Shortridge, K.F. & Melville, D.S. 2006. Domestic poultry and migratory birds in the interspecies transmission of avian influenza viruses: a view from Hong Kong. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 427-431.

## ABSTRACT

Agricultural practices in southern China provide an abundance of avian influenza viruses in the environment through the medium of the domestic duck. This is the backdrop to a series of remarkable genetic changes by the recently recognized Asian lineage of highly pathogenic H5N1 virus involving multiple poultry hosts, particularly the chicken, and in the case of the 2003/2004 outbreak in east and south-east Asia, the domestic duck as well as the chicken. While there is little evidence to support the role of migratory birds in the spread of this outbreak, the widening range of hosts suggests that they could in the future. The implications arising from the spread of the H5N1 virus for humans, poultry and wildlife in the Asian region and beyond are great. Ornithologists have much to contribute in dealing with these issues.

## INTRODUCTION

The recognition of an antigenic relationship between the surface haemagglutinin glycoproteins (HA) of the pandemic H3N2 influenza A virus that emerged through Hong Kong from neighbouring Guangdong Province, China, in 1968, and a virus previously isolated from a duck in the Ukraine, engendered a zoonotic perspective of pandemic influenza (Webster & Laver 1975). It led the World Health Organization (WHO) to foster studies on the ecology of influenza viruses (1) to determine the range of influenza viruses in nature, (2) to see if it is possible to recognize a virus before it appears in pandemic form in humans, and (3) to see whether this would facilitate quick and effective vaccine production. In other words, it was the goal to try to get ahead of the next pandemic influenza virus – a first-ever step toward significant influenza pandemic preparedness (Stuart-Harris 1970).

Financial and other support through the National Institutes of Health, Bethesda, USA, were instrumental in getting this goal off the ground in the early 1970s. More structured ecological studies have been pursued by influenza virologists since then, but with little input from ornithologists. The apparent lack of interest by ornithologists may have its roots in the fact that there have been no observable signs of avian influenza recorded for wild birds (Hansen 1999), there being only one case of large-scale mortality in Common Terns *Sterna hirundo* apparently caused by an H5N3 virus (Rowan 1962, Becker 1966).

Given the historical association of Asia and especially China as the source of a number of pandemics over the last 1 000 years (Potter 1998), narrowing to southern China in the last century, ecological studies of influenza viruses have been conducted in Hong Kong since 1975 on local and imported domestic poultry and animals, notably the pig, as well as migratory birds, with a view to getting ahead of the next pandemic. In this sense, Hong

Kong has functioned as an influenza sentinel post for southern China and the wider region for almost 30 years.

In 1997, a highly pathogenic avian influenza (HPAI) virus, H5N1/97, was detected in chickens in the sentinel post itself, leading to human deaths and sparking fears of the next pandemic (Claas *et al.* 1998). A pandemic was probably averted by the slaughter of poultry across the Hong Kong SAR (Shortridge *et al.* 2000). A second H5N1 pandemic alarm occurred in late 2003 and early 2004. This time, an H5N1 virus manifested in chickens and ducks en masse in a number of countries in east and south-east Asia, resulting in human fatalities in two of them, and raising the question of whether wild birds played a role in the spread of the virus (see Melville & Shortridge 2004 & this volume). This report notes factors, past and present, contingent upon the dynamics of avian influenza virus (AIV) in the region.

## SOUTHERN CHINA

Waterfowl (Anatidae), and to a lesser extent shorebirds and gulls (Charadriiformes), are the primary reservoirs of AIV. The virus occurs asymptotically in the birds, multiplying mainly in the intestine and being spread by faecally contaminated water (Markwell & Shortridge 1982, Webster *et al.* 1992). The domestication of the duck in eastern China, notably in the south around 2500 BC (Needham 1986), brought AIV into the “influenza farmyard” where these birds were mainly raised along river banks (Fig. 1). The system changed around the start of the Ching Dynasty (1644 AD), when the ducks were raised as an adjunct to rice farming, initially as a means of controlling rice pests, in a beautifully balanced ecosystem conserving precious grain needed for humans (Fig. 2). This practice of duck raising reached its zenith in southern China and spread to varying extents throughout south-east Asia. (The goose was probably domesticated in China at about the same time as the duck.)

This practice meant that AIV could occur year-round in domestic ducks in southern China, a situation confirmed through virus surveillance studies. The overall isolation rates from the cloaca and trachea of aquatic ducks, partially aquatic geese and terrestrial chickens in a study conducted in Hong Kong from 1975-1980 on poultry from southern China were 6.5%, 1.11% and 0.41%, respectively (Shortridge 1992). The isolation rate of AIV from migratory ducks and shorebirds sampled over a number of years at a Hong Kong wetland was about the same as that from chickens (Chin, Shortridge, Liu, Suen & Melville unpubl. data).

