Pelican *Pelecanus crispus*, White Pelican *Pelecanus onocrotalus*, Glossy Ibis *Plegadis falcinellus*, Lesser White-fronted Goose *Anser erythropus*, Marbled Teal *Marmaronetta angustirostris* and White-tailed Eagle *Haliaeetus albicilla*. Some of them, such as the Dalmatian Pelican, Lesser White-fronted Goose, Marbled Teal and Corncrake *Crex crex*, are globally threatened. The lagoons thus directly contribute to the conservation of these and other rare birds. The Turalin and Sulak lagoons are the most important as, unlike others, they are little affected by fluctuations in the level of the Caspian Sea and changes in groundwater levels because of rivers running into them. The ecological importance of the lagoons continues to grow as most birds migrating through this region now stop here regularly to rest and feeding; whilst some nesting birds have since spread along a wider area of the central Daghestan Caspian coast.

The lagoons of Daghestan are unique and have transformed a coast previously deserted and scorched by the sun into a unique wetland filled with life. Now the lagoons are a popular place for zoological excursions, where anyone can become

familiar with the biodiversity of the region. The gulfs are unique places for ecological education and training, where not only young ornithologists and ecologists, but also teachers, biologists, students and pupils can learn. This “open-air study” will undoubtedly develop an active environmental and civic responsibility in the new generation, and change society as a whole.

The increased numbers of fish and birds now attract poachers who hunt for anything from the widespread Coot *Fulica atra* or Purple Gallinule *Porphyrio porphyrio* to the ordinary wild duck, endangered Ferruginous Duck *Aythya nyroca*, Red-breasted Geese *Branta ruficollis* and Lesser White-fronted Geese. However, poaching does not cause as much devastation as the remodeling of the beach around the Turalin lagoon, where a four hectare area of sandy bar separating the lagoon from the sea was leveled in the spring of 1999. That September, drainage of the lagoon was begun through a deep channel connected to the sea. The level of water in the lagoon catastrophically decreased by 0.7-0.9 m, causing a reduction in the composition, number and species of waterfowl present.

The fact is that the land occupied by Turalin lagoon represents a perfect place for the construction of country villas, where future owners, potentially ignorant of their own actions may one day replace the lagoon with luxury housing. This means that the Turalin and Sulak lagoons are under active threat of destruction. The unique habitats as well as a number of new bird species will be lost forever unless we undertake urgent measures to preserve them. In this respect there is an urgent necessity to establish Natural Areas of Preferential Protection (NAPP) in the area of the two most important lagoons of Daghestan: Turalin and Sulak. Fortunately, three years ago the author of this paper managed to register these wetlands in the official list of “Key Ornithological Territories of Russia of World Importance.” Subsequently, two projects aimed at the establishment of NAPP in areas of Turalin and Sulak lagoons were prepared and passed assessment by the Ministry of Nature of the Republic of Daghestan, the Makhachkala Interregional Committee on Ecology and Nature Management of the Makhachkala Administration with the Center of Preservation of Biodiversity at the State Committee of Ecology of Russia, and the Union of Protection of Birds in Russia.

In 2000, the ornithological association of pupils “Berkut,” together with the research club “Ecosphere” (Azerbaijan) successfully implemented a project called “Ecological education of pupils for revealing potential NAPP along the Western Caspian Coast”. This bilateral project has received the highest marks of experts in the Initiative for Social Action and Renewal in Eurasia’s (ISAR) Caspian Program. This group is currently trying to promote the establishment of ornithological micro-reserves at Turalin and Sulak lagoons through the city administration, and urging the Government of Daghestan to promote the official assignment of NAPP status to these areas.

## An overview of the Office National de la Chasse et de la Faune Sauvage (ONCFS) research programmes on Anatidae

Schricke, V. 2006. An overview of the Office National de la Chasse et de la Faune Sauvage (ONCFS) research programmes on Anatidae. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 373.

The Office National de la Chasse et de la Faune Sauvage (ONCFS) Anatidae research team have developed programmes on duck and geese population dynamics, studies of monitoring schemes, waterfowl habitats, and hunting bags, and contribute to several actions at European and international scales, such as the EU management plan for species with an unfavourable conservation status (Schricke 2001, 2002), and the African-Eurasian Waterbird Agreement international action plan for the Dark-bellied Brent Goose *Branta b. bernicla*.

The duck population studies concern Teal *Anas crecca*, Pochard *Aythya ferina* and Tufted Duck *Aythya fuligula*. A new research program in 2002 included the launch of a new ringing and marking scheme involving individual nasal marks applied to several hundred birds in 2003, a population dynamics model based on capture-recapture (in contrast to previous models using other parameters and population sizes), and behaviour-based individual models with predictive aspects (Guillemain *et al.* 2003). These studies were made in cooperation with CNRS Montpellier and Chizé, University of Coimbra (Portugal) and Kristiansad (Sweden).

A further research programme, concerning the physiological state of ducks in winter, has been undertaken in cooperation with CNRS Strasbourg; the main objective being to build a model to estimate the body condition of four species, Teal, Pochard, Tufted Duck and Mallard *Anas platyrhynchos* in normal winters or during cold spells.

Studies of geese are focussed on two species: Brent Geese, in co-operation with CNRS Chizé (involved in the EU funded Coast Bird Diversity programme); and Greylag Geese *Anser anser*, studied on the Atlantic coast to determine how geese use saltmarshes in relation to different management actions and disturbances (Fritz *et al.* 2004), and also, on the Mediterranean coast, to determine the impact of Greylags on the increasing use of *Scirpus maritimus* communities in a nature reserve (in co-operation with Tour du Valat, Camargue).

Monitoring schemes at a national scale include: midwinter counts in co-operation with Ligue pour la Protection des Oiseaux (BirdLife France), winter counts during December to February, studies of spring migration and breeding chronology, and at an international scale: waterfowl monitoring in West Africa, particularly since 1989 in the Senegal Basin in co-operation with Wetlands International and the Senegal National Parks Directorate (Diouf *et al.* 2003). Waterfowl habitat studies include the impact of management of a maritime hunting reserve on wintering ducks (Baie du Mont Saint-Michel), the evaluation of trophic potential for ducks, and the management of pond banks for breeding ducks.

Rabarisoa, R., Rakotonomenjanahary, O. & Ramanampamonjy, J. 2006. Waterbirds of Baie de Baly, Madagascar. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 374-375.

The Baie de Baly, Mahajanga province, is located c. 450 km north-east of Antananarivo, the capital of Madagascar. It is in the centre of the 57 418 ha National Park of Baie de Baly, created in December 1997, and was identified as an Important Bird Area in 1999. The establishment in 1999 of a commercial shrimp farm inside the mangrove habitat, necessitated the development of a strategy to maintain the stability of the wetland ecosystem. Since 2000, the Malagasy League for Bird Conservation in Madagascar (Asity) in collaboration with the shrimp farm society "Aquaculture des Macareigne" have made regular visits to record waterbirds as a tool for monitoring changes to the wetland ecosystem.

The survey site (15°57' - 16°08'S, 45°17' - 45°27'E) includes 7 200 ha of mangrove, 700 ha of marshes, approximately 35-40 km of rivers and coast, and the 300 ha Sarika lake. The mangrove vegetation is dominated by *Avicennia* spp. and *Rhizophora* spp. with 220 ha of the mangrove area converted into a shrimp farm (Aurant & Rafomanana 1998). Sarika is an open permanent lake (3 200 m long) in a savannah palm area, with dry deciduous forest at its south eastern end. The lake shore is partly covered by aquatic reeds, mostly *Phragmites* spp., used as bird roosts. The marshes are the flood plain of the Amboloboza river which joins the eastern part of the mangrove, and is used by the local community for growing rice.

Since 2000, waterbird counts have been conducted in January, July and September. Surveys were carried out by boat, using African Waterbird Census techniques (Perennou 1991).

During the 12 counts undertaken from 2000 to 2003, 54 species of waterbirds were recorded (Table 1). The most diverse families were Ardeidae (11 species), Charadriidae (nine species) and Scolopacidae (seven species). Seven were endemic Malagasy sub-species (Young *et al.* 1993). Nine other species are also endemic to Madagascar, of which five are globally threatened: the Madagascar Heron *Ardea humbloti*, Black-banded Plover *Charadrius thoracicus*, Madagascar Fish-eagle *Haliaeetus vociferoides*, Madagascar Sacred Ibis *Threskiornis bernieri* and Madagascar Little Grebe *Tachybaptus pelzelni*. In addition, two individuals of Madagascar Squacco Heron *Ardeola idea* were recorded in one count. This species breeds only in Madagascar from October to March and leaves from May to October to spend the austral winter in east and central Africa, visiting coastal and inland waters (Stevenson & Fanshawe 2002). Both Lesser Flamingo *Phoenicopterus minor* and Greater Flamingo *Phoenicopterus ruber roseus* were recorded during July and September visits, but rarely seen in January.

Six species, including Little Grebe *Tachybaptus ruficollis*, Madagascar Little Grebe, African Pygmy Goose *Nettion auritus* and Hottentot Teal *Anas hottentota* were particularly dependent on freshwater lake ecosystems. However, the most important waterbird concentrations, mainly waders and herons, foraged on mudflats near mangroves and in the coastal zone.

During high tide, herons and egrets rested on mangrove trees, and waders and flamingos moved to the back of the mangroves. Two important nesting sites were noted at Sarika lake: a nesting and roosting site for the Yellow-billed Stork *Mycteria ibis* and Madagascar Sacred Ibis and a nesting area for Darter *Anhinga rufa*, Cattle Egret *Bubulcus ibis*, Dimorphic Egret *Egretta dimorpha*, Great Egret *Egretta alba*, and Madagascar Sacred Ibis in a group of mangrove trees in the eastern part of the study area, which is also used by roosting bats *Pteropus rufus*.

Five tern species frequent the Bay de Baly, the most important being the migratory Lesser Crested Tern *Sterna bengalensis* (now known also to breed in north-west Madagascar, Le Corre & Bemanaja 2004) and the Common Tern *Sterna hirundo*. Two species breed in Madagascar, Greater Crested Tern *Sterna bergii* and Caspian Tern *S. caspia* (Goodman & Benstead 2004), whilst the others are migratory. These species usually frequent the bay and were abundant during January, but were infrequent or absent in July and September. Lesser Crested, Greater Crested and Caspian Terns were attracted by the shrimp farm and sometimes followed fishing boats all along the coast. The fifth species, Saunderson's Tern *Sterna saundersi* was always seen inside the bay near the mangrove estuary. Changes in physico-chemical parameters inside the shrimp farm force shrimps to the surface which attracts terns and other bird species like the Dimorphic Egret *Egretta dimorpha* and Black Kite *Milvus migrans*.

Out of the 19 migratory species recorded, 16 were Palaearctic waders, but numbers were very low compared with those visiting mainland African wetlands. Only one species, the Crab Plover *Dromas ardeola*, occurred in numbers over their 1% population threshold. The Pacific Golden Plover *Pluvialis fulva* is considered as a vagrant species in Madagascar (Goodman & Benstead 2004) but was seen regularly in low numbers, two to six individuals, in the coastal area of Baie de Baly, usually associated with other waders such as the Greater Sand Plover *Charadrius leschenaultii* and the Common Greenshank *Tringa nebularia*. Numbers of migratory waders are low in July and September, but much higher in January.

Despite four years of regular monitoring, it is likely that not all waterbirds using the area have been recorded. For example, the Madagascar Teal *Anas bernieri*, a globally threatened and endemic species to Madagascar, was recorded in the mangroves in 1999 (Safford 1993), but has not been seen during monitoring counts.

From the waterbird monitoring, the Baie de Baly has been identified as qualifying as a wetland of international importance since it supports more than 1% of the populations of 12 waterbird species (Wetlands International 2002). Of these, five species exceeded 1% thresholds in at least half the counts: Dimorphic Egret, Madagascar Heron, Madagascar Sacred Ibis, Madagascar Openbill *Anastomus lamelligerus madagascariensis* and White-fronted Plover *Charadrius marginatus*. In addition, three pairs (6% of the world population) of the Madagascar Fish-eagle were

regularly recorded at Baie de Baly (Rabarisoa *et al.* 1997).

Using waterbirds as a tool to monitor changes in the wetland ecosystem has led to recommendations that both the National Park and Shrimp Farm management take measures to avoid biodiversity loss. The presence of a shrimp farm in the National Park requires not only good collaboration between these two institutions but also the involvement of local authorities. Shrimp aquaculture attracts many people for employment which in the long term can threaten biodiversity without any adequate prevention. Recommendations have been made for an effective public awareness campaign concerning the importance of wetland biodiversity and the sustainable use of natural resources, since commercial shrimp farming can induce changes in natural resource use and livelihoods resulting in environmental deterioration through the acceleration of mangrove habitat destruction, water pollution, land encroachment, and social disruption (Barracough & Finger-Stich 1996). Continued waterbird monitoring is recommended to provide early warning of any changes in the Baie de Baly wetlands.

## ACKNOWLEDGEMENTS

We would like to thank all counters for their active participation and the following institutions for their support: the Aquaculture des Mascareignes (Aquamas), The "Eaux & Forêts" representative at Soalala, the Commune of Soalala, the "Association National pour la Gestion des Aires Protégées" (ANGAP), Wetlands International, and the Ministère de l'Environnement à Madagascar.

## Trends in numbers of migrant waders (Charadrii) at Langebaan Lagoon, South Africa, 1975-2003

Doug M. Harebottle<sup>1</sup>, Rene A. Navarro<sup>1</sup>, Les G. Underhill<sup>1</sup> & Manfred Waltner<sup>2</sup>

Harebottle, D.M., Navarro, R.A., Underhill, L.G. & Waltner, M. 2006. Trends in numbers of migrant waders (Charadrii) at Langebaan Lagoon, South Africa, 1975-2003. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 376-378.

Population trends of seven Palearctic wader species were investigated at Langebaan Lagoon, South Africa. Over 28 years, summer (January/February) counts indicated there were major declines for Curlew Sandpiper *Calidris ferruginea*, Red Knot *C. canutus* and Sanderling *C. alba*, and smaller declines for Grey Plover *Pluvialis squatarola* and Ruddy Turnstone *Arenaria interpres*. In contrast, data for Whimbrel *Numenius phaeopus* and Bar-

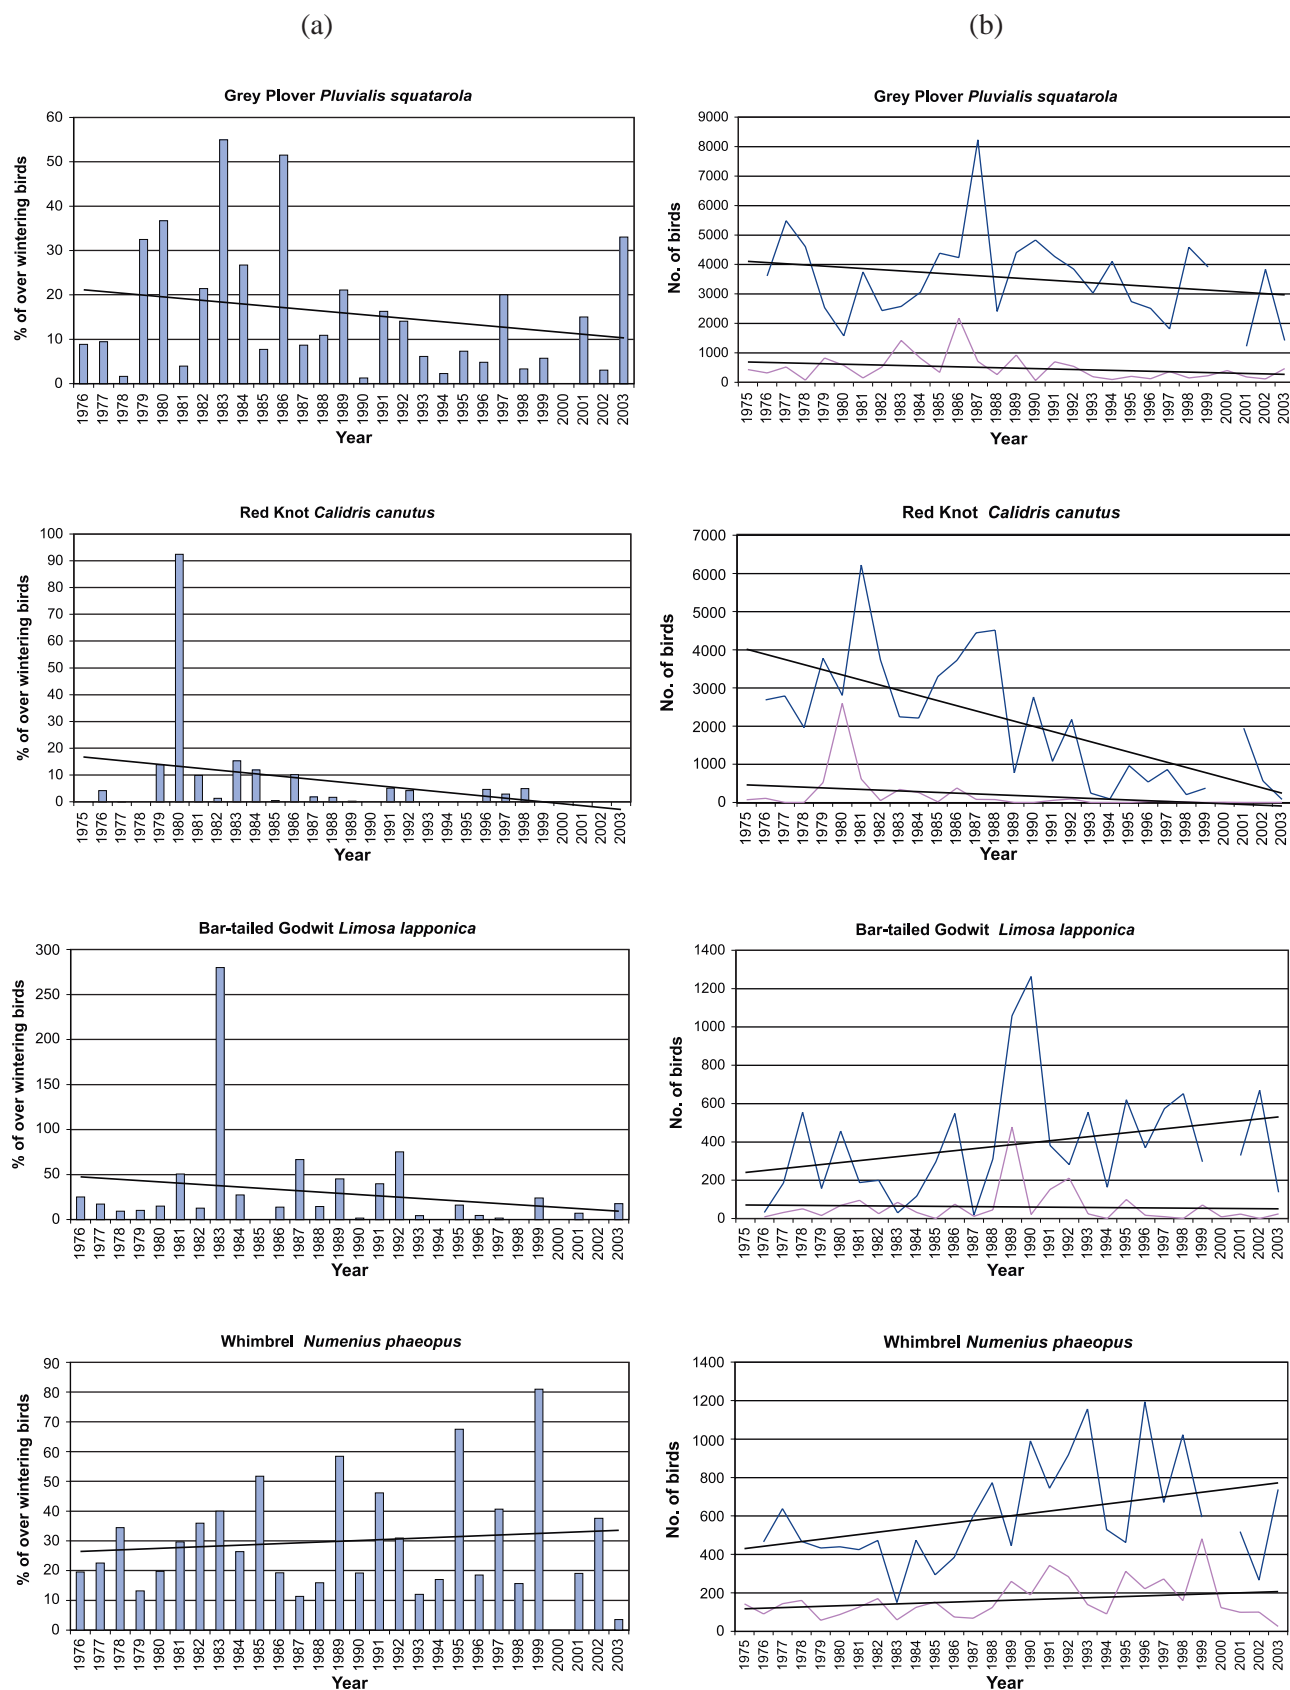

tailed Godwit *Limosa lapponica* suggest that populations may be increasing. Winter counts (July/August) were used to assess breeding productivity based on over-wintering juveniles and suggested declining productivity for Grey Plover, Curlew Sandpiper, Ruddy Turnstone, Red Knot and Bar-tailed Godwit. The results are discussed in light of monitoring population changes for Arctic waders at the end point of their migratory range.

(a)

(b)

A large number of Palearctic waders occur annually during the austral summer at Langebaan Lagoon which is the southernmost major wetland on the East Atlantic and West Asia/East Africa Flyways (Underhill 1987). Counts of migrant waders at this locality started in 1975 and an earlier analysis of this dataset revealed no clear trends for migrant wader species (Underhill

1987). This paper updates (for 1975-2003) trends for seven of the most common migrant wader species occurring at the lagoon.

Langebaan Lagoon is a large (5 600 ha), sheltered arm of Saldanha Bay situated on the west coast of South Africa. It is located within the West Coast National Park, which is also a

designated Important Bird Area (Barnes 1998). The lagoon was designated as a Ramsar site in 1988 and includes 1 650 ha of intertidal sand- and mudflats and over 600 ha of saltmarshes, the latter representing about 32% of the total saltmarsh habitat in South Africa. Most Palearctic waders are found in these saltmarshes.

Bi-annual counts of non-breeding Palearctic waders and other waterbirds have been conducted at Langebaan Lagoon since July 1975. Data from 28 mid-summer (January/February) counts were used to determine long-term trends using linear regression while data from the 28 mid-winter (July/August) counts were used to assess breeding productivity based on the proportion of over-wintering juveniles (see Summers *et al.* 1995).

Population trends (summer) and breeding productivity (winter) are shown for Grey Plover, Ruddy Turnstone, Curlew Sandpiper, Sanderling, Red Knot, Bar-tailed Godwit and Whimbrel in Fig. 1.

Declines are evident for Curlew Sandpiper, Grey Plover, Red Knot, Sanderling and Knot, but are most noticeable for Curlew Sandpiper, Red Knot and Sanderling. In contrast, an increasing trend in numbers is evident for Whimbrel and Bar-tailed Godwit.