The isolation of H3N2 viruses resembling the 1968 pandemic and contemporary human variants in virus surveillance studies of pigs in 1976 indicated that this domestic animal

**Fig. 1.** A photograph taken in 1980 in the Pearl River Delta, Guangdong Province, China, showing the traditional method of raising ducks along river banks. The “duck herder” can be seen amongst the ducks. This method of duck raising would be rare today.

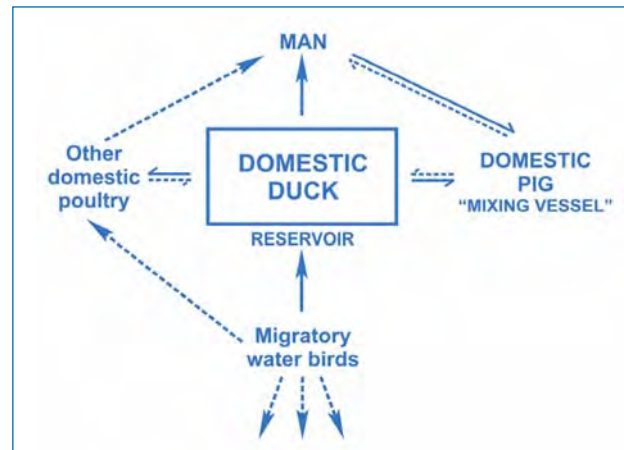

**Fig. 2.** Ducks on a flooded rice field in Guangdong Province, China. The ducks feed on insects, crabs, etc. and are removed from the field when the rice blossoms, held on waterways and ponds, and introduced onto the dry field to fatten on unharvested, fallen grain. There are five crops of ducks a year, the two main ones in conjunction with the summer and autumn rice crops (Shortridge 1992 & 1997).

had a role to play in the “influenza farmyard” of southern China (Shortridge *et al.* 1977), possibly as a “mixing vessel” for the two-way exchange of avian and human influenza viruses (Scholtissek *et al.* 1985).

The newly recognized influenza ecology outlined above, the close association of the large human population with domestic animals in the region providing increased opportunity for inter-species transmission of avian influenza viruses, and the historical link of China (particularly southern China) with influenza

pandemics, led to southern China being designated as a hypothetical epicentre for the emergence of pandemic influenza viruses (Shortridge & Stuart-Harris 1982). This was the anchor for pandemic preparedness. Humans are considered as part of a matrix of interconnected AIV ecology (Fig. 3), with recognition of untoward respiratory disease or virus activity at any point in the matrix offering the prospect of preparedness and action. The key to this would lie in virus surveillance at all levels.

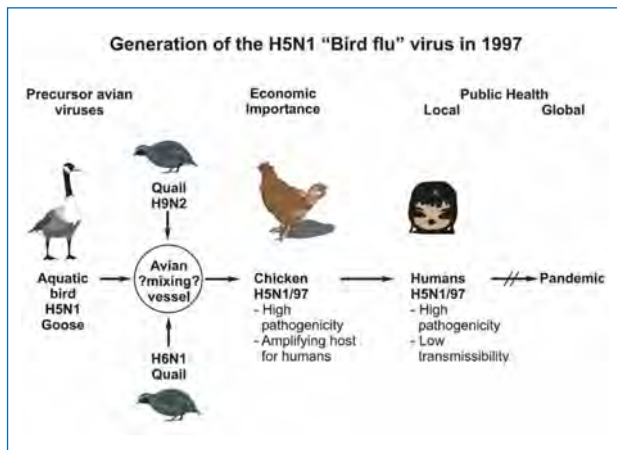

**Fig. 3.** Diagram showing the likely ecological relationship among the influenza A viruses of birds, pigs and humans in southern China, with the domestic duck as the central reservoir. The solid line indicates a more certain relationship, which in the case of ducks, humans and pigs has a genetic basis. The broken line indicates a less certain relationship (Shortridge 1988 & 1992).

### THE H5N1/97 VIRUS AND CONSEQUENCE

In 1997, Hong Kong found itself in the midst of an incipient pandemic situation; the first time that it had been possible to recognize one. The chicken in retail, live poultry markets was the principal source of H5N1/97 virus for humans (Shortridge 1999, Shortridge *et al.* 2000). Ancestry of this incident can be traced back to a precursor H5N1 virus that caused an outbreak of disease in domestic geese with 40% mortality in Guangdong Province in 1996 (Tang *et al.* 1998, Xu *et al.* 1999). It is worth noting that H5 viruses had been isolated from domestic ducks and a goose in the 1975-1980 surveillance studies (Shortridge 1992). Perhaps the most striking aspect of the generation of the triple reassortant H5N1/97 virus was the apparent role of the quail *Coturnix* sp., a minor poultry (Guan *et al.* 2000, Li *et al.* 2003), as the facilitator or avian “mixing vessel” for this (Fig. 4). More recent studies on H9 viruses have indicated that the quail can act as an intermediate host facilitating interspecies transmission from ducks to chickens (Perez *et al.* 2003).

The importance of domestic poultry, i.e. chickens rather than migratory birds, as the principal H5N1/97 virus source lies in the fact that in east Asia, and particularly in southern China, they are raised in close proximity to humans on small holdings and farms, making them a potential source of virus for humans. This situation has been exacerbated in the last 20 years or so because of the intensification of chicken production in southern China (and elsewhere around the world) increasing the opportunity for inter-species transmission, virus amplification and disease. The fact that precursor H5N1, H9N2 and H6N1 viruses continued to exist after 1997 (Guan *et al.* 2002a, Chin *et al.* 2002, Webster

**Fig. 4.** Results of intensive virus surveillance post-1997, showing the most likely chain of events in the generation of the H5N1/97 virus, a triple reassortant highly pathogenic for chickens and humans. A goose H5N1 virus provided the gene encoding the H5 HA surface glycoprotein, a quail H9N2 virus provided the six genes encoding the internal proteins, and a quail H6N1 virus provided the gene encoding the second surface glycoprotein, the N1 neuraminidase, with the quail probably acting as a "mixing vessel" for these events (Guan *et al.* 1999, Hoffmann *et al.* 2000).

*et al.* 2002) suggested that an H5N1/97-like virus could be regenerated or that each of the precursors could be of pandemic potential in this changing AIV milieu (Shortridge *et al.* 2001).

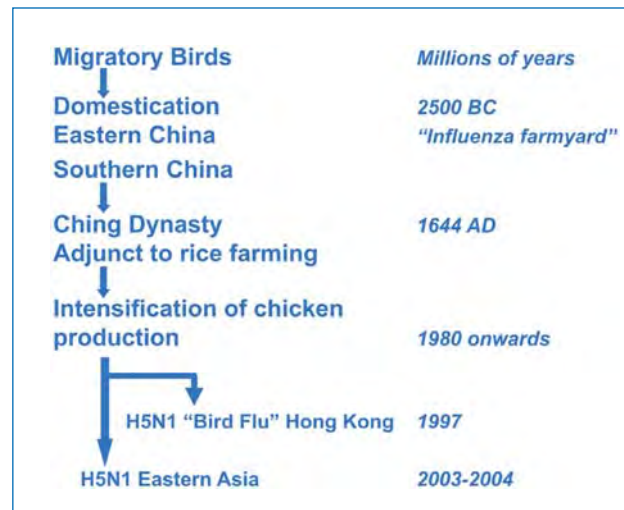

#### H5N1 VIRUS REAPPEARS

The HPAI H5N1/97 virus has not been isolated in the Hong Kong sentinel post since 1997. Instead, the precursor H5N1 virus was detected in geese in 1999 (Cauthen *et al.* 2000), changing hosts to ducks and undergoing re-assortment with unknown, aquatic AIV in 2000 (Webster *et al.* 2002, Guan *et al.* 2002b). It moved to chickens in 2001 and 2002 in changing ranges of genotypes (Guan *et al.* 2002a, Sturm-Ramirez *et al.* 2004), with one genotype, "Z", predominating and, in some cases, a closely related genotype "Z+" being detected. These genotypes, particularly the "Z+" genotype, were isolated from fatal infections in wild and captive waterfowl in Hong Kong in 2002 (Sturm-Ramirez *et al.* 2004, Guan *et al.* 2004), the first time a lethal influenza virus had been isolated from wild aquatic birds since 1961 (Becker 1966). The "Z+" genotype was also isolated from two Hong Kong residents following a visit to Fujian Province, to the north of Guangdong Province, in early 2003 (Guan *et al.* 2004). An H5N1 virus was isolated from a dead Peregrine Falcon *Falco peregrinus* in Hong Kong in early 2004 (Li *et al.* 2004).