In terms of breeding success, trends suggest declining productivity for Curlew Sandpiper, Ruddy Turnstone, Red Knot, Bar-tailed Godwit and Grey Plover.

This analysis has demonstrated that population trends of arctic waders can be monitored at the end point of their migratory range, which may be significant in light of these wetlands being sensitive to global climate change and changes in overall population sizes. Future monitoring at the lagoon should focus on more frequent (i.e. monthly) monitoring in order to reduce the variability of the six-monthly counts.

We thank the Western Cape Wader Study Group and numerous other observers for helping with the counts; South African National Parks are thanked for permission to conduct

The southern shoreline of Langebaan Lagoon. Photo: Doug Harebottle.

counts in the West Coast National Park; The National Research Foundation provided financial assistance.

## The breeding sites and distribution of Red-crested Pochard *Netta rufina* in Hungary

Attila Bankovics

Hungarian Natural History Museum, H-1088 Budapest, Baross u. 13. Hungary.

Bankovics, A. 2006. The breeding sites and distribution of Red-crested Pochard *Netta rufina* in Hungary. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 379.

The Red-crested Pochard *Netta rufina* is one of the least studied European duck species (Keller 2000). Overall breeding distribution in the western part of Europe in the first half of the 20th century is well reported (Cramp *et al.* 1977), but its occurrence and current status in the Carpathian basin is less well known. Hagemeyer and Blair (1997) mentioned it, but even recently published field identification books on European birds do not show Hungary as a breeding area for Red-crested Pochard. This paper summarises the current status of this species since its status has changed in Hungary during the last three decades.

Sporadic records published in different Hungarian ornithological periodicals and this author's, so far unpublished, observations were compiled, covering records from the period between 1960 and 2003.

Until 1960 Red-crested Pochard was one of the rarest duck species in Hungary. Keve (1960) mentioned only 16 earlier records. Between 1960 and 1975 observations increased slowly with a total of 23 records by 1975, i.e. seven new observations were made in this 15 year period (Keve 1976, 1984, Schmidt 1973). The first four of which came from Transdanubia.

There were three observations in the eastern half of Hungary in the spring of 1967 at Petőfiszállás, on Lake Péteri, with three males and one female observed on 12 and 15 March and one male and one female on 3 April (Bankovics 1968).

Since 1975 the number of records has grown more rapidly. There were 33 new reports between 1975 and 1983, most from the Lake Fertő area in Transdanubia (Kárpáti 2000). During that period the species was regarded as a rare, but regular, passage migrant in Hungary.

The first breeding of Red-crested Pochard was proved in 1986 at two breeding sites: the Kis-Balaton (in the newly established water-reservoir) and Lake Fertő (Futó 1990, Kárpáti 1987). Since then it has become a regular breeding bird in both sites and has begun to spread as a breeding bird, initially into the area of Transdanubia in the western half of the country.

From the mid-1990s Red-crested Pochard have started to occupy new breeding sites east from the Danube, in the area between the Danube and the Tisza rivers. It has bred at Lake Riha on Mohács Island in the Danube in the Duna-Dráva National Park (Kárpáti 2000). In 2003 it was first confirmed as breeding in Dzsidva Fishponds at Szakmár (Tamás, Ádám pers. comm.). The breeding population has also continued to spread in the Transdanubian region, in 2001 there was a new breeding site in the Fertő-Hanság National Park, in the Hanság region at Bösárkány (Bankovics *et al.* 2002).

The most important recent breeding sites and the estimated numbers of breeding pairs (in parenthesis) are: 1. Lake Fertő (30),

2. Hanság (2), 3. Kis-Balaton (20), 4. Fonyód (5), 5. Balatonlelle (5), 6. Dinnyés (15), 7. Mocsá (3), 8. Rétszilas (3), 9. Soponya (3), 10. Riha-tó (Mohácsi-sziget) (3), and 11. Szakmár (1).

Comparing numbers of Red-crested Pochard in Hungary between the 1960s and the 1990s indicates major changes: it was a rare vagrant until the mid-1960s, became a regular visitor locally after 1975, and a regular passage migrant in the 1990s. It has bred in Hungary since 1986, with a current estimated breeding population of approximately 90 pairs.

I am grateful to Erika Bankovics and Orsolya Mile for their help in elaborating the data, Péter Batáry for helping with the English translation and all the field-workers for providing the records.

## The Lesser White-fronted Goose *Anser erythropus* at the verge of the millennium

Vladimir V. Morozov

Russian Research Institute of Nature Protection, Znamenskoye-Sadki, Moscow, 113628, Russia.

Morozov, V.V. 2006. The Lesser White-fronted Goose *Anser erythropus* at the verge of the millennium. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 380-381.

This paper analyses the current state of the Lesser White-fronted Goose *Anser erythropus* in Russia, discusses present threats and proposes conservation measures.

Members of a specially formed Lesser White-fronted Goose group undertook a number of field trips to ring and mark Lesser White-fronted Geese in breeding areas in Western Siberia, Taimyr, and Yakutia and the Bolshezemelskaya tundra.

One of the main goals of the field studies was to obtain information on the current migration stopover sites of the Lesser White-fronted Goose and on the location of their wintering grounds. Previously, we had postulated the existence of several geographical populations of the Lesser White-fronted Geese which differed greatly in numbers and habitats (Morozov 1995). New data did not confirm this supposition: on the contrary, the results of satellite tracking of birds marked in Fennoscandia and ringed on the Polar Urals favoured the concept of a single population inhabiting the territories from the north of the Scandinavian peninsula to the east of Taimyr. Nevertheless, the structure of mtDNA of the Fennoscandian Lesser White-fronted Geese differs considerably from that of the birds from other areas of the species' breeding range (Ruokonen & Lumme 1999), indicating a great degree of isolation and allowing us to consider them as a separate geographical population.

Lesser White-fronted Geese inhabiting the tundras of European Russia, like some Fennoscandian ones, cross the Ural mountains in autumn heading to the Turgaiskaya depression. Migration routes of Lesser Whitefronts with satellite transmitters demonstrate that geese from breeding grounds located in the European part of the Russian tundras cross the Ural and migrate along the Ob River valley to the stopover sites in Northern Kazakhstan (Morozov & Aarvak in press).

The migration stopovers in Northern Kazakhstan gather Lesser White-fronted Geese not only from Taimyr, Gydan and Yamal but also from the Bolshezemelskaya tundra and even Fennoscandia, as demonstrated by the structure of mtDNA of the birds hunted in Kazakhstan (Ruokonen & Lumme 1999). Unfortunately, no data on migrations of the Lesser White-fronted Geese nesting east of Taimyr confirmed by ringing or marking results are available. The structure of mtDNA of the geese shot in China indicates a considerable genetic isolation of these birds (Ruokonen & Lumme 1999). However, we know nothing about the distribution of these individuals within the breeding grounds because no samples have been collected there. Thus, we can only assert that the eastern part of the breeding range of this species is occupied by at least one geographic population, though the existence of more than one is also possible.

The total estimate presented in the previous review was 30 000–50 000 individuals at the end of the breeding season (Morozov 1995). The number of 50 000 birds was rather an assumption, because we had no data on the Lesser White-fronted

Developing awareness of the conservation needs of waterbirds, including the requirement to limit hunting, is key in Russia and neighbouring countries. Awareness mural, Dunaiskie Plavni Nature Reserve, Danube Delta, Ukraine. Photo: David Stroud.

Goose numbers on Taimyr, which was supposed to be inhabited by one of the largest territorial groups of these geese. The first special studies carried out on Taimyr have yielded quite different results: numbers of Lesser White-fronted Geese appear to be much lower than expected (Syroechkovski Jr. 1996), and the total number inhabiting Taimyr and the areas west of it was re-estimated at 8 500–17 000 birds (Lorentsen *et al.* 1999).

Analysis of the current estimates made on the migration stopovers in Kazakhstan suggest that the present numbers of the species may be estimated by the end of the breeding season as follows: Western Siberia and Taimyr, including the Putorana Plateau - 8 000 to 11 000; Kanin Peninsula and Taimyr - 9 000 to 12 000. Winter censuses conducted in China over the last years are fairly reliable, and we agree with the mid-winter estimate of 12 000–17 000 inhabiting Yakutia and the Far East. The total world population of the Lesser White-fronted Geese in the post-breeding period may thus be 20 000 to 25 000 individuals in different years, although the estimate of our colleagues from Western Europe is 24 000–30 000 individuals (Lorentsen *et al.* 1999, Markkola 2001).

Increased mortality of birds due to the hunting pressure along the migration routes and on the wintering grounds is considered now the main and virtually the only cause of the decline in numbers. The losses of the marked birds during migration vividly demonstrate a very high mortality rate in this population after the breeding season (Loretsen *et al.* 1998, 1999, Øien *et al.* 1999). However, other populations also suffer from both legal and illegal hunting. For example, in autumn 2000, eight people using poisoned grain baits killed 667 Lesser White-fronted Geese at Lake Dongting (Lei 2001): 5 to 10% of the total number of this species wintering in China. Population losses on the wintering grounds will be considerably higher, taking into account the difficulties in distinguishing the Lesser White-fronted Geese from the White-fronted Geese in flight, the low level of the public hunting standards, and the fact that the hunting legislation is very often violated in Russia and in a number of neighboring countries (Ukraine, Kazakhstan and Azerbaijan).

Hunting pressure, especially in spring, is a crucial factor in the dramatic decline of the Lesser White-fronted Goose, which is the rarest goose species in Eurasia. The following measures seem realistic and constructive:

- wider advocacy of Lesser White-fronted Goose protection by hunters' societies and the Department of Game Management at the federal and regional levels;
- strict regulation and banning of hunting on all goose species in spring and autumn along the migration routes, on the breeding grounds and in the stopover sites; and
- support for professional and qualified amateur ornithologists in Lesser White-fronted Goose studies.

The widespread and long-term retreat of glaciers in Greenland is a signal of the changes currently occurring in the arctic environment. Modelling has shown that climate change will profoundly affect the extent and ecological character of arctic waterbird habitats. Photo: David Stroud.

Climate determines the distribution and movements of waterbirds and the wetland habitats they use. Global climates, however, are changing, and as a result of human activities are doing so faster than historic levels. Importantly, species within communities will respond differently to climate change, and will alter their distribution at different speeds, thereby creating the potential to form new assemblages. Some waterbird populations will be able to track changes in resource/habitat distribution (Rehfishch & Austin give examples of changing distributions of wintering waterbirds in the UK), although some will not be able to adapt in this fashion. In relation to climate changes and waterbirds the research community has four key conservation challenges, outlined below,

### 1. To describe what will happen

To be able to tease out effects of climate change from long-term fluctuation and effects of a range of human activities, there will be a need for relevant information and data at the flyway level. A further need will be to understand impacts of climate change on wetland processes and functions, as well as some of the 'hidden' effects of climate change on waterbird populations, such as some of the subtle differential effects of return rates of seabirds to their breeding colonies (as described by Favero & Becker). It will also be important to understand the capacity of waterbirds to react to extreme weather events, and to understand and agree what constitutes a 'significant' population change.

### 2. To identify where it will happen

The generic challenges will be to identify potential changes in the distribution of flyway resources (both abiotic and biotic), and to predict how waterbirds will spatially track these changes.

### 3. To develop or enhance research methods

There will be a need to ensure research access to relevant data and information as well as the supporting development of appropriate methods for determining what will happen and where it will happen (above).

### 4. To support the action agenda

It will be particularly important to facilitate the flow of relevant information and data to support the action agenda, for example as part of action plans within flyway Agreements and other multilateral instruments. It is therefore of high priority to ensure that the results of climate change studies are disseminated appropriately and that stakeholders are engaged fully at all stages of future research.

As well as undertaking new work to fill gaps in current knowledge, scientists must also consider how to utilise the considerable amount of information that is already available for analysis. There is also a universal need to support financially the continuance of long-term, wide-scale monitoring of species and habitats. These data are the foundation on which our response and adaptation to climate change will be based.

The consequences of climate change for waterbirds will be multiple and greatly exacerbate ongoing negative impacts such as habitat loss and degradation. Landscape scale planning will be required to reduce or mitigate the impacts of climate change on waterbird populations and their habitats. Research that explores a range of potential future scenarios will therefore be required to underpin this landscape scale planning, and will need data from long-term monitoring and surveillance (as described by O'Connell *et al.* in the specific case of north-west European goose populations).

## Developing an integrated approach to understanding the effects of climate change and other environmental alterations at a flyway level

### ABSTRACT

The environmental consequences of global climate change are predicted to have their greatest effect at high latitudes and have great potential to impact fragile tundra ecosystems. The Arctic tundra is a vast biodiversity resource and provides breeding areas for many migratory geese. Importantly, tundra ecosystems also currently act as a global carbon "sink", buffering carbon emissions from human activities. In January 2003, a new three-year project was implemented to understand and model the interrelationships between goose population dynamics, conservation, European land use/agriculture and climate change. A range of potential future climate and land-use scenarios will be applied to the models and combined with information from field experiments on grazing and climate change in the Arctic. This paper describes the content of the research programme as well as issues in relation to engaging stakeholders with the project.

### INTRODUCTION

#### Changes to European landscapes

Socio-economic, agricultural and demographic changes have imposed modifications on the European landscape to such a degree that habitats over most of the region have been altered in some way, degraded, or removed entirely. Although many of these changes have resulted in negative impacts for European fauna and flora, some species have benefited, and indeed increased their distribution and abundance to a point where they come into "conflict" with human interests (Patterson 1991, Cope *et al.* 2003). In addition to the direct impacts of change on different elements of the European landscape, human activities involving the burning of fossil fuels during the last two hundred years have now altered climate and weather patterns beyond pre-industrial "background" levels (Jones *et al.* 1998, Huang *et al.* 2000, IPCC 2001, Jones & Mann 2004). Many of these environmental alterations have not been in the form of large "step" changes, but have often been slow, insidious, ongoing, patchy, and spread over wide spatial extents. These characteristics complicate efforts to detect and measure the changes as they happen, and to predict future patterns of change. They also make it difficult for appropriate authorities to develop strategies to halt and reverse the impacts of such change (O'Connell & Yallop 2002, Caro *et al.* 2004).

#### Changes to European migratory goose populations

The relatively large size and aggregative behaviour of geese, coupled with a large number of skilled volunteer observers

across Europe, have made it possible to measure general changes in goose populations, i.e. overall abundance, distribution, and use of key sites (for a review, see Madsen *et al.* 1999). Long-term and large-scale capture-recapture efforts (e.g. ringing) have also produced data that can be used to model the trajectory of goose populations by analysing the demographic factors of survival, fecundity, dispersal and recruitment (e.g. Alisauskas 2002, Cope *et al.* 2003, Frederiksen *et al.* 2004). However, quantifying general changes in goose abundance and knowing their population trajectory does not necessarily provide an understanding of the causes of the changes in measured demographic parameters, or facilitate the development of holistic approaches to conservation strategies (i.e. those encompassing the widest possible range of biotic, abiotic and human factors that operate at an ecosystem or landscape level).

#### Holistic research: the "ecosystem approach"

The term "ecosystem" came to prominence in the 1930s, but had been in use as a general concept since the 1860s (Botkin 1990). The view of populations connected through interactions with their proximate biotic and abiotic environment developed into a paradigm where ecological groupings were viewed within reasonably closed and self-regulating systems. Ecologists later expanded these ideas within a framework of "systems analysis" which provided a methodology to understand very complex systems and feedback loops (Odum 1953). However, the "ecosystem approach" (Hartig *et al.* 1998, Wang 2004) has a number of conceptual problems. O'Neill (2001) highlighted three key issues: (1) the selection of elements to be included within a named ecosystem is often subjective and based on *a priori* knowledge; (2) ecosystem research foci are often selected subjectively and based on favoured or "easy target" ecosystem elements; and (3) human activities are invariably seen merely as "external" disturbances to ecosystems.

In relation to ecosystem management, a further critical assessment was made by O'Connell (2003) who identified five assumptions underlying actions to protect ecosystems and manage them on a sustainable basis:

- There is adequate inventory and monitoring to provide appropriate information for action;
- That change in the ecosystem can first be detected and then measured;
- That it is possible to identify the underlying causes of change;

- d) There is the ability to predict the likely consequences of change in all parts of a system; and
- e) There is knowledge of remedial action to halt or reverse the detected and measured change.

In most cases, these assumptions will not be met, and there is a great deal of fundamental research needed to address this situation.

### The “flyway” concept

Migratory birds also raise additional difficulties for the ecosystem approach. Migration results in species moving between and within a variety of “systems”, and this presents problems when trying to understand the full range of their environmental interactions and population drivers. To address some of these problems, the idea of avian “flyways” was developed. Conceptually, a flyway can be thought of as possessing ecosystem-like qualities (i.e. many interacting biotic and abiotic elements interacting within a relatively closed and self-sustaining system). But for practical applications, a flyway can also be defined simply as the network of sites (and routes) required to fulfil the annual life cycle of individuals within a migratory population. As well as providing a useful research framework for migratory species, the flyway concept also facilitates trans-boundary conservation measures and monitoring (Boere 2003).

### Integrated flyway studies

An increasing number of migratory bird studies are being made at the conceptual level of flyways, i.e. they consider life-history events at the breeding, non-breeding and migration sites (Francis *et al.* 1992, Hoffman *et al.* 2002, Hötter *et al.* 1998,

Malcolm & ReVelle 2002, Otis 2004). However, although covering appropriate spatial scales, many of these studies still focus on only one or a small number of life history factors occurring at this scale, e.g. survival, habitat requirements, hunting levels, phenology, etc. Data limitations and research costs mean that few studies have been able to take a more holistic “whole system” approach integrating the large number of different biotic and abiotic elements impacting both species and landscapes within a flyway. The potential benefit of an integrated approach is to go beyond quantitative description, and to generate an understanding of the relative importance of different processes within a flyway system and how these interact at different spatial and temporal scales. In turn, this provides a means to forecast the likely impacts of change on individual system elements, and explore system responses under a combination of different environmental change scenarios. The central components of a framework for flyway level research is shown in Fig. 1.

### COMPONENTS OF ARCTIC BREEDING GOOSE FLYWAYS

Eight species of geese breed on Arctic tundra habitats in the European Arctic (mostly beyond 65°N) and migrate to wintering grounds in climatically temperate zones (generally between 40°N and 60°N). The study described in this paper refers to a Northern Hemisphere flyway where two goose populations utilize tundra systems on the Svalbard archipelago for breeding and then migrate (via a number of stopover sites) to wintering areas on estuarine and agricultural habitats in north-western Europe. The two goose populations (described in detail below) have very different breeding site requirements and feeding ecology, and have spatially separated wintering areas.

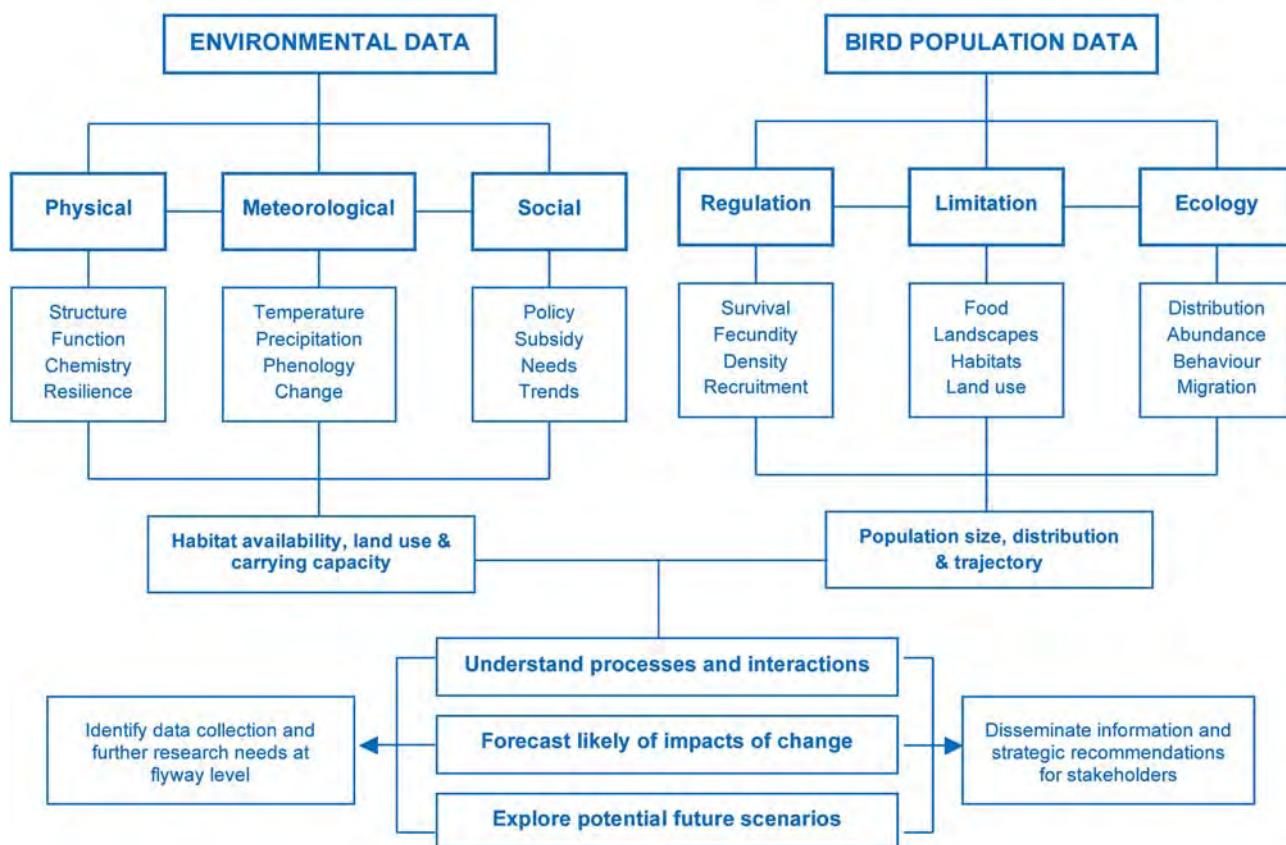

Fig. 1. Information needs and analytical outcomes of a flyway-level, integrated research approach.

### Structural and functional characteristics of tundra

Globally, tundra habitats cover approximately 9% of the world's surface (Clausen 1996), with Arctic tundra occupying a circum-polar area of nearly six million sq. km. Tundra is characterized by low biotic diversity, short and simple vegetation structure, and shallow root systems. Many of the 1 700 species of plants recorded in the Arctic region can photosynthesize at low temperatures and light intensities, and most are wind-adapted and robust to soil perturbation (Epstein *et al.* 2004). Tundra soils are generally thin, generated slowly, seasonally thawed, and lie on a layer of permanently frozen subsoil (permafrost) consisting mostly of gravel and finer material. This vertical profile results in poor drainage, and where water saturates the upper surface, bogs and ponds are often present. Rainfall varies considerably within the Arctic region, but average yearly precipitation (including melting snow) is often less than 25 cm.

This combination of physical, chemical and climatic factors results in environmental conditions where atmospheric carbon dioxide is sequestered by tundra habitats, which have been estimated to contain up to 30% of the world's soil carbon stocks (Gilmanov & Oechel 1995, Waelbroeck *et al.* 1997, McGuire *et al.* 2002). This makes tundra systems particularly important in terms of global carbon balance. Tundra plant communities which are grazed by geese are often dominated by graminoids and bryophytes. However, elevated temperatures and over-grazing by geese cause a shift towards increased graminoid and decreased bryophyte dominance, and result in warming and drying of the soil, faster nutrient cycling, and increased carbon efflux. Another key characteristic of tundra ecosystems is their low nutrient status, particularly in relation to nitrogen. Increases in the rate of nutrient cycling may result from both soil warming and grazing. This is known to alter species composition and increase productivity of both terrestrial and aquatic tundra communities. In addition, increased nitrogen availability decreases the carbon : nitrogen ratio of plant tissue, thus increasing the rate at which it will decompose and hence the carbon efflux from the system (Fahnestock *et al.* 1999, Brooks *et al.* 2005). The responses of habitats to elevated temperatures can be characterized by their sensitivity, adaptability and vulnerability. "Sensitivity" defines the thresholds of climate change that result in altered composition, structure and functioning of an ecosystem. "Adaptability" is the degree to which systems can adjust in response to altered environmental conditions. "Vulnerability" defines the extent to which climate change may damage or harm a system, i.e. is related to both sensitivity and adaptability. Empirical evidence suggests that tundra habitats show high sensitivity, low adaptability and high vulnerability (Forbes *et al.* 2001, Chapin *et al.* 2004).

### Svalbard tundra

The Svalbard archipelago (78°30'N, 18°00'E) consists of nine main islands with an area of just over 62 000 sq. km. The islands are mountainous (up to 1 700 m), with glaciers and snowfields covering more than 60% of the land surface in high summer and 100% in winter. The relatively milder western areas comprise a large number of steep-sided fjords with tundra habitats in the lower drainage basins and river beds.

### Arctic climates and climate change

The Arctic experiences both polar maritime (i.e. influenced by oceanic factors) and continental (i.e. influenced by terrestrial

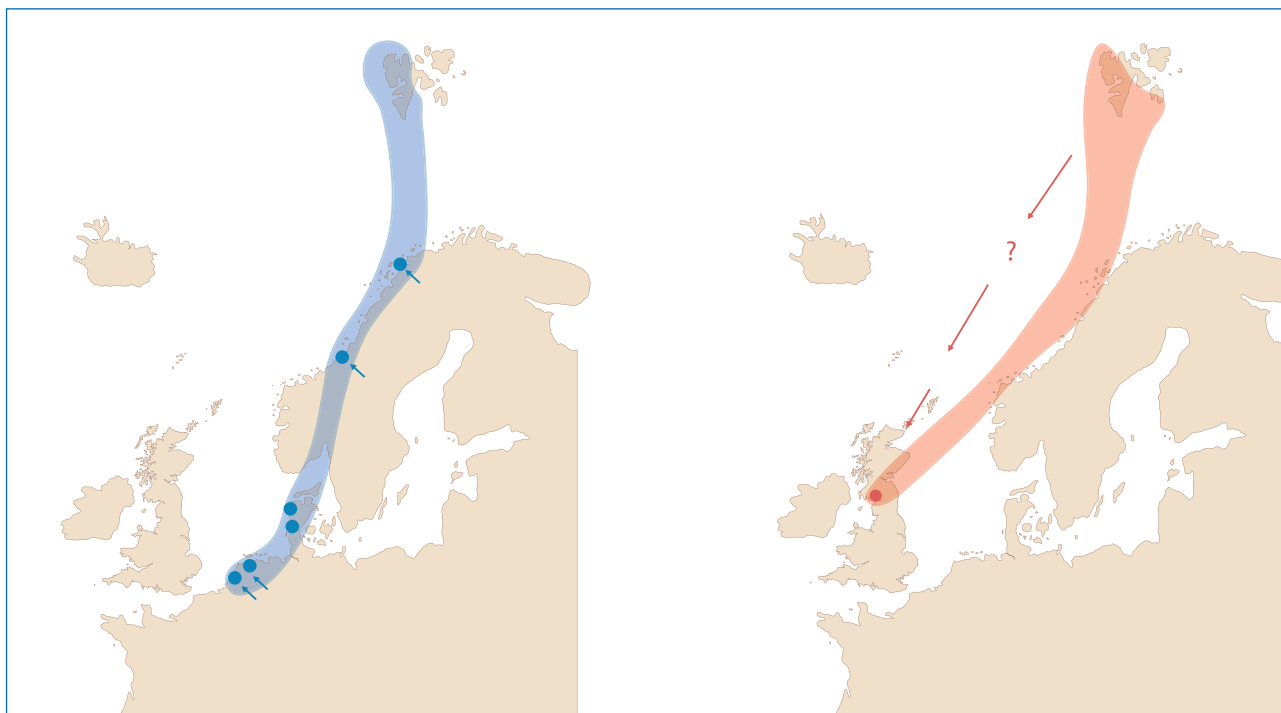

land masses) climates. Weather patterns are characterized by high spatial variability, and although the region receives a large amount of solar energy in summer, the high reflectivity (albedo) of snow and ice surfaces keeps absorption of solar energy low. Heat gained during long summer days can therefore be relatively small. Maritime climate conditions prevail in coastal Alaska, Iceland, northern Norway and adjoining parts of Russia. Winters are often cold and stormy; summers are cloudy but mild with a mean temperature of about 10°C. Annual precipitation is generally between 60 cm and 125 cm, and there are normally at least six months of snow cover. At lower latitudes, "continental" climates result in much more severe winters, although precipitation is lower. Permanently frozen ground (permafrost) is widespread and, in summer, only the top one to two metres of ground thaws. This results in a poorly drained "active layer" that often remains waterlogged and on which tundra habitats can develop.

Since the end of the nineteenth century, the average temperature of the earth's surface has risen by 0.6°C, and sea levels have risen by between 10 cm and 20 cm. By 2100, temperatures are predicted to increase further by between 1.4 and 5.8 degrees, with an additional sea level rise of 9 to 88 cm. The 1990s were the warmest decade of the last millennium, and 1998 the warmest year. Mean air temperatures in the Arctic have increased by about 5°C over the last 100 years, and the extent of sea ice has decreased by 14% since the 1970s. These increases in temperature represent larger changes than any century-long trend in the last ten thousand years (Weaver & Green 1998). By the year 2100, winter temperatures in many parts of the Arctic are predicted to rise by 40% more than the global average change.

### Arctic migratory geese

The Arctic region provides vast areas of relatively disturbance-free wilderness in which animals can breed. There are plentiful food resources (although relatively limited in variety) and, at higher latitudes, up to 24 hours of daylight in which to feed offspring. Approximately 430 bird species breed in the Arctic (Zöckler 1998), of which 130 are migratory waterbirds (Wetlands International 2002). There are 15 species of "true" geese within the genera *Anser* and *Branta*, and 12 of these breed both in the Arctic and elsewhere, with eight breeding exclusively in the Arctic region. Thirty-four subspecies are represented in the region (with 24 exclusive to the Arctic), comprising 67 populations of which 50 breed in the Arctic. The latter group has been estimated to total more than eight million individuals, representing 67% of the total world population of the genera *Anser* and *Branta* (Madsen *et al.* 1996).

All Arctic breeding populations of geese migrate to lower latitudes during the non-breeding season. Many species migrate on a narrow geographical front, with fixed routes and a small number of stopover sites at which the birds rest, socialize and replenish body fat reserves (Choudhury *et al.* 1996, Madsen *et al.* 2002, Prop *et al.* 2003). Traditionally, wintering birds made use of coastal and estuarine habitats, particularly coastal marshes. In these areas, large numbers of birds have been hunted by humans, and by the middle of the twentieth century the population of many species had been reduced to levels that were a fraction of their previous "natural" state (Madsen 1991, Pettifor *et al.* 2000). During the latter half of the century, changes in agricultural practices resulted in new, plentiful and seasonally reliable food sources for wintering geese (van Eerden *et al.* 1996,

**Fig. 2.** Principal breeding, migration and wintering areas of Svalbard Barnacle Geese *Branta leucopsis* (red) and Pink-footed Geese *Anser brachyrhynchus* (blue).

Therkildsen & Madsen 2000). This, coupled with improved legislative protection and positive site management regimes (e.g. refuge areas and cold-weather hunting bans), resulted in a change in the fortunes of many goose populations, many of which are increasing or stable (Wetlands International 2002).

### Svalbard geese

Geese breeding on the Svalbard archipelago are recognized as distinct “populations”, i.e. are groups that do not experience significant immigration or emigration (Wetlands International 2002). The Svalbard Barnacle Geese *Branta leucopsis* breed colonially, mainly in the west of the archipelago. They often (but not exclusively) utilize steep rocky areas, and many colonies are on islands (Mitchell *et al.* 1998). Most of the population overwinters on the Scottish side of the Solway Firth in the UK (Fig. 2), although changes have been occurring in the timing and spatial extent of the population’s wintering distribution. It is likely that the population constituted as few as 300 individuals in 1948, and came close to extinction (Pettifor *et al.* 1998). As a result of conservation measures in the mid-1950s and a switch to feeding on agricultural habitats, there was a gradual increase in the population during the last half of the twentieth century. The population is currently estimated to be nearly 28 000 birds. Although density dependence in productivity and survival has been found on the breeding grounds, it does not appear to regulate the population as a whole. At present the population is growing (Fig. 3a), presumably because birds are still colonizing new breeding habitat (Black 1998, Trinder *et al.* 2005). There is no evidence that the population has reached the carrying capacity of either the summer or winter ranges. If breeding is being regulated by population density, then further increases in population size may be small. Aggregation into relatively confined breeding and wintering areas makes this population vulnerable to stochastic events, such as adverse conditions on

the breeding grounds, disease or adverse conditions during migration. The most sensitive demographic factor is adult survival (Tombre *et al.* 1998, Schmutz *et al.* 1997), and Trinder *et al.* (2005) suggest that the loss of as few as 350 individuals annually produces a median equilibrium population at its current size of nearly 28 000, with the likelihood of long-term population decline increasing markedly if additional annual losses exceeded 1 000.

While Barnacle Geese are restricted to nesting on cliffs or islands that offer protection from Arctic Foxes *Alopex lagopus*, Svalbard Pink-footed Geese *Anser brachyrhynchus* nest more widely in loose colonies on the open tundra, being capable of defending the nest from fox attacks. The species breeds in the western part of Svalbard, whereas in the eastern part, the summer season is too short to execute both nesting and brood-rearing. The population migrates via stopover sites in Norway to wintering grounds in Denmark, The Netherlands and Belgium (Fig. 2). The population increased from 12 000–20 000 in the mid-1960s to 40 000–50 000 by 2003 (Fig. 3b). The rapid increase in the 1970s was probably due to improved survival caused by relaxation of winter shooting pressure (Ebbinge *et al.* 1984), but changes in winter food supplies towards agricultural crops may also have played a role in the more recent increase (Fox *et al.* 2005). Today, the species is still subject to hunting in Svalbard, Norway and Denmark, but hunting mortality does not seem to be a factor controlling population size (Madsen *et al.* 2002).

Although not included in the present study, Brent Geese *Branta bernicla* also breed on Svalbard. The Brent Goose has a circumpolar breeding distribution with a range extending from Greenland to Svalbard and northern Russia, continuing through Alaska to the Canadian Arctic Archipelago. There are three subspecies. One of these, the Light-bellied Brent Goose *B. b. hrota*, occurs generally in the western Arctic (Canada to Svalbard and Franz Joseph Land), and has three distinct popula-

**Fig. 3a.** Svalbard Barnacle Goose *Branta leucopsis* ( $\log_e$ ) population size: 1957 to 2004.

**Fig. 3b.** Svalbard Pink-footed Goose *Anser brachyrhynchus* ( $\log_e$ ) population size: 1965 to 2003.

tions breeding in Canada, Greenland and Svalbard. The population on Svalbard currently numbers only about 5 000 individuals. It is probable that the population was previously around 50 000 individuals during the early twentieth century, but had declined to 2 000 individuals by the 1970s (Scott & Rose 1996), with a more recent recovery to about 6 600 (Denny *et al.* 2004). This decline, in common with other Brent Goose populations, has been attributed to a disease-related die-off in their favoured food resource (eel grass *zostera*), combined with shooting and disturbance. Despite currently being protected throughout its range, the Svalbard Light-bellied Brent Goose population remains depressed and is one of the most vulnerable goose populations in the world. Suggested explanations for this slow recovery include competition with the expanding Barnacle Goose population on Svalbard, and predation there by Polar Bears *Ursus maritimus* and Arctic Foxes (Madsen *et al.* 1989, 1992).

### Herbivory by geese

Grazing by geese and other herbivores can have a large effect on tundra systems (Cooch *et al.* 1991, Jano *et al.* 1998). The selective removal of biomass can alter vegetation composition and the amount and quality of litter produced. Goose grazing can also alter the nitrogen cycle (when goose droppings function as a source of nitrogen), and hence increase the productivity of their forage. It is clear that increases in the populations of geese grazing on tundra will have implications for the carbon and nitrogen balance of the system. Geese have also direct and indirect effects on Arctic freshwater ecosystems, by altering nitrogen and phosphorous regimes in lakes and ponds. For very nutrient-poor sites, faecal droppings provide a valuable input for the systems, while coastal ponds may be severely eutrophied by increased loading of nutrients. Nitrogen and phosphorous are key determinants of productivity, biodiversity, ecosystem processes and food-web dynamics in these freshwater systems (Antoniades *et al.* 2003, Graneli *et al.* 2004).

### Goose migration sites

Barnacle Geese spend approximately one month on their traditional spring staging areas in Helgeland in mid-Norway (Gullestad *et al.* 1984, Black *et al.* 1991, Prop & Black 1998). In recent years, the outer islands in Helgeland have been depopulated, and Barnacle Geese have spread into new areas in the north and east (Black *et al.* 1991, Prop *et al.* 1998, Shimmings 1998). In these areas, they feed on sown pastures and heavily managed and fertilized swards (Black *et al.* 1991). Today, the geese therefore stage in either traditional maritime habitats (e.g. outer islands), or newly-exploited agricultural habitats on inland islands. In recent years, Barnacle Geese also stage in Vesterålen in northern Norway (Shimmings 2003, Tombre *et al.* 2004). Here they overlap with Svalbard Pink-footed Geese, feeding mainly on farmland close to the coast. Most of the farmland is cultivated grassland used for sheep and cattle grazing and hay. Along the coastline, some areas of salt-marsh and seashore vegetation remain, although most are overgrown through the lack of summer grazing by livestock.

The Svalbard population of Pink-footed Geese has spring staging areas in mid-Norway and Vesterålen in northern Norway. Here the population aggregates during April and May, foraging on a combination of pastures and spring-sown cereals (mid-Norway only). In recent years, conflicts between farming interests and Pink-footed Geese have given rise to organized scaring of geese from pastures in Vesterålen, which has resulted in geese departing earlier to the breeding grounds without accumulating essential nutrient stores (Madsen & Klaassen 2006) which are a prerequisite for successful breeding as well as survival (Fox *et al.* 2005, J. Madsen & M. Klaassen, unpubl. data). A spring migration dynamic model predicts that an abrupt intensification of the scaring campaign, which is currently being considered in both staging areas in Norway, will have dramatic impacts on the population due to the scale of the campaign and the limited possibilities that the geese will have to gain sufficient experience and, hence, adapt to the scaring regime (Klaassen *et al.* 2006).

### Goose wintering grounds, land use and climate

Up to the 1960s, Europe was a net importer of many food items, and most agricultural production was achieved by low intensity, high labour methods. As agriculture mechanized and intensified during the immediate post-war period and the European

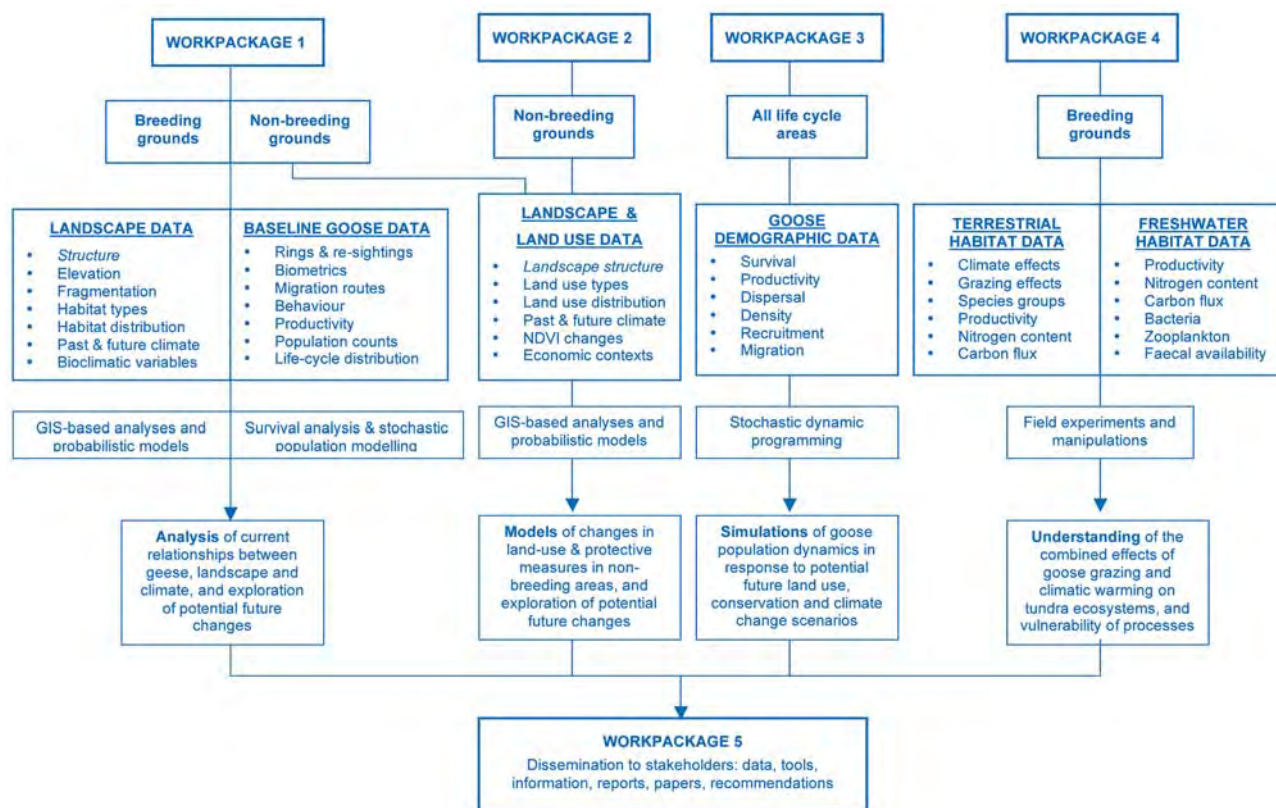

Fig. 4. Flyway area, data, methods and outputs of the five FRAGILE work packages.

economy became more service-oriented, the proportion of the labour force working on the land dropped from more than 20% in the 1950s to 5% today. However, more than ten million Europeans still work in the agricultural sector and more than 40% of the land area is dedicated to food production. Agricultural intensification in the European Union has been facilitated by the development of the Common Agricultural Policy (CAP) in the 1960s, which had the effect of favourably regulating internal and external agricultural markets. During the 1980s, the prohibitive costs associated with maintaining the CAP and a number of trade disputes with other countries prompted the EU to adopt a series of policy reforms in 1992. The “MacSharry reforms” led to reductions in domestic intervention prices, the introduction of compensatory payments, and the implementation of compulsory land “set aside” provisions (Patterson 1997, Matthews 1996, Dauberg 2003). These reforms were further developed and extended through Agenda 2000. The EU has recently expanded its area to include ten central and eastern European countries. Further CAP reforms are, therefore, necessary and are currently being developed and implemented.

These important changes in agricultural policy have been accompanied by the additional drivers of rapidly shifting consumer food preferences, and changes in crop phenology resulting from new “cold hardy” plant varieties that can be sown in winter (Commission of the European Communities 2003). This dynamic and often radically changing system has meant huge changes in what is grown, where it is grown, how it is grown, and when it is grown. In the past, Svalbard geese have spent the winter months on a mixture of naturally occurring salt-marsh (merse) and other coastal and estuarine habitats. Most Svalbard Barnacle Geese spend the winter on the Scottish side of the Solway Firth, whilst Pink-footed Geese winter principally

in Denmark, The Netherlands and Belgium. Both populations now spend a considerable proportion of the winter feeding on agricultural fields, pastures and polders (Pink-footed Geese: Fox *et al.* 2005). This alteration in habitat preference has been a result of the geese exploiting new opportunities presented by changes in agricultural production methods and timing, as well as declines in the quality and extent of “natural” habitats.

Several studies have now attempted to analyse future changes in land use and agriculture through the use of scenario development techniques (for a review see Alcamo *et al.* in press). How human societies, technology and the climate will evolve in the future is simply unknown, and prediction of changes in these drivers is simply not possible. In the face of such large uncertainties, scenario development is an important research and decision support tool that can assist in the exploration of alternative futures. Scenarios of changes in the agriculture sector have now explored the role of socio-economic, policy, technology and climate change on future land use and agricultural production strategies (e.g. Alcamo *et al.* in press, Abildtrup *et al.* 2006, Ewert *et al.* in press, Rounsevell *et al.* in press). Whilst each scenario has its own particular assumptions and interpretations, a general trend from many scenarios is of declining agricultural land-use areas. Some scenarios also suggest an increase in extensive land management practices either in combination with declining areas, or as an adaptation to the pressures that cause the area changes. Whilst such trends do not constitute a prediction, they suggest very strongly that future agricultural landscapes will be very different from the present. One of the major areas of concern for goose population dynamics is that grassland areas may decline significantly in some regions of Europe. This will result from continued technological development and the reduced demand for livestock products, but also depends entirely on the ways in which policy

makers will or will not respond to such developments. Currently, large areas of agricultural grassland in Europe are protected through measures such as the Less Favoured Areas scheme (LFAs). Thus, the future of goose over-wintering sites may depend as much on future European rural development policy as on, for example, the direct effects of climate change. Most authors seem to agree that climate change will, in practice, have a much less important effect on agriculture in north-west Europe than socio-economic, technological and policy change (Rounsevell *et al.* 2006). There is still an open question, however, about what will happen to the areas of land that are no longer used for agriculture. Further development in the cultivation of bioenergy crops (such as biofuels, short-rotation coppice or *Myscanthus*) seems plausible, but the “abandonment” of agricultural land in some areas seems likely. These types of land-use changes will have important implications for goose overwintering areas.

## DEVELOPING AN “INTEGRATED” APPROACH

### European framework research

Every four years, the European Commission sets out a “framework” of the priorities for research, technological development and demonstration activities to be commissioned during a particular time period. Framework 5 (1998 to 2002) included an area of work on “Global Change, Climate and Biodiversity”, with a sub-action on “Ecosystem vulnerability”. The aim was to “develop the scientific, technological and socio-economic basis and tools necessary for the study and understanding of changes in the environment”. In 2002, a partnership of twelve organizations and universities across Europe put together a successful bid for funding under Framework 5. The research team combined the requisite skills, experience, knowledge and long-term data needed to attempt a holistic flyway level study. The study was called: “FRagility of Arctic Goose habitats: Impacts of conservation, Land use and climate changeE” (FRAGILE).