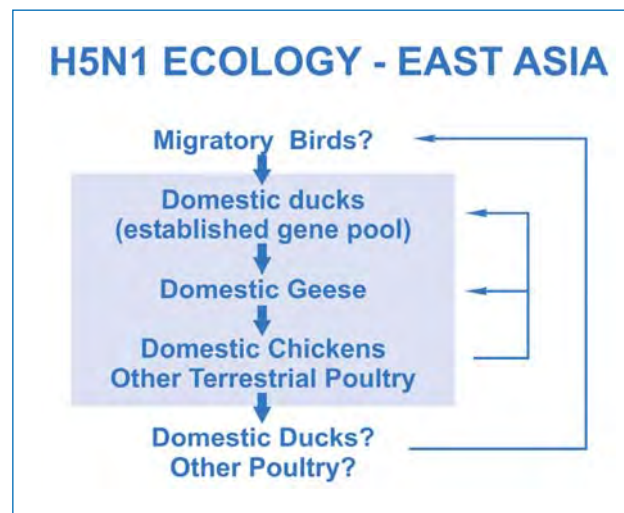

The "Z" genotype that predominated in chickens by 2002 also predominated in chickens and ducks in the disastrous H5N1 virus outbreak in east and south-east Asia in late 2003 and early 2004 (Li *et al.* 2004). Although the "Z+" genotype was isolated from dead wild birds in Hong Kong, there was no convincing evidence that wild birds played a role in the spread of H5N1 virus in the region. Indeed, intensive virus surveillance around this time at a Hong Kong wetland did not yield H5N1 virus (Y. Guan pers. comm.). Poor hygiene and biosecurity probably played the major role in the spread of the virus (Melville & Shortridge 2004 & this volume).

#### RINGING IN CHANGES

Given the lack of transparency in acknowledging a virus disease that was undoubtedly spreading in the region from an epicentre in south-eastern China over at least two years, there is every prospect that the H5N1 virus, in particular the "Z" genotype, will become endemic in avian hosts (Melville & Shortridge 2004, Li *et al.* 2004). The H5N1 situation is another phase in the influenza story (Fig. 5), the virus having established itself as a threat to the world. The fact that the chicken "Z" genotype has transferred to ducks (Li *et al.* 2004) not only affects the evolutionary dynamics of H5N1, but also makes the virus more available for spread by migratory birds. Better understanding of the elements of the Asian-Australasian Flyway, including systematic

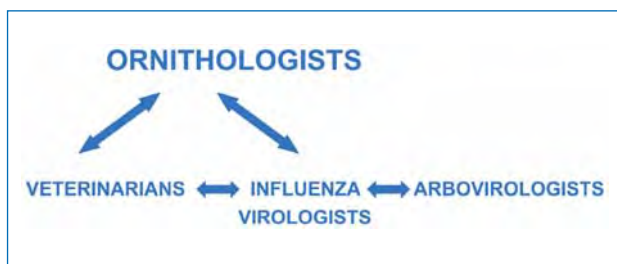

**Fig. 5.** A chronology of notable events in relation to current H5N1 problems.

**Fig. 6.** A schematic approach for exploring a possible link between migratory birds and domestic poultry against the background of the 2003/2004 H5N1 incident in east Asia. The shaded area indicates a more certain relationship and the outer area a less certain relationship.

Note. Since this article was written in mid 2004, H5N1 virus has been isolated from Migratory birds in eastern and western China and has become endemic in domestic poultry, notably ducks and geese in southern China and probably in parts of southeast Asia (Chen *et al.* 2006).

**Fig. 7.** The need for greater interaction in dealing with avian influenza problems. Ornithologists can make important contributions to understanding, disease control and prevention.

AIV surveillance and exploration of the domestic poultry/migratory bird niches that facilitate AIV exchange, are of paramount importance (Fig. 6). Ornithologists have an important role to play in this scenario, interacting with veterinarians and influenza virologists who can learn much in virus ecology from their arbovirus colleagues (Fig. 7). The spreading of West Nile virus exemplifies this (Rappole & Hubalek 2003). Such interaction serves to enhance our understanding of infectious zoonotic diseases.

The Migratory Animals Pathological Survey (1963-1971) laid the groundwork for bird migration studies in Asia (McClure 1974). There has been considerable progress in bird ringing in a number of countries over the past three decades, but no attempt has been made to synthesize the results across the region, and many data remain unpublished and inaccessible. As a priority, ringing schemes should co-operate in a regional review of ringing data for waterbirds, as this would facilitate a greater understanding of the relationships between species and between flyways which may be important in considering the natural spread of novel AIV forms. Consideration should be given to the establishment of long-term AIV intelligence at ringing stations in east Asia, as is currently undertaken at some sites in Europe (De Marco *et al.* 2003), and wildlife managers should be encouraged to submit dead birds for post-mortem examination. There remain many unknowns regarding the ecology of AIV in wild birds, and there is scope for extensive work on topics such as the effects of changes in gut morphology and physiology before/during/after migration (Piersma & Gill 1988) on the survival of viruses, and hence their possible spread. "Only when we are at peace with Nature will disease begin to melt away" (Shortridge 2003).