### Project drivers

The development of the project was precipitated by five observations:

- The effects of global climate change will be most acute at high latitudes;
- The distribution and abundance of many tundra breeding geese have been increasing for 40 years;
- Arctic tundra ecosystems can be functionally damaged if over-grazed by geese;
- Severe alterations to tundra result in system switches, i.e. from carbon sink to source; and
- Interactions between geese and agricultural interests in north-west Europe have increased as geese have exploited new agricultural areas during the wintering period.

These observations and the potential impacts arising from them have been recognized (and studied) within individual fields of expertise for some time. But scientists, conservationists, competent agencies, and stakeholder groups recognized a large gap in our knowledge in terms of the interactions and combined effects of these factors at large spatial extents (flyway level). Developing strategies, legal instruments and management regimes to address potential impacts requires outputs that: (a) quantify the current ecosystem/flyway state, and then (b) allow

a range of potential future states to be explored on the basis of different socio-economic and climate scenarios. The FRAGILE project was therefore designed to integrate the five driver elements (above) and answer questions within four main areas:

- *Goose populations*: what have been the primary demographic parameters driving population changes?
- *Tundra landscapes*: how are tundra habitats distributed in relation to landscape and climatic factors, and how are geese spatio-temporally distributed within and between available habitats?
- *European land use*: how is European land use influenced by landscape, policy, socio-economic factors and climate?
- *Tundra ecosystems*: how do climate and grazing by geese influence tundra ecosystem function?

These areas form the main themes of the FRAGILE project. In their own right, each will generate a range of extremely useful data, information and analyses. However, the central rationale of the project is to integrate the four elements to provide:

- An understanding of the environmental and climatic drivers of observed changes in goose population parameters. This will allow an exploration of how the distribution and abundance of goose populations might change given a range of future socio-economic, land use and climate scenarios; and
- An understanding of which tundra ecosystem processes are most vulnerable to the combined effects of goose grazing pressure and climatic warming, and an ability to determine thresholds for ecosystem degradation.

Using the above framework, the overall project aim is therefore to provide a mechanistic and explorative basis for understanding the relationships between goose populations, habitats and land use. The three major contexts to this research framework are climate change, European socio-economic and agricultural policies, and international conservation instruments.

### Stakeholder engagement

The project will produce a range of outputs in the form of data, information, models, analyses, exploration tools, reports, scientific papers, etc. An explicit element of the FRAGILE approach has been to engage stakeholders and potential end-users of these outputs. A stakeholder group was established at the start of the project, and a workshop held. This served to inform the group of proposed methods and outputs, and provided an opportunity to discuss and incorporate stakeholder perspectives. A post-project stakeholder workshop will also be convened.

### Methods, data sources and integration

The project is divided into a series of discrete “work packages”, representing different skill, knowledge and data groupings within the FRAGILE research team. Fig. 4 shows the data requirements, generic methods and analytical outputs of the five work packages. The vast amount of data and information used within the work packages was accessed from five generic sources:

- *Monitoring data*: counts of birds and productivity assessments at key sites, largely provided through volunteer-based moni-

- toring schemes and records from individual fieldworkers;
- *Ringling and re-sighting data*: records of individually marked birds, again largely sustained by volunteer-based activities and records from key fieldworkers;
- *Remote sensing data*: Landscape and climate data in the form of satellite images, and data from satellite tracking devices attached to migrating geese;
- *Publicly accessible data*: Climate, land use and many other types of data available on the internet or on request from specific institutions; and
- *Empirical field data*: behavioural observations, experimental plots and habitat ground-truthing.

Fig. 5 schematically represents the integration of outputs from the different work elements.

### How can outputs from flyway studies be utilized?

Outputs from integrated research of this nature have a variety of direct and indirect uses. Through pro-active dissemination to appropriate agencies, FRAGILE data, information, models, simulation tools and recommendations will be used to support policy and legislative instruments within the Svalbard-Northwest Europe flyway (and possibly beyond). The major relevant instruments are shown in Table 1. Most of these instruments were created in such a way as to respond directly to what was, at the time, perceived to be the main environmental problem, i.e. habitat loss. Whilst habitat loss and degradation remain major environmental issues, climate change may speed up these processes, render them irreversible in many areas, or create a new suite of issues not adequately addressed by the obligations and actions of established legislative instruments (Boere 2003). For example, UNEP/CMS (2002) identified that climate change will impact migratory species by (1) changing physiological responses, (2) altering the timing of life-cycle events, (3) changing the physical location, extent and condition of breeding,

staging and wintering areas, and (4) altering atmospheric and oceanic circulation thus impacting elements such as food resources. Whilst it would be impossible to alter current international conventions in the light of these new factors, it is vital that information on all impacts of climate change are made available to competent agencies involved in their implementation. This is a major role of integrated projects such as FRAGILE and the exploratory tools they can produce. The ability to explore potential population and behavioural outcomes in response to a range of future scenarios also provides an invaluable tool in formulating and improving local, national and flyway level goose management policies (Kruse *et al.* 2004).

In addition to outputs such as data, models, simulation tools, etc., projects that attempt to analyse and integrate such a wide gamut of data also provide other indirect strategic benefits. For example, the FRAGILE project has highlighted the importance of financial support for volunteer-based monitoring activities (often seen as a poor cousin to “hard science”). Long-term, repeated measure, large-scale monitoring and ringing data are central pillars to flyway research, although our analyses have also identified a number of shortcomings in these data where improvements and modifications could be made. These will be fed back to relevant organizations and individuals and reported in later papers. The project has also provided useful lessons in relation to the actual process of attempting such a large integrated flyway research programme (considered in more detail below), and in identifying future research needs.

### DISCUSSION

At the time of writing, the FRAGILE project still has a year left to run, and our results, data, models and other outputs will be published elsewhere. The aim of this paper is to provide a working example of: (1) how an integrated and flyway level project can be constructed; (2) the types of data required; (3) the types of outputs that can be produced; and (4) how the outputs

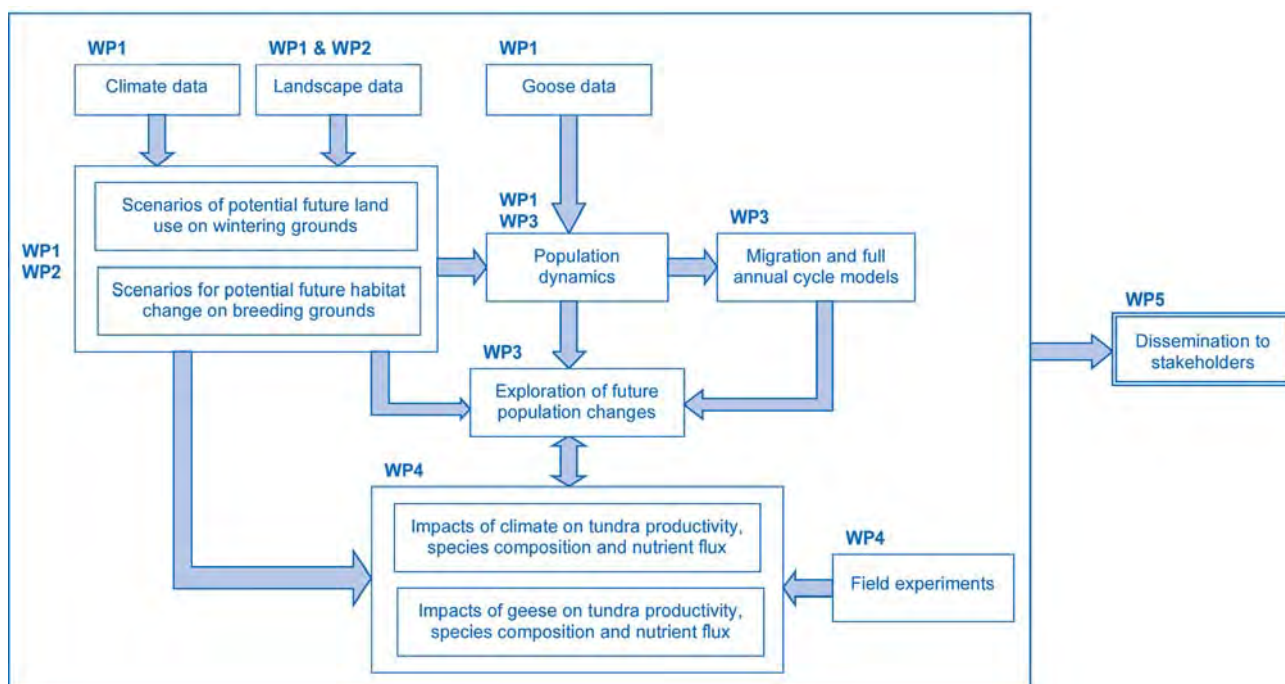

Fig. 5. Integration of the five FRAGILE work packages (WP1-5).

**Table 1.** Key legislative instruments where FRAGILE outputs can be used.

Legislative instrument	Relevant articles	Relevant actions
Council Directive on the conservation of wild birds	Articles 2, 3.1, 3.2, 4.1b, 4.1c, 4.1d, 4.2, 4.3, 4.4, 7.4, 10.1, 10.2, 12.	Deterioration of habitats within and outside SPAs; protection of habitats for migratory species; information needed to ensure sustainable use of quarry species; encouraging research on bird population dynamics; national reporting.
Council Directive on the conservation of natural habitats and of wild fauna and flora	Articles 2.1, 2.2, 2.3, 3, 4, 6.1, 6.2, 10, 11, 12.1d, 17, 18.1, 18.2.	Protection of goose wintering areas; research needs for protecting habitats; inventory of important sites; development of management plans; prevention of deterioration of breeding habitats; national reporting.
Framework Convention on Climate Change	Articles 5a-b, 6, 9, 12 Decision 5/CP.1 Recommendation 9/CP.3 Kyoto Protocol.	Methodologies and tools to evaluate climate change impacts and adaptation; transference of scientific knowledge; quantification of C and N fluxes; assessment of ecosystems as carbon sources/sinks.
Ramsar Convention on Wetlands	Articles 3.2, 4.4. Operational objectives 2.5, 2.7, 3.1, 3.2, 5, 6.	Prevention of ecological change of wetlands; encourage research and data exchange; environmental impact assessment; management including local people; develop education and public awareness of wetland habitats and issues.
Convention on Biological Diversity	Articles 7a-d, 12a-c, 13a-b, 17.1, 17.2, 25.	Identification of processes and categories of human activities likely to have adverse effects on habitats and species; encourage research and training; raise public awareness; exchange of scientific and technological information; national reporting.
Convention on the Conservation of Migratory Species of Wild Animals	Articles 2.3a, 3.4a, 5.5b-f.	Promotion of research into migratory species; conservation of habitats for migratory species; develop management plans; research ecology and population dynamics of migratory species; exchange information; maintain networks of suitable sites; AEWA Action Plan.
Convention on the Conservation of European Wildlife and Natural Habitats	Articles 2, 4.3, 4.4, 5, 10.1, 11b, 14. SC recommendation 3/84.	Maintenance of tundra habitats and species; establishment of peatland inventories. Norway has agreed to include Svalbard under this convention (except with reference to the Arctic Fox <i>Alopex lagopus</i> ).
European Landscape Convention	Articles 5, 6a-c, 7, 8, 9.	Promotion of landscape protection; information on landscapes and transformation threats; raising public awareness; trans-frontier co-operation.
Pan-European Biological and Landscape Diversity Strategy	Action themes 1.1, 1.4, 3.1, 3.2, 4.1, 7.1, 7.2, 7.5.	European ecological network sites in goose wintering areas; Action 7.5 focuses on regions with emphasis on tundra in northern Europe.
Council Directive on reporting	Transfer of information from Member States to European Commission.	Results will be submitted for national reporting under Birds & Habitats Directives, FCCC, CBD, CMS, Berne, Ramsar.

can be used for conservation and sustainable resource management. We also hope that lessons can be learnt from some of the problems encountered during the implementation of the research.

The varied nature and sheer volume of the data required are two major problems with undertaking a research programme at ecosystem level. Many of the data are in “raw” format (from field observations) and need to be collated, managed, manipulated and interrogated. This raises a range of issues in terms of quality assessment and control, and where “sampling” data are used, information about sampling effort is required. Where long-term species data are employed, there can be significant changes in the number and quality of observers within the temporal extent of the data, as well as changes in the spatial extent of the data. The analytical methods for analysing presence/absence data and changes in species/habitat distributions also need careful consideration and methodological development in relation to the types of data available to the study (Fielding & Bell 1997, Brito *et al.* 1999, Thuiller *et al.* 2003, Wisz 2004). Even the range and spatial scale of information from satellites have changed radically in the last ten years. At the opposite end of the scale, where field-based data are newly acquired, three years of

research funding may not be an adequate time-scale for observation. It is also true that for research into some ecosystems, data at any spatial or temporal scale simply will not be available.

Using an enormous amount of varied environmental data from a range of sources also requires a broad array of appropriate data management and analytical skills within the collaborating research groups. This and other factors inevitably make the costs of research at this scale a significant aspect of attempts to fund such work. It will therefore be important to learn and disseminate lessons from the FRAGILE project, as well as to develop rapid assessment techniques in parallel with more detailed research programmes (Boere 2003). One of the other major lessons is that true integration of outputs needs to be carefully considered. It is very easy to implement a study where different elements are being researched independently and are merely under the same project title, but quite a different matter to ensure that outputs and results (not just data) from one group are actually being utilized within the conceptual framework of the research in another collaborating group.

One of the most important features of the FRAGILE project has been the avoidance of references to making “predictions”.

A prediction implies a single discernible trajectory or end point for the processes being studied. For many elements of the project, this would have been at best irrelevant, and at worst enormously misleading. Instead, the project is seeking to present species, habitat and system responses under a range of potential future scenarios of climatic, environmental and socio-economic change. Whilst in some quarters this tool-based and explorative approach might be perceived as not producing “concrete” results, it is in fact of far greater application to the intended stakeholder groups.

An explorative approach also recognizes that potential changes in habitat-species associations under new scenarios of climate change will present a number of difficult issues in relation to developing appropriate conservation and management strategies. At the present time, most strategies, conventions, action plans and management policies are fundamentally centred on “current” and narrowly defined ecosystem assemblages. However, differential species’ responses to climate change will almost certainly lead to structural and phenological realignment between species comprising an ecosystem, thus making it likely that some current definitions (e.g. those within the current EC Habitats Directive) will cease to exist (Visser *et al.* 1998, Carpenter & Turner 2000). This is also another reason why integrating field experimentation (e.g. the FRAGILE manipulations on Svalbard) is so important in evaluating the combined impacts of climate change on the structure and function of systems, and empirically testing causal links suggested by analyses of numbers from monitoring, etc. Far more research of this nature (i.e. exploring re-combination and structuring at an ecosystem level) is urgently needed.

## ACKNOWLEDGEMENTS

The FRAGILE project was funded by the EC under Framework 5, and is a collaboration between 13 organizations and universities across Europe. We would like to take this opportunity to acknowledge the work of all members of the team.

## Climate change and coastal waterbirds: the United Kingdom experience reviewed

Mark M. Rehfish & Graham E. Austin

British Trust for Ornithology, The Nunnery, Thetford, IP24 2PU, UK. (email: Mark.Rehfish@bto.org)

Rehfish, M.M. & Austin, G.E. 2006. Climate change and coastal waterbirds: the United Kingdom experience reviewed. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 398-404.

### ABSTRACT

Climate change is occurring world-wide, and its effects are already visible in species and their habitats. The internationally important populations of waterbirds in the UK, and waders in particular, are already affected by climate change. So far, changes in distribution, timing of arrival to winter and to breed, and laying dates have been linked to it. Changes in the distributions of certain wintering waders, linked to changing winter temperatures, have affected the proportions of their flyway populations on sites designated as being of conservation importance for the species. This has major implications for conservation policy. Waders are declining in the UK and world-wide, and it is possible that climate change is in part responsible, both directly by affecting their energy balance, and indirectly by affecting the availability, quantity and quality of their habitats. Waders appear to be good indicators of climate change, and the development of reliable scenarios of waterbird distributions occurring under future, changed climate scenarios would help with nature conservation planning, raise public awareness and, perhaps, lead to constructive political action to curb greenhouse gas emissions. However, before such scenarios can be developed, much work is necessary to help define appropriate parameters for such models.

### INTRODUCTION

Globally, the ten hottest years on record occurred between 1991 and 2004; during the last century temperatures have risen by 0.6°C, and global sea level has risen by 20 cm (Houghton *et al.* 2001). Ice caps are disappearing from mountain peaks, and Arctic sea ice has thinned by 40% (Wadhams 1997). Thus, climate change is occurring and the causal link to increased greenhouse emissions is established (Houghton *et al.* 2001). The Chief Scientific Adviser to the British Government has suggested that climate change is the most severe problem being faced today (King 2004). In 2003, in France and the United Kingdom (UK), 20 000 people died as a consequence of an unprecedented heat wave that the French Ministry of the Environment expects to occur henceforth every three to four years. By 2080, extreme tidal events that are now expected in the UK once every 100 years could be occurring every three years, and 3.5 million people could be at "high" risk of flooding, with hundreds of millions at risk world-wide (King 2004). The distribution and phenology of a wide range of biota have been affected by changing weather over recent decades world-wide (Parmesan & Yohe 2003, Root *et al.* 2003).

The UK, with its extensive coastline and low-lying land, is internationally important for its wintering waterbird populations. This paper concentrates on the Sub-order Charadrii or waders (shorebirds), of which the UK holds over 20% of the flyway populations of 10 species (Rehfish *et al.* 2003a). World-wide, 103 out of 207 wader populations with known trends are prob-

ably extinct or in decline for reasons that are unclear (International Wader Study Group 2003, Stroud *et al.* 2006). In Great Britain, the numbers of eight out of 14 common species of wintering wader are in decline (Rehfish *et al.* 2003a), with particularly large declines being apparent on non-estuarine coasts (Rehfish *et al.* 2003b). Waders include the world's longest-distance migrants, with some breeding in the circumpolar tundra and wintering in the Southern Hemisphere. These "integrators" of change could be particularly prone to the effects of factors, such as climate change, that occur on vast spatial scales (Piersma & Lindström 2004). In the UK, it has been suggested that declines may be due to a combination of factors that include habitat changes resulting from land-claim, dredging, loss of salt-marsh and urbanization (Goss-Custard *et al.* 1995, Dolman & Sutherland 1995), shell-fisheries (Atkinson *et al.* 2003), human disturbance (Liley 2000, Burton *et al.* 2002), and water abstraction. Furthermore, recent legislation that is limiting the amount of organic nutrients entering coastal waters could be lowering the biomass of the invertebrate prey of waders (Burton *et al.* 2003).

Principally using the example of the present and predicted future situation in the UK, this paper briefly reviews climate change itself, and considers its effects on sea level and coastal geomorphology, on the plant and invertebrate food resources and habitats of waterbirds, and on the waterbirds themselves. The possible mitigation of any adverse effects within present legal frameworks is considered, and research priorities that could help make it possible to develop scenarios of the likely effect of climate change on waterbirds are identified.

### REVIEW

#### Climate change

In the UK, summer and winter isotherms increase from north to south, and east to west, respectively. During the twentieth century, temperatures in central England rose by almost 1°C, and the decade of the 1990s was the warmest since records began in the 1660s. Average sea level is rising by about 1 mm per year, and winters across the UK have been getting wetter, with a larger proportion of the precipitation falling on days of heavy rainfall (Hulme *et al.* 2002a). Average minimum temperatures increased by about 1.5°C between 1984/85 and 1997/98 (Austin & Rehfish 2005).

Some degree of further climate change is inevitable over the next 30-40 years as a consequence of past and present emissions of greenhouse gases and the inertia of the climate system. However, the greenhouse gases emitted over the next few decades will influence the climate of the second half of the twenty-first century and beyond. Based on future global emissions of greenhouse gases, Hulme *et al.* (2002a, 2002b) detail four scenarios (low emissions, medium-low emissions, medium-high emissions and high emissions) of how climate change will affect the UK

climate by 2020, 2050 and 2080. By 2080, under the medium-high emissions scenario, the UK climate will become warmer by 2.3–3.2°C. Warming will be greatest in the south and east and in the summer and autumn. Temperatures in coastal waters will increase, and very cold winters will become increasingly rare. Winters will become wetter and summers drier. By 2080, summer soil moisture may be reduced by over 40% over large parts of England, while snowfall will decrease on average by 60–90% in Scotland. Heavy winter precipitation will become more frequent. The relative sea-level rise around the UK will vary according to local isostatic forces, and will range from -2 to 86 cm above the current level in Britain. Under the medium-high emissions scenario, extremely high sea levels could occur 10–20 times more frequently by the 2080s than at present.

### Coastal geomorphology

The present coastal configuration of the UK reflects unregulated pre-twentieth century development. In England alone, over 860 km of soft cliffs are protected from erosion (23% of the coastline), and in excess of 1 259 km of sea-defences provide flood protection for 2 347 square km of embanked lowlands where over two million people live and half of the highest-grade agricultural land is found (Crooks 2004). The remaining coastal natural resources, including coastal birds, are suffering from a sustained net decline largely related to coastal squeeze of intertidal habitat (Carpenter & Pye 1996). Large-scale coastal landforms are currently adjusting to two major perturbations: rising sea level and the loss of flood plains with their hydraulic functions (Crooks 2004). Because of the land-ward migration of coastal landforms, coastal “roll-over” and the redistribution of sediments, maintaining the coast in its present state is not possible. The existence and quality of certain landforms, such as dune-fields and shingle ridges, are dependent upon allowing natural migration. Management intervention to prevent migration will result in degradation of the natural form of these systems and their associated biodiversity values. Maintaining fixed flood defences will, with rising sea level, result in the loss of many of the inter-tidal foraging grounds of the UK’s waders unless a policy of land ward coastal realignment is enacted. Such a policy, however, would conflict with the maintenance of freshwater lowland habitats (Lee 2001) and the interests of a human population with assets entrenched behind flood defences.

### Plant and invertebrate resources

Salt-marshes are areas of high primary productivity subject to tidal inundation. Their greatest significance for coastal birds is probably as the base of estuarine food webs, for salt-marshes export considerable amounts of organic carbon to adjacent habitats, particularly to the invertebrates of mudflats; in addition, they provide sites for feeding, nesting and roosting (Hughes 2004). Climate change can affect salt-marshes in a number of ways, including through sea-level rise. When the sea level rises, the marsh vegetation moves upward and inland, but sea-walls that prevent this lead to coastal squeeze and loss of marsh area. However, evidence from south-east England indicates that sea-level rise does not necessarily lead to loss of marsh area, for marshes accrete vertically and maintain their elevation with respect to sea level, where the supply of sediment is sufficient. Lower down the shore, the abundance and productivity of brown algae is likely to decrease as the climate warms and the

increasing size of waves and frequency of storms increase exposure (Kendall *et al.* 2004). This would represent a loss of feeding grounds for species such as Ruddy Turnstone *Arenaria interpres* that feed on invertebrates associated with the seaweed. Furthermore, algal debris exported to sediments boosts the production of bacteria at the base of the food web.

In the British Isles, some coastal invertebrates live close to the geographical limits of their distribution. With climate change, some of these southerly species might be expected to extend their range as climatic restraints are relaxed (Kendall *et al.* 2004). In most cases, the effects on the distribution of waterbirds are likely to be small; for example, the replacement of the northern limpet *Patella vulgata* by the southern *Patella depressa* is unlikely to have an adverse effect on predators such as Eurasian Oystercatchers *Haematopus ostralegus*. An increase in sea level will only have a major impact on the extent of invertebrate communities on rocky shores, where shore topography prevents the upward migration of the biota. Where a seawall limits shores, for example, biological production will be curtailed as the area available for colonization decreases. However, environmental cues control or synchronize the reproductive cycle of many marine invertebrates, and climate change will modify the relationship between temperature and photoperiod (Lawrence & Soame 2004). It is uncertain whether such invertebrates, the major prey of overwintering coastal birds, will be able to adapt sufficiently rapidly to changing conditions to avoid major population change and local extirpations.

### Waterbird phenology

Meta-analyses confirm the changing phenology of bird populations (Parmesan & Yohe 2003, Root *et al.* 2003). The timing of arrival and breeding of migrant waders in the UK can be responsive to ambient temperatures and, where long-term trends exist, they can often be explained by trends in climate. Records of the first arrival of Common Sandpipers *Actitis hypoleucos* at four bird observatories around the British Isles show no trend over time or relationship with spring temperatures (Loxton & Sparks 1999). Similar results are obtained for the Common Sandpiper, Eurasian Oystercatcher, Northern Lapwing *Vanellus vanellus* and Common Redshank *Tringa totanus* in north-east Scotland over the period 1974–1999, although the arrival date of the Eurasian Curlew *Numenius arquata* became 25 days earlier (Jenkins & Watson 2000). Between 1950 and 1998, the first arrival dates of Little Ringed Plovers *Charadrius dubius* and Whimbrels *Numenius phaeopus* in south-east England became earlier by six and 22 days per decade, and three and six days per °C in relation to mean January to March temperatures, respectively (Sparks & Mason 2001). In a study that included seven species of waterbirds wintering in Britain, the duration of stay did not change, but the first arrival date of Tundra Swan *Cygnus columbianus* advanced by seven days per decade, while that of Jack Snipe *Lymnocyptes minimus* regressed by six days per decade, between 1966–67 and 2000–01 (Sparks & Mason 2004).

In the UK, the Common Ringed Plover *Charadrius hiaticula* exhibits no overall trend in laying date between 1944 and 1995. However, its laying date has become earlier in relation to mean monthly temperatures at a rate of 1.1 days per °C, the temperatures in the relevant months showing little trend over time (Crick & Sparks 1999). Although the Eurasian Oystercatcher demonstrates a curvilinear trend in average laying date between 1962

and 1995 (peaking in the mid-1970s), this is not related to temperature, but partially to precipitation in May, becoming earlier at the rate of 0.06 day per mm.

### Waterbird distributional shifts

The breeding distributions of some British birds have extended northwards with climate change (Thomas & Lennon 1999). Eurasian Golden Plover *Pluvialis apricaria* and Common Sandpiper populations in the Pennine Mountains of England fluctuate in relation to changes in the North Atlantic Oscillation (NAO), a meteorological feature that determines the weather affecting north-west Europe (Forchhammer *et al.* 1998). Eurasian Golden Plover numbers increase two years after warm and moist winters, presumably as a result of improved juvenile survival. Common Sandpiper numbers increase after cool, dry winters, perhaps due to changes in food supplies or habitat on their African wintering grounds.

The distribution of wintering waders in Britain has changed since the 1970s (Austin *et al.* 2000). Since the mid-1980s, with an increase of 1.5°C in the mean winter temperature in the UK, the estuarine distributions of seven out of nine common wader species have moved in an eastwards direction across the winter isotherms (Fig. 1), with the smaller species showing the greatest shifts, as is expected if mediated by temperature (Austin & Rehfish 2005). Between the 1984-85 and 1997-98 winter surveys of Britain's non-estuarine coasts, the distributions of eight wader species moved in an eastwards and/or northwards direction with increasingly mild winter temperatures and changes in mean rainfall, wind speed and wind-chill (Rehfish *et al.* 2004). In both instances, the waders appear to be wintering closer to their breeding grounds, which are predominantly to the north and east of Britain, as milder winter weather has diminished the risk of cold-induced mortality in the colder east. The recent decline in eight of the 14 species of common coastal waders in Britain (Rehfish *et al.* 2003a, 2003b) could be due to the waders now wintering even further to the north and east, on the European mainland (Rehfish & Crick 2003).

**Fig. 1.** Relationship between the median longitude of Common Ringed Plover *Charadrius hiaticula* distribution in Britain and the average number of days with ground frost recorded across 39 British weather stations (Rehfish & Austin 1999).

### Conservation implications for waterbirds

Waders are designated features of Special Protection Areas (SPAs) that regularly hold one percent or more of their flyway population or British wintering population, the international and

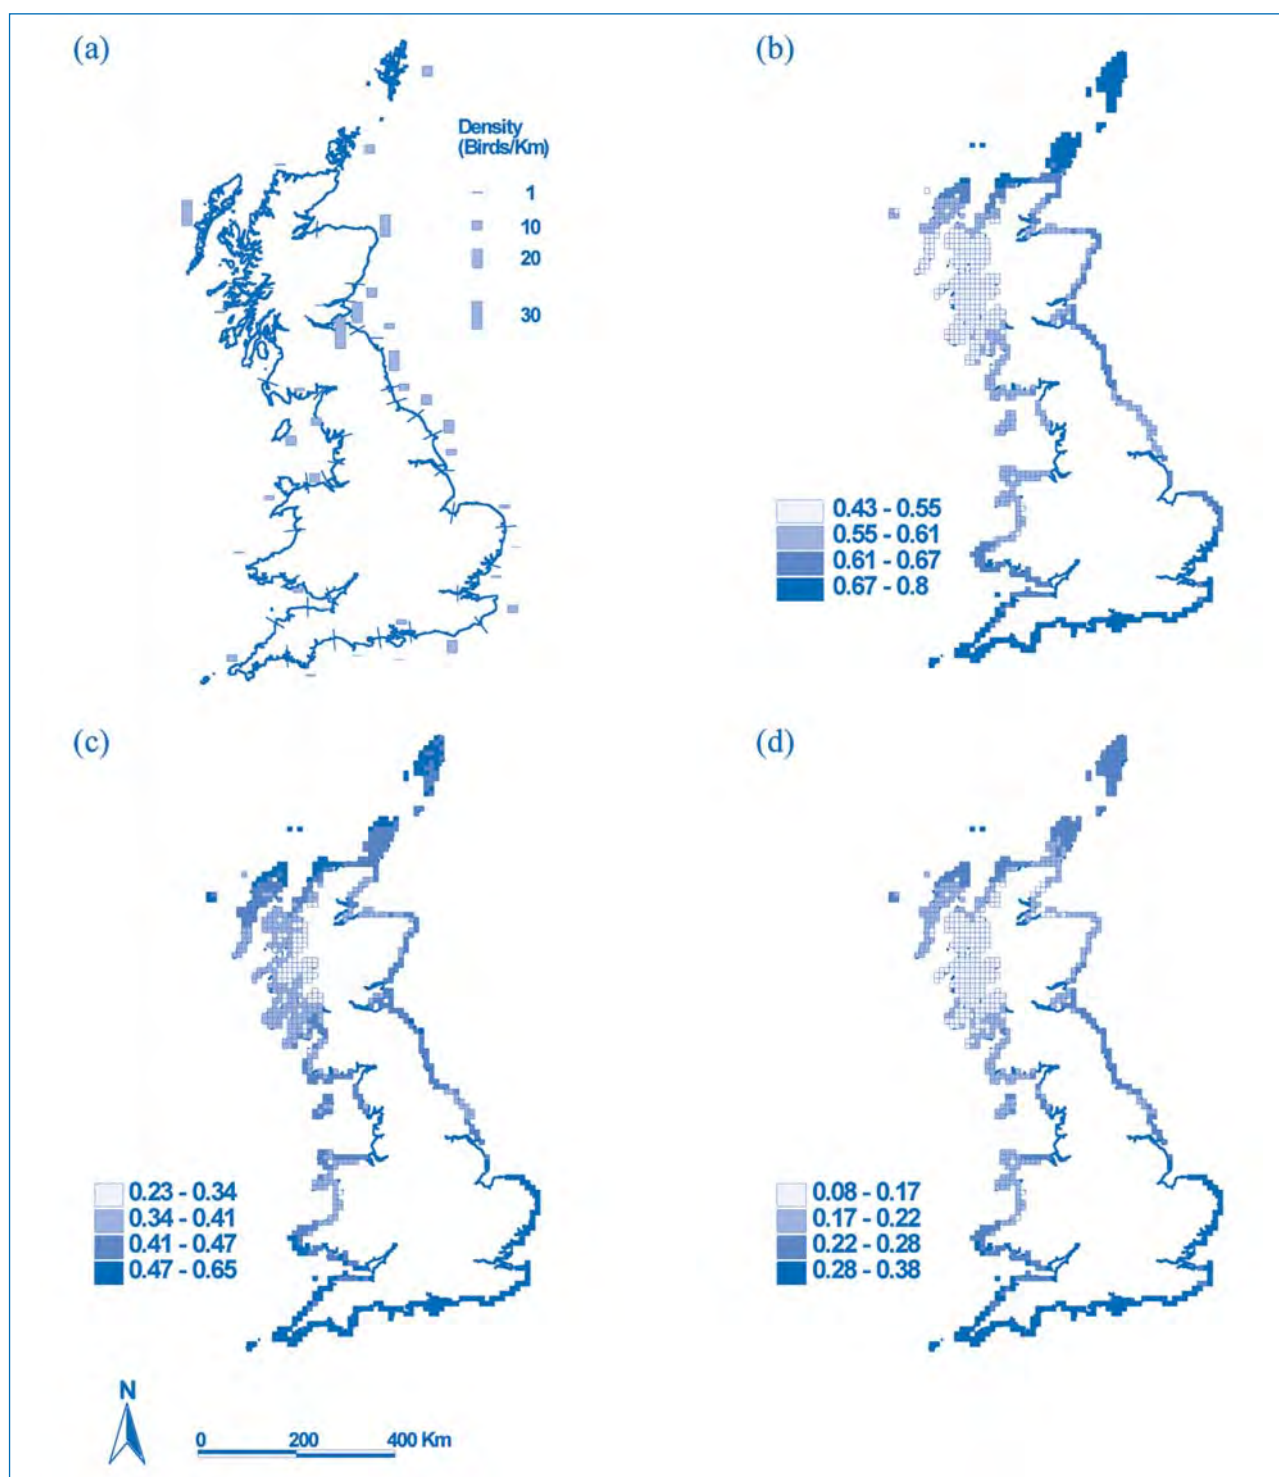

national thresholds, respectively (Baker & Stroud 2006). As wader distributions in Britain change with climate change, the numbers of some species at some British SPAs are dropping below the thresholds upon which the designations are based. For example, the number of Dunlin *Calidris alpina* wintering on the Severn Estuary has dropped from an average count of over 40 000 in the mid-1970s to below the international threshold of 14 000 in recent winters up to and including the winter of 2000-01 (Austin & Rehfish 2005). This is not an isolated example. Many species of wader are declining more rapidly in the west of Britain than in the east, as illustrated by the Common Ringed Plover (Fig. 2: Austin *et al.* 2004).

**Fig. 2.** Change in Common Ringed Plover *Charadrius hiaticula* numbers on Britain's SPAs designated for the species (Austin *et al.* 2004). Upward- and downward-pointing arrows indicate SPAs where numbers increased and decreased between 1994-95 and 1999-2000, respectively; filled and hatched arrows indicate changes of 50% and 25% in smoothed numbers during that period, respectively.

### Scenarios of future change

Hughes (2000) suggests that the challenge for ecologists, physiologists and land managers is to predict the effects of human-induced climate and atmospheric change on species and on communities. Such predictions should include effects on physiology, distribution, phenology and individual adaptation. Whereas it is impossible to predict accurately future responses of biota to climate change, it has become acceptable to suggest a range of scenarios of possible change (Lawton 1996, Danell *et*

**Fig. 3.** (a) Ruddy Turnstone *Arenaria interpres* densities on the non-estuarine coast of each of Great Britain's counties during the winter of 1984-85; and (b) to (d) predicted relative change in their numbers at a scale of 10-km square under various UKCIP climate change scenarios: (b) 2020 medium-low versus 1961-1990 baseline; (c) 2080 medium-low versus 1961-1990 baseline; (d) 2080 high versus 1961-1990 baseline. 1 = no change, <1 = decrease, > 1 = increase (Rehfishch *et al.* 2004). All changes in (b) to (d) are <1, thus indicating declines.

*al.* 1999). However, modelling the future status of waterbirds or any other biota under climatic conditions that are out of the range of human knowledge is a major challenge. To develop realistic models of the likely effect of climate change on waterbirds that can migrate annually over huge distances, the factors and interactions that influence their demographics must be much better understood than at present (Rehfishch & Crick 2003, Piersma & Lindström 2004). For example, the single issue of

time-lag leading to phenological disjunction is of considerable conservation importance (Sutherland 2004), since climate change is expected to occur very rapidly (Houghton *et al.* 2001), and yet there is much uncertainty as to whether biota have the capacity to respond sufficiently quickly and whether habitat responses will take years or centuries. Examples of biota finding it difficult to remain in step with their environment already exist. Although Great Tits *Parus major* can lay earlier in response to

early, warm spring weather, often in parallel to the emergence of the caterpillars of winter moths on which they feed their young (Perrins 1991), they cannot significantly decrease their incubation period. However, the caterpillars can halve their development time in sufficiently warm weather, leading to an early shortage of food for young Great Tits (Buse *et al.* 1999). There is also some evidence that long-distance migrants have not responded as rapidly to climate change as short-distance migrants (Jenkins & Watson 2000, Penuelas *et al.* 2002).

Scenarios of how biota may change with climate change already exist, but their value is dependent on critical assumptions being met. Three examples are discussed. First, Austin and Rehfish (2003) use habitat association models to suggest that in 2020 and 2050, sufficient estuarine habitat will be available to sustain the present numbers of waterbirds wintering in the UK under four UK Climate Impacts Programme (UKCIP) scenarios of sea-level rise. For these predictions to be correct, the present associations between estuarine morphology and habitat must remain true in the warmer future, and habitats must continue to hold at least the present quantity of the resources of waterbirds. Rehfish *et al.* (2004) tentatively suggest that the numbers of some wader species wintering on the UK's non-estuarine coasts may decline considerably under the 2080 UKCIP scenarios (Fig. 3). However, for these scenarios of decline to be correct, at the very least the observed relationships between weather and wader distributions must continue to hold true outside of the present range of weather, and flyway wader populations must be large enough to provide sufficient numbers of potentially overwintering individuals. Finally, to help guide UK conservation policy, the MONARCH project (Monitoring Natural Resource Responses to Climate Change) was established to attempt to predict how biodiversity will change with climate change. The first set of MONARCH predictions, based on a bioclimatic approach, took no account of plant and animal dispersal capabilities, geographical impediments to movement, and changing socio-economic conditions with a warming climate (Harrison *et al.* 2001). Subsequent regional predictions have addressed some of these factors, but the dispersal capacity of the organisms and phenological disjunction that may occur between interdependent species remain to be considered. Thomas *et al.* (2004) may also be underestimating the scale of future extinction of species, as their work also suffers these limitations. At best, without major information gathering to increase the reliability of model parameters, such scenarios of change can only be broadly indicative of what could happen, and must be treated with caution.

## DISCUSSION AND CONCLUSIONS

Climate is changing now (Houghton *et al.* 2001, Hulme *et al.* 2002a, 2002b), and its effect on biota is apparent world-wide (Parmesan & Yohe 2003, Root *et al.* 2003). Waterbirds are, and will continue to be, increasingly affected by rising temperatures and rising sea levels that change their habitat (Crooks 2004) and the communities of plants and animals on which they depend (Hughes 2004, Kendall *et al.* 2004, Lawrence & Soame 2004). These changes are reflected in existing changes in waterbird phenology (Crick & Sparks 1999, Rehfish & Crick 2003, Crick 2004, Sparks & Mason 2004) and distributional shifts (Austin *et al.* 2000, Rehfish *et al.* 2004, Austin & Rehfish 2005). However, much of the basic information necessary to describe the existing effects of climate change on waterbirds, quite apart from allowing the development of realistic predictions to be

made, is missing. Existing analyses have been patchy. For example, distributional changes with changing weather have been described for wintering waders, but not for other wintering waterbirds such as swans, geese and ducks. Only recently have wider scale analyses started to determine whether there is evidence that similar winter distributional shifts are occurring outside the boundaries of the UK and into Continental Europe. There has been no attempt to detect large-scale distributional changes in breeding waterbirds with changing weather. A few changes in the arrival and departure dates of migrant waterbirds have been described, but no systematic attempt has been made to analyse the main data sets of counts of breeding or wintering birds to determine whether there is evidence that changes in phenology are detectable at a national level or in the sequential usage of sites. Critically, no attempt has been made to determine whether the observed changes in wader distributions are causally related to the changes in the weather itself (temperature, Austin & Rehfish 2005; temperature, precipitation and wind, Rehfish *et al.* 2004), or whether the weather is having an indirect effect on the waders by affecting their habitat and resources. Increasing temperature has a direct effect on waders by lessening their energy losses and thus their energy requirements (Wiersma & Piersma 1994) and, as such, could allow birds living near the limit of their metabolic requirements (Piersma 1994) to winter in areas previously too energetically expensive. Changing weather can also have indirect effects on waterbirds. For example, increasing temperatures lead to rising sea levels and thus habitat change, as well as changing distributions (Kendall *et al.* 2004) and availability (Pienkowski 1983) of wader invertebrate prey. Determining the causal drivers of change would make it possible to generate more realistic scenarios of changing waterbird numbers with climate change.

## Planning for the future

Realistic scenarios of change allow statutory agencies to plan for the future. Understanding how wildlife will react to climate change makes it easier for them to attempt to fulfil their legal obligations towards wildlife on designated sites and to help species at risk of major decline. Already some of the legal tools necessary to protect waterbirds in a changing environment exist (Boere & Taylor 2004), and there is an increasing understanding of how suitable waterbird habitat can be created (Atkinson *et al.* 2004, Zedler 2004). The latter is useful, for example, if bird distributions are changing rapidly at a time when rapid sea-level rise is leading to major habitat loss.

Scenarios of change can (i) allow generally scarce conservation resources to be effectively targeted at priority species, (ii) concentrate the public's attention on the effects of human-induced climate change on wildlife (e.g. Thomas *et al.* 2004) and by extension themselves, and (iii) following raised public awareness, make it easier for politicians to take action that may be unpopular with voters.

However, much work is necessary before scenario models inspiring confidence can be generated. If the future weather scenarios of the Intergovernmental Panel on Climate Change (IPCC) are correct, the predictions will have to be made for climatic conditions not yet encountered, making it particularly difficult to predict accurately the likely scale of changes to waterbirds and other biota. The development of scenarios will be particularly complex for waterbirds, as the scenarios will have to allow for events occurring on often spatially extensive flyways.

## Opportunities

Assuming that the IPCC future weather scenarios are broadly correct, the Earth is about to change radically with possibly largely disastrous consequences for humans and the first human-induced massive extinction of biota (Thomas *et al.* 2004). Even with a complete and immediate switch to renewable energy, the Earth would continue to warm and sea level to rise for decades due to the time lags within atmospheric systems. Solutions to the effects of climate change on waterbirds and other fauna require changes in human behaviour. A useful first step would be to radically change the discounting philosophy that gives a very low value to long-term benefits and makes politicians reluctant to affect present economic growth for even major long-term benefits (Henderson & Sutherland 1996).

A change in the direction of the economy presents great opportunities for technological development in almost all fields of human endeavour, including renewable energy, energy conservation and thus car, house and industrial design, and agriculture. This would provide a major stimulus for growth, and the fact that countries are largely rejecting this opportunity is disappointing. The excuse that reducing carbon emissions makes humans poorer is apparently false: between 1990 and 2000, Great Britain's economy grew by 30%, employment increased by 4.8% and yet the intensity of greenhouse gas emissions fell by 30% and overall emissions fell by 12% (King 2004).

## ACKNOWLEDGEMENTS

The waterbird research cited here would have been impossible without the combined efforts of the counters who supply the data to the Wetland Bird Survey, a partnership of the BTO, WWT, RSPB and JNCC (on behalf of EN, SNH, CCW & EHS (NI)), the British Atmospheric Data Centre that allowed access to their weather data, and the UKCIP that allowed access to their baseline data and predictions. Thanks are due to Mark O'Connell for organizing the session at the Waterbirds Around the World Conference, to an anonymous referee for improving the manuscript, to the British Ornithologists' Union for providing the opportunity to produce the volume on the effects of climate change on waterbirds that much of this paper is based on (available free online <http://www.bou.org.uk/pubibis.html>), and to Sarah Jackson for producing Figure 2.

## ABSTRACT

Environmental variability at breeding and wintering areas may have complex effects on populations of migratory seabirds. Here, we report on the correlation of climate variability in the winter quarters and at migration stopover sites with return rates, individual condition and migration strategy of Common Terns *Sterna hirundo* breeding in northern Germany. Climate variability was defined by the North Atlantic Oscillation Index (NAOI) and Southern Oscillation Index (SOI, a measure of the El Niño-Southern Oscillation). Data on Common Terns were obtained over the last ten years at a breeding colony in the Banter See (northern Germany) by systematically marking adults and fledged chicks with transponders. The return rate of breeders was negatively correlated with the NAOI in the previous year, but for two-year-old sub-adults was positively correlated with the lagged SOI, indicating possible dependence for survival on food availability at migration stopover sites and in the wintering areas, respectively. Sub-adults also arrived later at the breeding colony after years of high NAO, suggesting that conditions at the wintering sites and during spring migration strongly influence the survival and behaviour of prospecting terns. The sub-adults appear to be more dependent on climatic conditions at wintering and migration stopover sites than adults, possibly as a result of different migratory behaviour, or foraging experience and the breeding requirements of adults. Studies on the wintering and migration strategies of the species are required to confirm the mechanisms linking migration and climate variability.

## INTRODUCTION

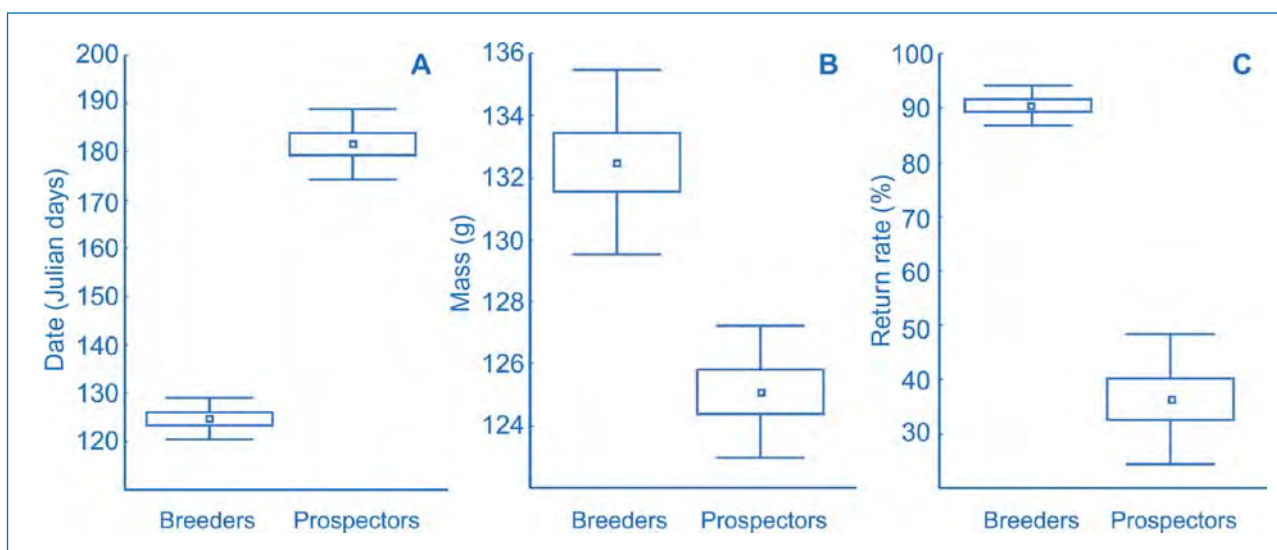

There is much evidence of biological responses to climate variability in marine and terrestrial ecosystems (Holmgren *et al.* 2001, Beaugrand & Reid 2003). Studies on bird species have demonstrated impacts of climate change and oscillations in climate on many aspects of their life history, including survival, recruitment, reproductive output, population dynamics and timing of migration. Many species of migratory birds now arrive considerably earlier in spring than just a few decades ago, and several studies have shown that fluctuations observed in populations are regulated by climate change (Silllett *et al.* 2000, Moss *et al.* 2001, Møller 2002, Both *et al.* 2004, Hüppop & Hüppop 2002, Saino *et al.* 2004). For seabirds, the impact of climate change and oscillations has been observed predominantly at breeding colonies (e.g. Thompson & Ollason 2001, Croxall *et al.* 2002, Simeone *et al.* 2002). Therefore, an understanding of the dynamic consequences of climate oscillations and environmental conditions operating in the winter quarters and along the migration routes is required for these marine predators.

The Common Tern *Sterna hirundo* is one of the most cosmopolitan tern species, breeding mostly in the Northern Hemisphere and wintering in the tropics and temperate regions of the Southern Hemisphere (Nisbet 2002, Becker & Ludwigs 2004). Common Terns breeding in Europe spend the winter along the coast of Africa, from north-west Africa to Cape Town, and migrate along the East Atlantic coast. The Common Terns from breeding colonies in the Banter See in northern Germany winter predominantly in West Africa between the equator and 20°N (Becker & Ludwigs 2004). Most of the 47 recaptures of birds ringed in the Banter Sea have been in West Africa, although some birds have been recovered as far south as 10°S (P.H. Becker unpubl. data). In general, sub-adult Common Terns remain in their winter quarters throughout their first two years, returning to the breeding colonies as prospectors when they are two years old. The age of first breeding ranges from two to five, but is most commonly three (Becker *et al.* 2001, Ludwigs & Becker 2002, Dittmann & Becker 2003).

A major source of inter-annual variability in the atmospheric circulation of the Northern Hemisphere is the North Atlantic Oscillation (NAO), which is associated with changes in the surface westerly winds across the North Atlantic into Europe. Whereas warm, wet and stormy winters in the north-east Atlantic and northern Europe are associated with a high North Atlantic Oscillation Index (NAOI), these conditions are associated with a low NAOI in southern Europe (Hurrell 1995). However, unlike the tropical Pacific, seasonal climate variability in the tropical Atlantic is not dominated by any single process (Sutton *et al.* 2000). This region is subject to multiple competing forces among which El Niño-Southern Oscillation (ENSO) teleconnections have been linked to important environmental processes such as enhanced upwelling phenomena in equatorial West Africa (Roy & Reason 2001). These large-scale climatic factors may affect ecological patterns and processes in both marine and terrestrial systems, changing the relative amount of resources and habitats available in the breeding grounds, and consequently affecting the life history, demography and population dynamics of the species (Alerstam & Hedenström 1998, Stenseth *et al.* 2002). Hemispheric systems, such as the NAO or ENSO, may potentially influence migrants beyond their breeding ranges – during migration as well as in the wintering areas. Variability in arrival mass and date of arrival for individual migration strategies could be an expression of phenotypic plasticity (Saino *et al.* 2004), and ecological conditions during winter may affect the energetic balance, individual condition and moult of birds, and therefore the timing of departure and migration strategy (Marra *et al.* 1998), with significant consequences for life history.

**Table 1.** Multiple regression and partial correlation analyses of arrival date, return rate and arrival mass of Common Terns *Sterna hirundo* breeding in Germany, with North Atlantic Oscillation (NAOI) and Southern Oscillation (SOI) indices as independent variables.

	Breeder			Prospectors

**Fig. 1.** Date of arrival (A), arrival mass (B), and return rate (C) of breeding and prospecting Common Terns *Sterna hirundo* throughout the study period. Means – dots; standard errors – boxes; standard deviations – error bars.

This study aimed to analyse the long-term variability observed in migration schedule, body mass at arrival and return rate of prospecting and breeding Common Terns in relation to oscillations in climate operating across the species' distribution, hypothesising a significant effect of climate on body mass, timing of migration and return rates.

## METHODS

Common Tern data were collected at a breeding colony located at Banter See, Wilhelmshaven, Northern Germany. Between 1992 and 2001, complete cohorts of fledged Common Terns ( $n = 2\,081$ ) and 101 adults were implanted with transponders. The migration schedule (date of arrival), individual arrival mass and return rates of breeders (individuals older than four years) and prospectors (two-year-old sub-adults; 91% of the sub-adults return at the age of two years; Dittmann & Becker 2003) were automatically recorded every season over a 10 year study period (1994 to 2003), using antennas and electronic balances located at resting sites throughout the breeding colony (for details, see Wendeln & Becker 1996, Becker & Wendeln 1997, Becker *et al.* 2001).

Environmental variability was defined in this study by the North Atlantic Oscillation Index (NAOI) and El-Niño-Southern Oscillation (ENSO; indicated by the Southern Oscillation Index, SOI). High positive values of SOI indicate La Niña conditions, and low, negative values indicate El Niño conditions. For all analyses, we used annual mean monthly values of the standardized NAOI and SOI for each calendar year. The NAOI data set was obtained from the Climate Prediction Centre website, and the SOI data set from the Commonwealth Bureau of Meteorology website. Temporal auto-correlation in the NAOI and SOI during the study period was found to be non-significant ( $F_{1,9} = 0.01$ ,  $r^2 = 0.001$ ,  $P = 0.939$ , and  $F_{1,9} = 0.48$ ,  $r^2 = 0.056$ ,  $P = 0.510$ , respectively).

We measured the effects of the NAO and ENSO on the return rates, timing of migration and individual condition of prospecting and breeding Common Terns. Mean index values from the year before were correlated to parameter values collected for Common Terns (i.e. average indices of the year  $i$  paired with parameters from the breeding season for the year  $i+1$ ). The annual schedule of Common Terns from the study site was assumed as follows: breeding season from May to late

August, autumn migration from September to November, winter season from December to March, and spring migration from late February to May. For each breeding season of the ten-year study period, average arrival mass, date of arrival and return rate were calculated. The arrival mass was the mean body mass during the first three days after arriving at the colony. The return rate for breeders was the percentage of birds breeding in the previous year that were recorded, and for prospectors was the percentage of successful fledglings from two years previously. The ranges of annual sample sizes were as follows: date of arrival of adults, 56–388 (total N = 1 785); date of arrival of prospectors, 14–228 (total N = 808); return rate of adults, 53–273 (total N = 1 466); return rate of prospectors, 103–502 (total N = 2 078); arrival mass of adults, 40–160 (total N = 947), arrival mass of prospectors, 9–113 (total N = 406). Multiple regression and partial correlation analyses of all three parameters were performed with NAOI and SOI as independent variables.

## RESULTS

Significant differences were found between breeders and prospectors in the three parameters under consideration. Breeders arrived at the colony significantly earlier than sub-adults ( $T_{18} = 21.41$ ,  $P < 0.0001$ , Fig. 1a). Breeders were about 5% heavier than sub-adults when they arrived at the colony ( $T_{18} = 6.53$ ,  $P < 0.0001$ , Fig. 1b), and the proportion of breeders returning to the colony was almost three times higher than the proportion of sub-adults returning after two years ( $T_{18} = 13.68$ ,  $P < 0.0001$ , Fig. 1c).

The return rate in breeders was negatively correlated with the lagged NAOI, while in prospectors it was positively correlated with the lagged SOI (Table 1, Fig. 2a). Prospectors arrived later following high NAO years, and both prospectors and

breeders showed similar but non-significant trends following low SOI years (Fig. 2b). All significant correlations explained nearly 40% of the variability in the parameters under consideration. The arrival masses of breeders and prospectors were not correlated with the NAOI or SOI.

Multiple regression models with both lagged NAOI and SOI as independent variables explained significant proportions of the variability in the prospectors' date of arrival (64%) and return rate (69%) (Table 1). Post-hoc partial correlations indicated that the NAOI explained nearly 66% of the variability in the prospectors' date of arrival, 50% in the prospectors' return rate and 68% in the breeders' return rate; the SOI explained 70% of the variability in the prospectors' return rate (Table 1).

## DISCUSSION

Higher adult survival and earlier arrival of prospectors following low NAO years were most likely attributable to favourable foraging conditions during the spring migration. Higher abundance of marine fish, including Herring *Clupea harengus* (a key prey for Common Terns in Europe; Greenstreet *et al.* 1999) in estuarine areas (Attrill & Power 2002), as well as higher copepod abundance in the North Atlantic (Heath 1999) have been observed following winters characterized by low NAOI values. Consequently low NAOI values should indicate better feeding conditions in breeding areas and along the migration routes between north-west Africa and Europe.

While the return rates in adults were not correlated with the SOI (an index of ENSO conditions), the return rates of prospecting terns were significantly explained by variability in the SOI, being higher after cold La Niña events (i.e. high SOI). The impact of La Niña on local climate and the intensification of Atlantic trade winds cause concomitant upwellings in coastal West Africa (Roy

**Fig. 2.** Correlation between return rate (RR) and date of arrival (AD) of breeding Common Terns *Sterna hirundo* (filled circles, continuous lines) and prospectors (open circles, dashed lines), and one year lagged (A) North Atlantic Oscillation (NAOI) and (B) Southern Oscillation (SOI) indices for 1994–2003 (n = 10 years). \* =  $P < 0.05$ ; n.s. = non-significant correlation.

& Reason 2001), which are likely followed by increases in food availability. Subsequent increases in rainfall (Nicholson & Selato 2000, Holmgren *et al.* 2001) might increase river runoff in the vicinity of wintering areas, enhancing local productivity and food availability for Common Terns, as has been observed in the winter quarters off southern South America (Favero *et al.* 2001, Acha *et al.* 2004). Individuals departing in better physical condition from the wintering areas should therefore arrive earlier at the breeding grounds than those departing in poor condition (Forchhammer *et al.* 2002), as observed for prospecting sub-adults (Fig. 2b).

Prospectors showed higher variability in all three parameters than did adult terns, and their parameters followed more closely fluctuations observed in the NAO and ENSO. This may be because adults have to return to the breeding colonies earlier than prospecting sub-adults in order to breed, irrespective of climatic conditions. Multiple regression models explained more than 80% of the variability in timing of migration and return rate of prospectors, showing the differential responses of age classes to climate and environmental variability (Alerstam & Hedenström 1998). The absence of an effect of large-scale climate variability on body mass at arrival could be related to the fact that local food availability (affected by short-term processes) may immediately influence body mass in small seabirds, such as terns, that possess low energetic reserves (Greenstreet *et al.* 1999). The lower variability observed in adult terns could be related to the fact that more experienced individuals might be able to cope better with fluctuations in environmental conditions, as the increase in body mass with age shows (Dittmann & Becker 2003, Limmer & Becker unpubl. data). The stronger effects of variability in the ENSO on the survival of sub-adults (expressed as the observed return rates over a two-year period) could also be related to the fact that the birds spend their first two winter seasons in West Africa (Becker & Ludwigs 2004), where ENSO teleconnections have a strong influence.

Higher adult return rates and earlier arrival of prospectors were observed after low NAO years, while higher return rates of prospectors corresponded with cold ENSO events. For the moment, the reasons for these parallel trends between climate variability and return rates, body mass and timing of migration in the Common Tern are rather speculative. Further analyses and experimental studies examining local weather and environmental manifestations of climate (e.g. sea surface temperature, productivity) at wintering, staging and breeding areas are required for a better understanding of the effects of climate on variability in the migration and survival of Common Terns.

## ACKNOWLEDGEMENTS

This study was supported by the DFG (Be 916/5) and German Academic Exchange Service (DAAD Grant A/02/19132), and was a collaboration between the Institute for Avian Research "Vogelwarte Helgoland" and the National University of Mar del Plata (15E/238). We give special thanks to Stephen Oswald for his helpful comments on this paper.

## 4.2 Disease emergence and impacts in migratory waterbirds. Workshop Introduction

**Tonie Rocke**

National Wildlife Health Center, 6006 Schroeder Rd., Madison, WI 53711, USA.

Rocke, T. 2006. Disease emergence and impacts in migratory waterbirds. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 410-411.

The increasing frequency of several waterbird diseases, many of which are zoonotic, has highlighted the important need for more systematic disease surveillance at national and international scales. Current concerns regarding avian influenza have focussed attention on how best to undertake the scientific support functions. Photo: Paul Marshall.

The frequency and magnitude of disease losses amongst waterbirds (from emerging or re-emerging disease agents) have increased to the extent that they demand attention. These diseases not only affect waterbirds, but have impacts on the economic, health and cultural values of humans. Solutions require the integration of numerous scientific disciplines in an ecological approach.

The symposium reviewed existing diseases frequently carried and transported by migratory waterbirds, including botulism (Rocke), avian influenza (Shortridge & Melville) and avian cholera (Samuel).

A number of common themes and conclusions emerged from the presentations:

- Disease (both newly emerging and previously established agents) has increased in prominence as a cause of mortality in wild waterbirds and significantly impacts certain water-

bird populations, as reported by Friend, Rocke and Kuiken *et al.*. Novel etiologies now cause recurring waterbird mortalities as reported by Cole & Franson.

- Some waterbird diseases also have human and domestic animal implications and vice versa. Communication, collaboration and co-ordination between ornithologists, conservation biologists, wildlife health experts, veterinarians, and public health officials are critical to improve knowledge of these diseases and facilitate their mitigation.
- Underlying factors for emergence of diseases are related to increases in human populations, human consumption patterns, the redistribution of species and/or further aggregation of gregarious species in a manner that facilitates disease transmission.
- Improvements in disease surveillance, diagnosis and prevention are critically needed to address and manage disease problems in waterbirds.

- Integration and understanding of underlying concepts and impacts of disease are critical for global waterbird conservation.
- Education of the public, government officials and the media on the role of wild birds in disease transmission should be mandatory to prevent common misperceptions. Proactive approaches to engage with the media are necessary.

The following four recommendations were made:

1. There is a need to increase awareness, and to educate others, that disease in waterbird populations should be viewed in an ecological context, responsive to environmental changes and perturbations.
2. A global wildlife health policy should be instituted that provides standardized methods for investigation, diagnosis and reporting of mortality events in waterbirds and other

wildlife (similar to those put in place for domestic animals and humans, by, for example, the World Health Organisation and the World Organisation for Animal Health - OIE).

3. Discourse and interaction between conservation biologists, animal welfare proponents and the food animal industry should be strongly encouraged so that animal welfare considerations do not jeopardise wildlife conservation (*i.e.* proximity of open range animal production to wetlands).
4. Active steps should be undertaken to curtail the excessive movement of wild animals through the exotic pet trade so as to reduce the risk of disease transmission and to enhance the conservation of wild species.

The workshop called, in particular, for urgent action to mitigate disease emergence and losses in waterbirds by integrating fundamental disease concepts into global strategies for waterbird conservation.

There is an urgent need to better integrate animal health surveillance into programmes of waterbird monitoring so as to better understand the consequences of disease for both individual birds and for populations. The UK Wildfowl & Wetlands Trust have embarked on long-term health screening of Greenland White-fronted Geese *Anser albifrons flavirostris* as an adjunct to the internationally co-operative research and monitoring of this population. ## Evolving changes in diseases of waterbirds

Milton Friend

National Wildlife Health Center, 6006 Schroeder Rd., Madison, Wisconsin 53711, USA. (email: milton\_friend@usgs.gov)

Friend, M. 2006. Evolving changes in diseases of waterbirds. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 412-417.

### ABSTRACT

The emergence of infectious diseases is a hallmark of the twentieth century, along with the resurgence of diseases thought to have been “conquered”. This continuing problem is global in scope, involves humans (e.g. AIDS, hantavirus pulmonary syndrome, and tuberculosis), domestic animals (e.g. bovine spongiform encephalopathy “mad cow disease”, Nipah virus infections, and foot-and-mouth disease), and wildlife (e.g. morbillivirus infections, chronic wasting disease, and inclusion body disease of cranes). The emergence of diseases in wildlife involves virtually all classes of vertebrates and is occurring in all types of habitats. The number of diseases involved and the magnitude of losses are such that disease emergence and resurgence are posing an unprecedented challenge for the conservation of wildlife, including some waterbird populations.

### INTRODUCTION

Changes over time in the occurrence of diseases in waterbirds are reflective of broader disease increases worldwide. This presentation focuses on the occurrence of disease in North American waterbirds, primarily waterfowl. The scientific literature, disease databases maintained by the U.S. Geological Survey’s National Wildlife Health Center (NWHC) and personal experiences gained during more than 40 years as a wildlife disease practitioner are the foundation for this evaluation. The great amount of North American literature involving waterfowl and diagnostic findings of their causes of mortality provide a reasonable basis for retrospective evaluations of the occurrence of major disease events and when various diseases reached sufficient notoriety to be reported. Changes that have occurred include the types of disease agents involved (noninfectious vs. infectious), geographic occurrence for specific diseases, and the magnitude of losses.

### HISTORICAL PERSPECTIVE

The foundation for investigations of waterbird diseases in the USA is the Bear River Wildlife Disease Station established early in the 1900s by the Bureau of Biological Survey. The station leader was Alexander Wetmore, who later became the most distinguished American ornithologist of the nineteen thirties and forties (Ripley & Steed 1987). Dr. Wetmore’s classical studies on what we now know to be type C avian botulism (Wetmore 1918) and his investigations of lead poisoning (Wetmore 1919) are the first in-depth studies of disease in wild waterbirds.

Avian botulism (type C *Clostridium botulinum*) emerged as a problem during the late 1800s (Jensen & Price 1987), and was the most common of the few diseases receiving attention by waterfowl biologists prior to the 1960s. Avian cholera (*Pasteurella multocida*) first appeared in North American waterbirds in 1944 (Quortup *et al.* 1946), but for several decades had only a limited geographic distribution (Friend 1981). Leucocytozoonosis (*Leucocytozoon simondi*) became a concern during the 1920s and 1930s. By the 1950s, this disease was a focus for investigation in Canada and some of the northern areas of the USA (Fallis & Trainer 1964, Wobeser 1981). Early in the 1950s, the gizzard worm *Amidostomum* spp. was incriminated as a factor in Canada Goose *Branta canadensis* mortality in localized areas of the Atlantic seaboard of the USA (Herman & Wehr 1954). Lead poisoning was recognized as a problem for waterfowl as early as 1874 in the USA (Friend 1999a). There also was an awareness of aspergillosis as an occasional cause of bird deaths (O’Meara & Witter 1971).

### INCREASED PROMINENCE OF INFECTIOUS DISEASE

The number of infectious diseases of concern in waterbirds has increased, as has the frequency of disease events they cause. Avian cholera, currently the greatest global cause of waterbird

mortality by an infectious disease, first appeared as a disease of wild waterbirds in Africa in 1940 and in the USA in 1944 (Rosen 1971). It is noteworthy that in their extensive review of waterfowl disease, Phillips & Lincoln (1930) state, “We do not have a single well-authenticated case of its occurrence [avian cholera] among wild North American waterfowl.” Because of concern about this disease, they urged that it be watched for. Since 1944, avian cholera has gradually expanded its North American range and is now enzootic in several major waterfowl areas across the USA and in Canada (Friend 1999b). Globally, avian cholera has caused epizootics among marine birds from the Antarctic to the coast of Africa and in other areas (Table 1), but most commonly occurs in freshwater environments. Avian cholera has also become a “disease for all seasons”, with outbreaks occurring on summer breeding grounds, in wintering areas, and along spring and autumn staging and migration areas.

A wide variety of other infectious diseases have appeared in captive and wild bird populations within the USA (Friend *et al.* 2001). Duck plague (duck virus enteritis - DVE) entered the USA in 1967 (Leibovitz & Hwang 1968), and has since become enzootic (Converse & Kidd 2001, Friend 1999c). The 1996 occurrence of the trematode *Leyogonimus polyoon* has resulted in enzootic establishment, with repeated outbreaks in Wisconsin (Cole & Friend 1999). American White Pelicans *Pelecanus erythrorhynchos* are among the many avian and other species being impacted by West Nile fever (WNF) since its appearance in North America in 1999 (NWHC unpubl. data).

Avian pox was first reported in wild waterfowl on the USA mainland in 1978 (Morton & Dieterich 1979), and pox in Bald Eagles *Haliaeetus leucocephalus* quickly followed (Hansen 1999). Personal investigation of a major epizootic of avian pox in Laysan Albatrosses *Diomedea immutabilis* and Black-footed Albatrosses *D. nigripes* on Midway Atoll within that same time-frame also involved the appearance of a new disease in a waterbird population. Many years of banding albatrosses on Midway by others had not disclosed the presence of this highly visible disease (pers. unpubl. data), except for an isolated case

report of pox in a Red-tailed Tropicbird *Phaethon rubicauda* (Locke *et al.* 1965).

Newcastle disease (ND) is another example of increased prominence by an infectious disease. Lethal strains of ND were eliminated from the poultry industries of Canada and the USA during the early 1970s. However, ND has periodically been killing large numbers of Double-crested Cormorants *Phalacrocorax auritus* since 1990 in Canada and since 1992 in the USA (Docherty & Friend 1999). These and other diseases that have appeared (Table 2) illustrate the increasing challenge that infectious disease poses for the conservation of wild birds (Friend *et al.* 2001).

## GEOGRAPHIC EXPANSION OF DISEASE

Expansion of the historic geographic distribution for many diseases is another outcome from disease emergence and resurgence, and involves both non-infectious diseases such as avian botulism and established infectious diseases such as avian cholera. Originally, type C avian botulism was considered to be a disease of western North America, but since the 1930s it has occurred throughout most of the USA, including Hawaii (Rocke & Friend 1999) and on all continents with the exception of Antarctica. During the winter of 2002/2003, Taiwan experienced avian botulism for the first time in wild waterbirds (Rocke, this volume).

The first reported avian cholera epizootic in waterbirds occurred in Kenya during 1940 (Rosen 1971). The global occurrence of this disease is attested to by Table 1. Continued global expansion is evident from the 2003 epizootic that killed more than 13 000 Baikal Teal *Anas formosa* wintering in Cheonseo Bay. This was the first occurrence of avian cholera in Korea (Kwon & Kang 2003). The geographic spread of avian cholera as a disease of North American waterbirds began during the 1960s after nearly two decades of localized occurrences in California and Texas. During the 1970s and 1980s, epizootics occurred across the USA and accompanied waterbirds from their breeding grounds in northern Canada to wintering areas in the southern USA and Mexico (Brand 1984, Friend 1999b).

**Table 2.** Examples of novel disease occurrences in North American waterbirds since 1960.

Disease	Type	Year	Primary Taxa	Comments
Duck Plague	Virus	1967	Anatidae	Now enzootic
Erysipelothrix	Bacteria	1975	Podicipedidae	Later die-off of Brown Pelicans <i>Pelecanus occidentalis</i>
Streptococcosis	Bacteria	1977	Podicipedidae	First record in any wild bird
Avian pox	Virus	1978	Anatidae	Pox in Bald Eagles <i>Haliaeetus leucocephalus</i> followed
Inclusion body disease of cranes	Virus	1978	Gruidae	Captive breeding colony
Newcastle disease	Virus	1990	Phalacrocoracidae	Recurring epizootics of highly virulent disease
Avian botulism	Bacterial toxin	Mid-1980s	Pelecanidae	First type C epizootics in fish-eating birds
Avian tuberculosis	Bacteria	1980s	Gruidae	Major causes of demise of “satellite” flock of Whooping Cranes <i>Grus americana</i>
Mycotoxiosis	Fungal toxin	1982	Gruidae	Associated with peanut farming
Unknown	Unknown	1992	Podicipedidae	Persistent problem recognizable by clinical signs
Avian vascular myelopathy	Unknown	1994	Rallidae, Anatidae, Accipitridae	Persistent and expanding problem first seen in Bald Eagles
Trematodiasis	Metazoan parasite	1996	Rallidae	Now enzootic
West Nile fever	Virus	2002	Pelecanidae	First occurrence in 1999 in Corvidae

**Table 3.** North American examples (excluding type C avian botulism) of disease emergence and geographic expansion causing 5 000 or more waterbird deaths since 1970.

Location	Disease	Year	Estimated loss	Primary species
Chesapeake bay, Maryland	Avian Cholera	1970	80 000	Scoters <i>Melanitta</i> spp., Long-tailed Duck <i>Clangula hyemalis</i>
Lake Andes, South Dakota	Duck Plague	1973	40 000	Mallard <i>Anas platyrhynchos</i>
Great Salt lake, Utah	Erysipelas	1975	5 000	Eared Grebe <i>Podiceps nigricollis</i>
Great Salt Lake, Utah	Streptococcosis	1977	7 500	Waterfowl, shorebirds
Hudson Bay, Canada	Avian cholera	1979	5 000+	Snow Goose <i>Chen caerulescens</i>
Rainwater Basin, Nebraska	Avian cholera	1980	80 000	Waterfowl
Texas Panhandle	Mycotocicosis	1985	5 000	Sandhill Crane <i>Grus canadensis</i>
Saskatchewan, Canada	Avian cholera	1988	5 000+	Redhead <i>Aythya americana</i>
Salton Sea, California	Salmonellosis	1989	5 000	Cattle Egret <i>Ardea ibis</i>
Lower Therien, Canada	Newcastle disease	1992	20 000	Double-crested Cormorant <i>Phalacrocorax auritus</i>
Salton Sea, California	Unidentified	1992	155 000	Eared Grebe
Banks Island, Northwest Territories	Avian cholera	1995	30 000	Snow Goose
Shawano Lake, Wisconsin	Trematodiasis	1986	12 700	American Coot <i>Fulica americana</i>
Salton Sea, California	Newcastle disease	1998	6 000	Double-crested Cormorant
Great Salt Lake, Utah	Avian cholera	1998	50 000	Eared Grebe
Tensas, Louisiana	Aflatoxicosis	1999	10 500	Snow Goose
Mid-and Western USA	West Nile fever	2003	5 000+	American White Pelican <i>Pelecanus erythrorhynchos</i>

The rapid geographic spread within North America by some newly emerged avian diseases such as WNF and house finch conjunctivitis has been without precedence. It took less than four years for WNF to appear in all of the contiguous 48 states within the USA following its appearance in New York City in 1999 (NWHC unpubl. data). In less than three years following the 1994 index case of conjunctivitis in a House Finch *Carpodacus mexicanus* at a bird feeder in the Washington D.C. area, this disease spread across the entire geographic range of the eastern populations of this species (Fischer *et al.* 1997). Further geographic spread to the western House Finch population followed. Spread to Canada and Mexico has also occurred for WNF and conjunctivitis. The rate of spread for duck plague across the USA and into Canada (Friend 1999c) has been less aggressive than the infectious diseases just noted. Isolated and sporadic epizootic with limited geographic spread has been characteristic of still other avian diseases (Friend & Franson 1999). However, further spread of these diseases may still occur.

### MAGNITUDE OF LOSSES

The greatest loss of waterbirds from a single disease event may have been the 1910 avian botulism outbreak that occurred on the Bear River marshes in Utah. That year also likely marked the greatest single-year loss from one disease. The millions of waterbirds that died from botulism that summer on the Bear River marshes and in California stimulated the beginning of real concern about the effects of this disease on waterfowl populations within the USA (Jensen & Williams 1964). There are no reports of disease events in wild birds of similar magnitude prior to that time. Also, although epizootics due to parasites, fungi, or bacteria may have occurred, Phillips & Lincoln (1930) stated that they "...have no knowledge that disease – which in modern times [1920s] has so decimated the [waterfowl] flocks – was an important factor..."

With the exception of the early avian botulism events, individual disease events involving waterbirds rarely exceeded losses of 5 000 until the occurrence of avian cholera. Past eval-

uations of North American waterfowl losses from disease resulted in a total estimated loss during 1930–1964 of nearly 1.9 million birds and a yearly average of approximately 55 000 birds (Stout & Cornwell 1976). Since the 1970s, single events during many years have killed more than 50 000 birds (NWHC unpubl. data). In another evaluation, Bellrose (1976) estimated that during the period of 1955–1973, non-hunting mortality (disease, predation, and accidents) resulted in the loss of 20 million game ducks each year and noted that "Disease directly or indirectly accounts for the largest proportion of non-hunting deaths". Much of this mortality (two to three percent of the waterfowl population) was due to lead poisoning (1.6 to 2.4 million game ducks).

Since the 1970s, both the frequency of reported disease events in waterbirds and the number of large-scale losses due to individual events have increased greatly over the previous half-century (Table 3). The characteristics of these disease events also differ from previous times. A greater number of diseases are involved, disease is occurring over a greater geographic area, and these events are occurring throughout the year rather than being seasonal.

### POPULATION IMPACTS

In 1948, Ira Gabrielson, then Director of the Fish and Wildlife Service, referred to botulism and other disease as minor factors in the decline of North American waterfowl populations (Gabrielson 1948). Gabrielson's perspectives towards disease were consistent with long-reigning beliefs by many within the wildlife conservation community. Those beliefs minimized the toll of avian botulism within the western USA despite reports that "...the disease outbreaks in the West are particularly disastrous and it is conceivable that because of them it might be necessary to shorten shooting seasons or bag limits..." (Phillips & Lincoln 1930).

As noted by Toft (1991) and others (e.g. Haldane 1949, May 1988), the long-standing failure of many within the wildlife conservation community to accept the importance of disease has

deep roots that have their origin in the teachings and writings of eminent ecologists and biologists. In the past, "...ecologists and evolutionary biologists virtually ignored parasites [including microbes]..., even as a source of mortality for host species [wildlife] of primary interest" (Toft 1991). However, within recent years, a shifting in perspective towards the impacts of disease on avian populations has emerged within some components of the wildlife conservation community. In 1980, Price noted that "...parasites [includes microbes] affect the life and death of practically every other living organism" and a decade later (1991) stated "...parasites are likely to play a role in practically every aspect of the evolutionary biology of birds, and probably vertebrates in general. Such a view has been a long-time in gestation, probably because in a fetal condition it was roundly thwarted by two eminent ecologists".

Those ecologists were Charles Elton and David Lack. Their conclusions may have been appropriate for the time period and species for their study. However, the conditions of today are different and present an array of increased challenges for avian populations world-wide (Friend *et al.* 2001, Friend & Franson 1999). Admittedly, "the ability to determine and evaluate the effect of disease on the population dynamics of free-ranging avifauna is fraught with difficulties and confounded by a host of factors that complicate the determination of cause-and-effect relationships" (Friend *et al.* 2001). Regardless, examples of waterbird populations being threatened by disease are currently not difficult to find.

Although the cause has yet to be determined, disease is suspected to be a major factor in the decline of Common Eiders *Somateria mollissima* in the Gulf of Finland (Hollmén *et al.* 1999, 2000). That population is declining at an annual rate of 6-10% (Hario 1998). In the late 1980s, duckling survival dropped to 1-5% in some areas, and mortality events have killed large numbers of young and some adult Eiders (Hollmén *et al.* 1999, 2000). Also, the 2004 avian cholera outbreak on Dyer Island, South Africa, killed fledgling as well as adult Cape Cormorants *Phalacrocorax capensis* and Crowned Cormorants *P. coronatus*, two species whose populations are in decline and classified as near-threatened. This is the third consecutive year for outbreaks of avian cholera on this Cape Nature Conservation reserve (Pro Med 2004). Avian cholera is also a major mortality factor for the Ruddy Duck *Oxyura jamaicensis* at California's Salton Sea. Substantial numbers of Eared Grebes (Black-necked Grebes) *Podiceps nigricollis* have also been killed by avian cholera at the Salton Sea and the Great Salt Lake (Friend 2002).

In general, disease evaluations primarily involve fledged birds. Far less is known about disease as a factor in effecting recruitment, even though mortality occurs on a large scale. Newcastle disease, avian cholera, salmonellosis, and eustrongyides are diseases causing mass mortality in breeding colonies of waterbirds (Friend & Franson 1999). For example, Newcastle disease killed most of the production of Double-crested Cormorants at the Salton Sea during 1997 and again during 1998 (Friend 2002). The emergence of diseases that impact embryo survival and other aspects of reproduction are potentially of even greater importance. Therefore, the high prevalence of antibodies to infectious bursal disease virus (IBDV) in Common Eiders nesting in the Gulf of Finland (Hollmén *et al.* 2000) and antibodies to IBDV in wild Emperor Penguins *Aptenodytes fosteri* and Adelie Penguins *Pygoscelis*

*adalaiae* in the Antarctic (Gardner *et al.* 1997a, 1997b) is of special concern.

## DISCUSSION

Disease emergence is real, global in scope, and affecting wildlife as well as domesticated species and humans. Infectious disease has increased in prominence as a cause of mortality for wild birds, and is aided by environmental conditions that redistribute and further aggregate gregarious species in a manner that facilitates disease transmission. Aquatic environments are an important habitat for disease emergence in humans and should be viewed with similar concern for wild waterbirds. A recent evaluation cited 17 different pathogenic microbes and infectious human diseases recognized since 1972 for which water may play a role (Koopmans 2001). Examples of disease in waterbirds within this presentation clearly demonstrate that aquatic environments are also important for disease emergence in birds. It is important to recognize that examples have been provided, rather than a holistic overview of the increasing array of diseases taking a toll of waterbirds.

Losses from disease are much greater today than they have been for nearly a century. These losses have increased consequences because direct and indirect effects of habitat loss have reduced the resilience of wildlife populations to compensate for the cumulative impacts from disease. Further habitat degradation and loss are assured for the foreseeable future (Ayensu *et al.* 1999). Thus, past approaches to disease in wildlife need to be improved upon. Reactive response to epizootics is an inadequate approach and should not be our primary defense against disease in waterbirds. The conservation of these species requires a more proactive approach involving disease prevention and control as a mainstream activity if we are truly serious about global waterbird conservation.

## Emerging viral diseases in waterbirds

*Thijs Kuiken, Ron A.M. Fouchier, Guus F. Rimmelzwaan & Albert D.M.E. Osterhaus*

*Department of Virology, Erasmus Medical Centre, Dr. Molewaterplein 50, 3015 GE Rotterdam, The Netherlands.*

Kuiken, T., Fouchier, R.A.M., Rimmelzwaan, G.F. & Osterhaus A.D.M.E. 2006. *Emerging viral diseases in waterbirds*. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 418-421.

Emerging viral diseases in waterbirds include Newcastle disease, West Nile fever and avian influenza. These are important not only because of their impact on the species themselves, but also because they may be transmitted to domestic animals, humans, or both, with economic consequences and consequences for human health. Pathogenic Newcastle disease virus emerged in Double-crested Cormorants *Phalacrocorax auritus* in south-central Canada in 1990, and spread widely across North America in subsequent years. It affects mainly juvenile cormorants, with up to 90% mortality in affected colonies. Newcastle disease is economically important because it is a reportable disease infectious for poultry. Its emergence may have been associated with rapid population growth of cormorant populations, largely due to anthropogenic factors. West Nile virus first appeared in New York in 1999, and has spread rapidly across North and Central America. Mortality of infected wild birds, particularly crows (Corvidae) but also waterbirds, has been unexpectedly high. The virus is occasionally transmitted to humans, horses and other mammals. In 2003, over 9 000 human cases were reported in the USA, of which nearly 300 were fatal. Wild birds, mainly waterbirds, are thought to be the reservoir for influenza A viruses in nature. In 2003, highly pathogenic avian influenza A (H7N7) virus probably evolved from low pathogenic viruses in free-living Mallard *Anas platyrhynchos* and caused high mortality in poultry in The Netherlands. The virus was also transmitted to humans, resulting in conjunctivitis, influenza-like illness and one fatal case of pneumonia. The emergence of H7N7 virus may be related to the rapid growth of free-range chicken farms in The Netherlands. Overall, the underlying factors for the emergence of infectious diseases in recent years are anthropogenic social and environmental changes. We need to recognize and address these factors in order to decrease the rate of emergence and to make the transition to a more sustainable society.

### INTRODUCTION

Since the 1980s, the emergence and re-emergence of infectious diseases in humans, domestic animals and wildlife have been reported with increasing frequency (Daszak *et al.* 2000, Kuiken *et al.* 2003). Waterbird species around the world have also been affected by emerging infections, including viruses, bacteria and protozoa (Table 1). Here we concentrate on three outbreaks, Newcastle disease, West Nile fever and avian influenza, and discuss possible underlying factors and future measures.

### NEWCASTLE DISEASE

Newcastle disease in Double-crested Cormorants *Phalacrocorax auritus* (reviewed in Kuiken 1999) emerged in North America in 1990, when extensive mortality was observed in breeding colonies at several lakes in the central provinces of Canada. This was considered extraordinary because the causative agent, a pathogenic strain of Newcastle disease virus, was exotic to North America, and because it was the first time that this disease had caused high mortality in wild birds.

The clinical signs of Newcastle disease in Double-crested Cormorants include lameness of one or both wings or legs, loss of balance, uncoordinated movements, exudation from the eyes, and abnormal posture. The nervous signs correspond to a characteristic non-suppurative inflammation of the brain and spinal cord (encephalomyelitis) and the presence of Newcastle disease virus antigen in neurons, glial and endothelial cells, as shown by immunohistochemistry. Although the above clinical signs and pathologic changes are suggestive, the definitive diagnosis of Newcastle disease depends on identification of the virus by isolation or reverse transcriptase-polymerase chain reaction, and determination of its pathogenicity.

Since its emergence in 1990, Newcastle disease in Double-crested Cormorants has become more widespread, appearing in western Canada, the Great Lakes area and the north-central states

**Table 1.** Selected emerging infectious diseases in wild birds in the past two decades (data from Daszak *et al.* 2000 and Kuiken *et al.* 2003).

Disease	Pathogen	Hosts	Geography of emergence
Highly pathogenic avian influenza	Influenza A virus (H5N1)	Humans, waterfowl, waders, poultry	Asia
Highly pathogenic avian influenza	Influenza A virus (H7N7)	Humans, waterfowl, poultry	The Netherlands
West Nile fever	West Nile virus	Humans, horses, other mammals, birds, mosquitoes	North and Central America
Newcastle disease	Newcastle disease virus	Double-crested Cormorant, pelicans, gulls, poultry	Canada, USA
Mycoplasmal conjunctivitis	<i>Mycoplasma gallisepticum</i>	House Finch* and other garden birds	Canada, USA
Salmonellosis	<i>Salmonella typhimurium</i> DT40	Wild finches	UK
Avian malaria	<i>Plasmodium</i> spp.	Wide range of native birds	Hawaii

\* *Carpodacus mexicanus*

of the USA in 1992, and extending to the west coast of the USA in 1997. These outbreaks have affected mainly Double-crested Cormorants, and are limited to young of the year, with up to 90% mortality in affected colonies. In other bird species present at these outbreaks, Newcastle disease has been diagnosed only in an American White Pelican *Pelecanus erythrorhynchos*, a Ring-billed Gull *Larus delawarensis*, a Black-crowned Night-Heron *Nycticorax nycticorax*, and a Caspian Tern *Sterna caspia*. No evidence of Newcastle disease was found in 22 species of birds occurring at a breeding colony of Double-crested Cormorants where an outbreak of Newcastle disease was followed closely.

Newcastle disease is important for the poultry industry because of the devastating epidemics it causes, and because of its far-reaching effects on trade in poultry products. There is one recorded instance of transmission of Newcastle disease from Double-crested Cormorants to poultry. This was in 1992 at Devils Lake, North Dakota, where Newcastle disease was diagnosed in a flock of domestic free-range turkeys located less than 7 km from an affected cormorant colony (Meteyer *et al.* 1997).

A possible underlying factor for the emergence of Newcastle disease in Double-crested Cormorants is the dramatic increase in the size of its population since the late 1970s, resulting in a greater risk of transmission of the Newcastle disease virus and increased severity of the outbreaks. This is especially true for the population in the Canadian and US interior, which increased from about 6 000 in 1969 to 220 000 in 1992 (Hatch 1995). There appear to be five factors that have contributed to this population explosion (Wires *et al.* 2001):

- the ban on DDT in 1972;
- increased protection for the Double-crested Cormorant in 1972, under the Migratory Bird Treaty Act;
- human-induced changes (e.g. the introduction of exotic fish species and over-fishing of predatory fish) in lakes in the breeding range, resulting in an increased food supply;
- the development of aquaculture (e.g. catfish farms) in the wintering range, resulting in an increased food supply; and
- the creation of additional breeding and foraging habitat (e.g. reservoirs and artificial islands).

## WEST NILE VIRUS

The emergence of West Nile virus infection in North America is impressive because of its dramatic impact on the health of humans, domestic animals and wild birds. It spread from its original range in Africa, the Middle East and Europe to New York in 1999, where it was first described as a fatal neurological disease of unknown cause in humans. When mortality and nervous signs were also observed in a variety of exotic and native birds, especially crows (Corvidae), the investigators realized that they were dealing with a new disease in North America, West Nile fever (Lanciotti *et al.* 1999).

West Nile virus infection is mosquito-borne, and is amplified and maintained in birds. It is occasionally transmitted, usually by mosquito bites, to humans, horses and other mammals, but these are incidental hosts that do not play an important role in the life cycle of the virus. The nervous signs observed in West Nile fever are related to virus infection and subsequent inflammation of the central nervous system, with expression of virus antigen in neurons and glial cells of affected tissue (Campbell *et al.* 2002, Steele *et al.* 2000).

Wild birds are important for the epidemiology of West Nile virus. Modelling indicates that infected birds spread the virus over long distances along their migratory routes, while mosquitoes are important for local dissemination (Peterson *et al.* 2003). As a result, the West Nile virus has spread rapidly across North America, from New York in 1999 as far west as California and as far south as Mexico and the Caribbean by 2003, and is likely to spread further south into Central and South America (Kuiken *et al.* 2003). According to reports to the Centers for Disease Control and Prevention (2004a), mortality from West Nile virus infection has been recorded in over 100 wild bird species in the USA, including several species of waterbirds. This is surprising, because mortality in birds is low in the historic range of West Nile virus (McLean *et al.* 2002). Two possible reasons for the high mortality in wild birds in North America are that North American birds have not co-evolved with West Nile virus and are therefore more susceptible to disease, and/or that the strain of West Nile virus in North America is particularly pathogenic. Information on the impact of West Nile virus on wild birds at the population level remains scant. Yaremych *et al.* (2003) found an annual survival rate of 17.9% in American Crows *Corvus brachyrhynchos* in an area where West Nile virus occurred, compared with an average annual survival rate of 89.6% for breeding-age American Crows not affected by West Nile virus infection. In another study, West Nile virus infection was diagnosed as the cause of death in American White Pelicans at nine sites in the USA where more than ten pelicans died in 2002 and 2003 (Rocke *et al.* in press).

West Nile virus also has a large impact on the health of humans and horses in North America. As expected in a human population that had not previously been exposed to West Nile virus infection, there has been a relatively high proportion of potentially fatal neurological cases. A total of 9 862 human cases were reported in the USA in 2003 alone, and 264 of these were fatal (Centers for Disease Control and Prevention 2004b). In horses, a total of 5 181 cases were reported in the USA in 2003 (USDA 2004), with substantial morbidity and mortality from West Nile virus encephalitis (Kleiboeker *et al.* 2004).

The underlying factors for the emergence of West Nile virus in North America are poorly understood. There was an increase in the number of cases of West Nile meningoencephalitis in the original range of the West Nile virus between 1994 and 2000 (Campbell *et al.* 2002), and by phylogenetic analysis, the 1999 New York isolate most closely resembled that of an isolate from Israel in 1997, suggesting that it originated from the Middle East (Lanciotti *et al.* 2002). How this occurred is not known; possible mechanisms include migratory birds, legal or illegal importation of birds, persons travelling at the incubation stage of West Nile virus infection, and transport of infected mosquitoes by aeroplane.

## AVIAN INFLUENZA A VIRUS

Avian influenza A virus has recently received widespread attention because of large-scale outbreaks in poultry and virus transmission from poultry to humans, in some cases with fatal consequences (Fouchier *et al.* 2004, Tran *et al.* 2004). Wild birds, mainly waterbirds, are involved with these outbreaks because they are thought to be the reservoir for influenza A viruses in nature. For this reason, the Department of Virology at the Erasmus Medical Centre in The Netherlands is engaged in a long-term surveillance study to screen migratory birds for the presence of influenza A virus (Fouchier *et al.* 2003). To date,

influenza A viruses representing 15 haemagglutinin subtypes and nine neuraminidase subtypes have been described in birds. Of these, the subtypes H5 and H7 may become highly pathogenic in poultry and result in so-called fowl plagues (Fouchier *et al.* 2004). The recent H5N1 virus outbreaks are described elsewhere in these Proceedings (Melville & Shortridge 2006). Here we will concentrate on the H7N7 virus outbreak in The Netherlands in 2003 (Fouchier *et al.* 2004, Koopmans *et al.* 2004).

In February 2003, an infectious disease with high lethality for poultry emerged in The Netherlands and subsequently spread to poultry in Germany and Belgium. In total, around 30 million chickens, representing about 28% of the total chicken population in The Netherlands, died or were pre-emptively culled. The causative agent of this outbreak was identified as highly pathogenic avian influenza A (H7N7) virus. By sequencing and phylogenetic analysis of the genome of this virus, it was found to be most closely related to low pathogenic virus isolates obtained from Dutch Mallard *Anas platyrhynchos* during the course of the above-mentioned surveillance study. Evolution from a low pathogenic to a high pathogenic pathotype presumably occurred after the virus had been introduced into poultry farms, as has been shown on several other occasions (Ito *et al.* 2001).

Responses to health questionnaires revealed that 453 people involved in the control of the avian influenza outbreak had health complaints, consisting of conjunctivitis (349 cases), influenza-like illness (90 cases) and other complaints (67 cases). Influenza A (H7) virus was isolated from 89 of these cases, most of which had conjunctivitis. One veterinarian died from pneumonia followed by acute respiratory distress syndrome caused by H7N7 virus, two weeks after visiting an affected poultry farm.

Over 100 carcasses of free-living wild birds were collected around affected poultry farms to determine whether H7N7 virus was transmitted from poultry to wild birds ("spill-back"). However, none of these carcasses tested positive for influenza A virus, and there was therefore no evidence for a role of wild birds in spreading the H7N7 virus from affected poultry farms to other areas.

Underlying factors for the emergence of H7N7 virus in The Netherlands are unclear. It is possible, however, that it is associated with the rapid increase in the number of free-range chickens in The Netherlands, from none in 1991 to 305 000 in 2001. This fits with the association between outbreaks of highly pathogenic avian influenza outbreaks and the presence of free-range poultry farms or "wet" markets in other parts of the world (Kuiken *et al.* 2003).

## DISCUSSION

The above examples illustrate our lack of knowledge of the factors underlying the emergence of infectious diseases in individual cases. However, when reviewed together, emerging infectious diseases in humans, domestic animals and wildlife show a common set of underlying factors (Table 2). These result from the combined weight of human numbers and their consumption patterns that are overloading the planet's biophysical and ecological capacity (Daszak *et al.* 2000, Daszak *et al.* 2001, McMichael 2001).

Early detection of emerging infectious diseases will be facilitated by improved disease surveillance in humans, domestic animals and wildlife. Furthermore, we have the technological capability to respond rapidly to such events in terms of identifying the causative agent and developing diagnostic techniques,

**Table 2.** Factors underlying the emergence of infectious diseases (from Daszak *et al.* 2000).

- International travel and commerce (introduction of species)
- Demographic changes
- Agricultural changes
- El Niño Southern Oscillation
- Global climate change
- Technological change
- Microbial adaptation
- Breakdown in health or international traffic infrastructure
- Increased interaction with vectors/wildlife/humans/domestic animals
- Immuno-suppression/heightedened susceptibility
- Increased surveillance

and, to a lesser degree, developing vaccines and therapeutic agents (Kuiken *et al.* 2003). However, these measures do not deal with the source of the problem. The emergence and re-emergence of infectious diseases will only increase in the future, unless we address the increase in human population and consumption patterns, and make the transition to a more sustainable society.

## The global importance of avian botulism

Tonie E. Roche

National Wildlife Health Center, 6006 Schroeder Rd., Madison, Wisconsin 53711, USA. (email: tonie\_roche@usgs.gov)

Roche, T. E. 2006. The global importance of avian botulism. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 422-426.

### ABSTRACT

On a world-wide basis, avian botulism is the most significant disease of waterbirds. Type C botulism has been reported in waterbirds from every continent except Antarctica, and outbreaks with one million or more waterbird deaths have been reported by the USA, Canada, and Russia. Unfortunately, population impacts of avian botulism have not been well studied. Species that are numerous, geographically widespread, and have a high reproductive potential (e.g. Mallard *Anas platyrhynchos*) may be able to withstand sporadic high losses, while populations of other, less common or endangered species whose populations are disproportionately exposed to botulism, may not be as resilient (e.g. Northern Pintail *Anas acuta*, Black-faced Spoonbill *Platalea minor*). The effect of botulism on local or regional waterbird populations is also significant. The 1996 botulism outbreak at the Salton Sea, California, killed nearly 15% of the western population of American White Pelicans *Pelecanus erythrorhynchos*. Because the occurrence of avian botulism is largely controlled by environmental factors and not dependent on waterbird density, this disease has the potential to cause significant population declines in some species, seriously impeding conservation efforts.

### INTRODUCTION

During the last century, avian botulism killed many millions of birds, especially waterfowl and shorebirds, and was the most significant disease of waterbirds in total mortality. Large outbreaks of “duck sickness”, later recognized to be type C botulism, were first documented in the western USA and Canada in the early 1900s (Hobmaier 1932). Millions of waterfowl died in three widely separated regions of North America – the deltas of the Great Salt Lake, Utah, the southern San Joaquin Valley,

California, and the Elfros region of Saskatchewan, Canada. Outside North America, the first outbreaks of botulism in wild birds were recorded in Australia in 1934 (Pullar 1934), in Russia (formerly USSR) in 1957 (Kuznetsov 1992), and in Europe in 1963 (Jensen & Price 1987), first in Sweden and shortly after in Denmark (1965), Great Britain (1969), and The Netherlands (1970). Botulism was also confirmed in South Africa (1965), New Zealand (1971), Japan (1973), Argentina (1979) and Brazil (1981). To date, type C botulism has been diagnosed in wild waterbirds in at least 28 countries and on every continent with the exception of Antarctica. More than a million deaths from type C avian botulism have been reported during single outbreaks in some wetlands in North America and Russia (Table 1), and outbreaks with losses exceeding 50 000 birds have been relatively common. Even though most of the large outbreaks of avian botulism occurred in North America, the global importance of the disease and its potential to cause massive and even catastrophic losses of birds are evident.

### ETIOLOGY AND HOST RANGE OF THE DISEASE

The agent which causes avian botulism is a neurotoxin produced by the bacterium *Clostridium botulinum*, a strict anaerobe that forms dormant spores in adverse conditions. Botulinum toxin is produced only after the spores germinate during vegetative growth of the bacteria. Birds primarily acquire the disease by ingesting toxin-laden food items; thus, the disease is usually a food poisoning and not an infection. It can also be caused by “toxico-infections”, when botulinum toxin-producing bacteria colonize the intestinal tract of an individual or secondarily infect a wound. Seven different neurotoxins are produced by strains of *C. botulinum*, designated types A to G (Smith & Sugiyama 1988). Most botulism outbreaks in birds are caused by type C toxin, but sporadic die-offs among fish-eating birds, primarily in the Great Lakes of North America, have been caused by type E toxin.

Botulinum toxin causes a flaccid paralysis in birds, with loss of motor control, flight and ambulation. A common sign of botulism in birds is paralysis of the nictitating membrane. In the final stages of the disease, birds are unable to lift their heads; thus, the disease has also been called “limberneck”. Death usually results from respiratory failure or drowning. All birds are probably susceptible to botulinum toxin, with the exception of vultures and possibly other scavenging birds, which may have an innate resistance to the disease. Upon review of the literature and over 2 000 diagnostic records at the USGS National Wildlife Health Center (NWHC), confirmed reports of type C botulism were found for 264 species of birds representing 39 families; most of these (22) were waterbird families. Foraging behavior appears to be the most significant risk factor for avian botulism (Roche & Friend 1999). Filter feeding and dabbling waterfowl, such as Mallard *Anas platyrhynchos*, Green-winged Teal *A. crecca*, and Northern Shoveler *A.*

**Table 1. Type C avian botulism outbreaks with losses of over 50 000 birds.**

Location	Year	Estimated losses
Utah and California, USA	1910	Millions
Lake Malheur, Oregon, USA	1925	100 000
Great Salt Lake, Utah, USA	1929	100 000-300 000
Tulare Basin, California, USA	1941	250 000
Tule Lake, California, USA	1948	65 000-150 000
California, USA	1969	140 000
Montana, USA	1970	100 000
Great Salt Lake, Utah, USA	1980	110 000
Caspian Sea, former USSR	1982	1 000 000
Lake Pakowki, Alberta, Canada	1995	100 000
Whitewater Lake, Manitoba, Canada	1996	117 000
Old Wives Lake, Saskatchewan, Canada	1997	1 000 000
Great Salt Lake, Utah, USA	1997	514 000

*clypeata*, are among the species at greatest risk for contracting type C botulism, as well as probing shorebirds such as sandpipers (Scolopacidae), and avocets and stilts (Recurvirostridae).

## EPIZOOTIOLOGY

Much of the collective knowledge about the epizootiology of avian botulism derives from observations of the massive outbreaks in waterfowl in wetlands in western North America. However, the epizootiology of botulism in birds is more complex than previously believed and also quite diverse, being dependent on local environmental conditions as well as the foraging behavior of the birds involved. Several distinct patterns in the occurrence of type C botulism in waterbirds are evident and will be discussed here.

### Botulism in freshwater wetlands

Avian botulism in freshwater wetlands typically occurs during the warmer months of summer or autumn, but outbreaks are unpredictable, sometimes occurring annually in certain wetlands but not in adjacent ones with similar habitat and patterns of bird use. Also, losses from botulism vary greatly from year to year and from species to species. Only a few hundred birds may die from botulism in a wetland one year, whereas tens of thousands or more may die the following year at the same location.

Botulinum spores are highly resistant to heating and drying, can remain viable for years, and are widely distributed in wetland habitats (Smith *et al.* 1978). Spores can also be found in the tissues of most wetland inhabitants, including aquatic insects, mollusks and crustacea, and many vertebrates, including birds and fish (Reed & Rocke 1992). Wetlands where botulism outbreaks have occurred multiple times are heavily contaminated with spores and have a higher probability of subsequent outbreaks than wetlands with no known history of the disease (Wobeser *et al.* 1987). However, spores can be carried in the tissues of birds and distributed to new environments in their feces (Matveev & Konstantinova 1974), and outbreaks have occurred in recent years in wetlands with no known history of the disease (NWHC unpubl. data). In a 40 sq km multi-wetland complex where numerous botulism outbreaks have occurred in the past, Sandler *et al.* (1993) found no association between the density of spores in an individual wetland and the occurrence of outbreaks. Once botulinum spores are established in a wetland, their density is probably not a limiting factor for the occurrence of the disease.

Wetland conditions seem to be a more important determinant in the occurrence of botulism. A recent study of 32 wetlands with botulism outbreaks and paired control wetlands in nine states in the USA (Rocke & Samuel 1999) demonstrated that the risk of botulism outbreaks was associated with several measurable wetland characteristics. These relationships could be modeled, but they were complex, involving both non-linear and multivariate associations. The most important factor was water pH, but its effect was strongly influenced by water temperature and redox potential. In general, the risk of botulism outbreaks increased when pH was between 7.5-9.0, redox potential was negative, and water temperature was over 20°C. Risk declined in wetlands with a pH under 7.5 or over 9.0, when redox potential was positive (over +100 mv), and water temperature was lower (10-15°C). Although these variables have been shown to influence spore germination and bacterial replication in the laboratory, the

underlying mechanism for their association with the risk of botulism outbreaks in natural wetlands is unknown. Also, the investigators emphasized that even when wetland conditions were indicative of high risk, other, more proximate factors, such as invertebrate density, bird abundance and other sediment and water characteristics, probably interact to determine whether botulism actually occurs in a specific wetland and may also influence its severity. For example, in a multi-wetland refuge complex in northern California, botulism outbreaks in high-risk wetlands occurred in direct relation to increasing invertebrate abundance and increasing temperature (Rocke *et al.* 1999).

Presumably, wetland conditions enable bacterial growth and toxin production, resulting in a high-risk situation, but an outbreak will only occur if toxic food items are encountered and ingested by birds. In some cases, decaying organic matter that contains toxin may be directly ingested by birds. Toxin has been produced readily in high protein organic matter and decaying invertebrate tissues both in the field and in the laboratory (Hobmaier 1932, Kalmbach & Gunderson 1934, Bell *et al.* 1955, Rocke unpubl. data). Birds that sift through the mud to feed, such as Mallard and other dabbling ducks, and filter feeders, such as Northern Shoveler, are likely to ingest a wide variety of decaying organic matter or dead invertebrates that may contain sufficient levels of toxin to cause botulism. Waterbirds may also be poisoned upon consumption of zooplankton or wetland invertebrates that have consumed toxic material. The carcass-maggot cycle, described in more detail below, is a classic example of secondary poisoning through consumption of toxin-laden invertebrates, but other aquatic animals may serve in this role as well. Wetlands are home to numerous invertebrates and zooplankton that consume organic debris, particularly in the benthos, and type C botulinum toxin has been demonstrated in free-living aquatic invertebrates (Kalmbach & Gunderson 1934, Rocke unpubl. data), crustacea (Rocke unpubl. data), and zooplankton (Neubauer *et al.* 1988). Unfortunately, direct evidence that clarifies the role of invertebrates in the initiation of botulism outbreaks is lacking. Instead, most research has focused on the role of sarcophagous larvae on carcasses and the carcass-maggot cycle of botulism.

### Carcass-maggot cycle of avian botulism

It is well known that decomposing tissues containing botulinum spores can support high levels of toxin production (Bell *et al.* 1955, Reed & Rocke 1992). Fly larvae and other invertebrates are unaffected by the toxin and, as they feed on decaying matter, they effectively act to concentrate the toxin. Toxin levels in maggots as high as 400 000 mouse lethal doses (MLD)/g have been found on waterfowl carcasses (Duncan & Jensen 1976). With a 50% lethal dose for type C botulinum toxin in waterfowl estimated at 36 000-43 000 MLD/kg of body weight (Rocke *et al.* 2000), ingestion of only a single toxic maggot could be lethal. Although most waterfowl will not directly consume a vertebrate carcass, many would ingest maggots that fall off. In this way, botulism outbreaks in waterfowl often become self-perpetuating. This has become known as the carcass-maggot cycle of botulism, and it is thought that toxic maggots have the greatest potential to cause massive die-offs of birds (Wobeser 1997).

Waterbirds that have ingested botulinum spores and die from any cause are as likely to initiate outbreaks through the carcass-maggot cycle as birds that ingested pre-formed toxin and died from the disease (Reed & Rocke 1992). Thus the presence of

decaying carcasses from other mortality events can lead to a botulism outbreak. Bird collisions with power transmission lines have initiated botulism outbreaks in Montana, USA (Malcolm 1982) and elsewhere (NWHC unpubl. data). Other sources of mortality, e.g. hailstorms and algal poisoning, and even other disease agents may precipitate botulism outbreaks through the carcass-maggot cycle.

Many factors influence the carcass-maggot cycle, including fly density and environmental conditions such as temperature and wind speed that facilitate fly egg-laying, maggot development and maggot dispersal from carcasses (Reed & Rocke 1992, Wobeser *et al.* 1997). However, the most critical factor is the density of carcasses that are toxigenic, i.e. contain botulinum spores that germinate and produce toxin (Reed & Rocke 1992). Some investigators (Duncan & Jensen 1976) found that 85-90% of maggot-infested carcasses contained toxic maggots, while in another study (Reed & Rocke 1992), the rate varied from 29% to 69%. Although not every carcass will become maggot-infested or produce toxic maggots, factors that reduce the availability of toxic carcasses in wetlands, such as the presence of scavenging predators and carcass pick-up, may lower the risk of waterbird exposure to botulinum toxin.

### Winter outbreaks of avian botulism

Most outbreaks of botulism occur in the summer and autumn months when wetland temperatures rise and are more favorable for bacterial growth and toxin production. However, on occasion, outbreaks of type C botulism in waterbirds have been documented in late winter or early spring (Haagsma 1973, Graham *et al.* 1978, Wobeser *et al.* 1983, Hubalek & Halouzka 1991). Outbreaks of botulism have occurred in winter in California, USA, Saskatchewan, Canada, and also in the Norfolk Broads, UK. Typically, these outbreaks are preceded by a botulism die-off in the same location the previous autumn and often involve diving ducks. The spring outbreaks may be the result of toxin-bearing maggots that fell to the bottom of the wetland the previous autumn and are accessible in the spring only to diving ducks (Wobeser *et al.* 1983).

### Type C botulism in fish-eating waterbirds

In 1996, over 15 000 pelicans, herons, and other fish-eating birds became sick or died from type C botulism at the Salton Sea in southern California, a 97 000 ha (375 sq. miles) inland sea that provides critical wintering habitat for numerous birds. Nearly half the birds that died at the Salton Sea were either American White Pelicans *Pelecanus erythrorhynchos* or Brown Pelicans *P. occidentalis*. This was the largest die-off ever reported for pelicans anywhere in the world from any agent. Prior to this event, type C botulism in fish-eating birds was considered infrequent and incidental to larger outbreaks in waterfowl, and most previous reported botulism outbreaks that involved large numbers of fish-eating birds (mostly divers, Gaviidae, and gulls, Laridae), were caused by type E botulinum toxin (Rocke & Friend 1999). The largest reported loss of pelicans from botulism before 1996 was 223 birds at Long Lake, North Dakota, in 1988 (Rocke *et al.* in press). Although type C botulism recurred in fish-eating birds at the Salton Sea from 1997 to 2001, the total loss over this period (approximately 1 000-3 000 birds) was lower than in 1996.

The primary source of toxin for birds at the Salton Sea was

thought to be Tilapia *Oreochromis mossambicus*, an introduced fish that dominated the Sea at that time. Toxin was found in nearly 50% of sick and dead Tilapia and also in undigested fish remains regurgitated by sick pelicans (Rocke *et al.* 2004). Systematic research at the Salton Sea demonstrated that live Tilapia (both sick and healthy) harbored botulinum cells in their gastrointestinal tracts (Nol *et al.* 2004), and the prevalence of the bacteria varied from year to year as did mortality in pelicans. The investigators hypothesized that the high summer water temperatures (often over 37°C) and other environmental stresses, combined with the Tilapia's reduced foraging efforts in the summer months, created an altered, possibly static gut environment that was conducive to spore germination (Nol *et al.* 2004). The epizootiology of the disease at the Salton Sea appears to be very unusual.

### Avian botulism associated with landfills

Several outbreaks of type C botulism in gulls have been associated with landfills and refuse tips in Britain (Lloyd *et al.* 1976), Scotland (MacDonald & Standring 1978), Ireland (Quinn & Crinion 1984), the Virgin Islands (Norton 1986), and most recently Israel (Gophen *et al.* 1991). The refuse itself is not thought to be the source of the bacteria; rather, botulinum spores are probably transferred by birds attracted to the sites. The presence of the spores, coupled with rotting organic matter and the concomitant rise in environmental temperatures, promote bacterial replication and toxigenesis, and ultimately result in botulism in birds scavenging at the sites. In the case of the die-off in Israel, waste products from a chicken slaughterhouse were found to be improperly buried and probably contributed to the die-off (Gophen *et al.* 1991).

### DISCUSSION

Although avian botulism is arguably the most significant disease for waterbirds, its effect on populations is poorly understood. Unfortunately, the information required to measure its impact on populations, such as annual and spatial variation in botulism occurrence and estimates of populations at risk, is difficult to obtain for most waterbird species. Generally, mortality estimates during die-offs are based on the retrieval of carcasses. However, it has been demonstrated that the retrieval of carcasses underestimates mortality by between three times (Cliplef & Wobeser 1993) and as much as 10 times (Stutzenbaker *et al.* 1986). Also, numerous outbreaks probably go undetected as scavenging animals can consume large numbers of carcasses (Stutzenbaker *et al.* 1986).

Botulism outbreaks often involve several species of waterbirds. Some species may be able to withstand high losses, while others may not be as resilient. The Mallard, which is numerous and geographically widespread and has a high reproductive potential, can probably withstand sporadic heavy losses from botulism. Other, less common species whose populations are disproportionately exposed to botulism may be more severely impacted. From 1994 to 1997, outbreaks of avian botulism killed over four million waterfowl in Canada and the USA, and the Northern Pintail *Anas acuta* accounted for a large proportion (15-20%) of the recorded mortality (NWHC unpubl. data). At the same time, surveys showed that Northern Pintail populations in North America remained low, while populations of other dabbling ducks increased in response to improving water condi-

tions in the prairie pothole regions (US Fish and Wildlife Service 1998). Although the reasons for this trend are unknown, it is thought that botulism may be one of several factors contributing to low pintail numbers. The effects of botulism on local or regional populations can also be important. During the 1996 outbreak at the Salton Sea, an estimated 15% of the western sub-population of the American White Pelican died (Rocke *et al.* 2004).

Endangered species are especially vulnerable to a disease like botulism that is not density dependent. Threatened or endangered waterbirds in the USA that have contracted botulism include the Brown Pelican and four Hawaiian species, the Hawaiian Goose (Nene) *Branta sandvicensis*, Hawaiian Duck *Anas wyvilliana*, Hawaiian Coot *Fulica alai*, and Hawaiian Stilt *Himantopus mexicanus knudseni*. Waterbird species with a limited distribution or that winter or breed in only a few wetlands are most at risk. During the winter of 2002/2003, avian botulism killed 73 Black-faced Spoonbills *Platalea minor* out of about 500 individuals at the Tseng-Wen Estuary in Tainan, Taiwan, a critical wintering area for the species; this loss represented approximately 7% of the total global population of this species (BirdLife International 2004). If the disease recurs at the Tseng-Wen Estuary, it could have serious implications for the conservation of the Black-faced Spoonbill.

In the past, numerous management actions were recommended to prevent botulism outbreaks in wetlands, such as removing rotting vegetation, agitating stagnant water, stabilizing water levels, creating shorelines with steep banks, removing vertebrate carcasses that served to perpetuate outbreaks through the carcass-maggot cycle of botulism, and even killing invertebrates with pesticides. Of these recommendations, only the removal of carcasses has been effective in reducing botulism losses (Reed & Rocke 1992), but unfortunately, carcass monitoring and removal activities are costly, labor intensive and not an efficient prevention strategy, especially in very large wetlands. Additional research is needed to understand the various environmental factors that promote outbreaks in different situations. The development of predictive or risk-assessment models based on demonstrated associations between wetland and other conditions and the occurrence of botulism outbreaks could be used in an adaptive management approach to identify wetlands at high risk for waterbirds, to develop and evaluate alternative strategies for reducing the risk to waterbirds, and to evaluate how current wetland and waterbird management practices influence the risk of botulism outbreaks.

## ACKNOWLEDGEMENTS

The author's work on this manuscript was supported by the U.S. Geological Survey, Biological Resources Division. Many thanks to J. C. Franson and K. Converse for helpful editorial comments and to the organizers of the Waterbirds around the world Conference.