## ABSTRACT

Wild birds, especially waterfowl, can act as reservoirs for avian influenza A viruses and migrant wild birds may potentially transport viruses over long distances. Concern was expressed regarding the possible role of wild birds in the 2003-2004 outbreak of H5N1 avian influenza in East/Southeast Asia, but it seems unlikely that they directly contributed to the spread of the disease. There is an urgent need for increased virus surveillance work together with studies to increase understanding of bird migration in the region.

## INTRODUCTION

The outbreak of H5N1 highly pathogenic avian influenza (HPAI) in East and Southeast Asia in late 2003-early 2004 was unprecedented in both scale and severity. Over 100 million domestic poultry (mostly chickens) died or were slaughtered and there were 34 human cases, of which 23 were fatal (WHO 2004b, FAO 2004a). Media speculation suggested that wild birds had spread the virus (e.g. Kim 2004) and concern has been expressed regarding the potential pandemic threat posed by H5N1 (Guan *et al.* 2004). This paper outlines the ecology of avian influenza, considers the possible role of wild birds in the 2003-2004 outbreak and highlights the urgent need for multidisciplinary studies.

## ECOLOGY OF AVIAN INFLUENZA

There are 16 haemagglutinin and 9 neuramidase subtypes of avian influenza A virus (AIV), all of which have been isolated from wild birds (Alexander 2000, Fouchier *et al.* 2005). Poultry are not the normal host for AIV but some strains, particularly H5 and H7, can be highly pathogenic resulting in high mortality. AIV infection in wild birds is usually asymptomatic (Webster *et al.* 1992).

AIV in birds replicates mainly in the intestinal tract, being shed in the faeces (Webster *et al.* 1978). Infected wild ducks may shed virus for two to four weeks (Delogu 2003) and transmission is considered to be principally via the faecal-oral route (Webster *et al.* 1992). However contemporary H9 viruses show an increased ability to replicate in the respiratory tract (Webster *et al.* 2002, Perez *et al.* 2003), and Sturm-Ramirez *et al.* (2004) considered that aerosol transmission and oral-oral contamination via drinking water could be important avenues for transmission of the late 2002 early 2003 H5N1 virus. It has been suggested that this may have happened at a wildlife rescue centre in Cambodia in 2004 (FAO 2004d).

The method(s) of transmission between wild and domestic birds remain largely speculative. Some outbreaks have provided strong circumstantial evidence suggesting that virus was intro-

duced from wild birds (Campitelli *et al.* 2004), for example by contaminating drinking water (Karunakaran *et al.* 1983), whereas in some other studies it was possible that wild birds might have become infected from domestic birds (Nestorowicz *et al.* 1987).

Birds that occur in dense aggregations and which inhabit wetlands and/or aquatic environments are prime candidates for infection and this is reflected in relative infection rates. Waterbirds generally, and waterfowl (Anatidae) in particular, having higher infection rates (~15%) than terrestrial species (~2%) (Alexander 2000, Stallknecht & Shane 1988). Although Hansen (1999) reported 'frequent' occurrence of infection in waders, terns and gulls (Charadriiformes), it appears that waders generally are seldom infected (Melville unpublished).

Avian influenza, based on virus isolates and/or serological evidence, has been recorded from 47 species of wild birds in East Asia (Table 1), and from a further 70 species that occur in East Asia, but in which infection was recorded elsewhere (Table 2).

## THE 2003-2004 H5N1 OUTBREAK

The 2003-2004 outbreak of H5N1 occurred in poultry almost simultaneously throughout much of the East/Southeast Asian region with the first cases being reported in Cambodia on 15 December 2003 and in South Korea on 17 December. Outbreaks were confirmed in early January from Vietnam (8th), Japan (12th), Thailand (23rd), China and Laos (27th), and finally Indonesia on 2 February (FAO 2004d, WHO 2004a). Interestingly there was no outbreak in poultry in Hong Kong although H5N1 was isolated from a Peregrine Falcon<sup>1</sup> found dead on 19 January 2004.

These were the first ever outbreaks of HPAI in South Korea, Vietnam, Thailand, and Indonesia, and the first case in Japan since 1925. Subsequently no further countries reported incidents of H5N1. By March the outbreak appeared to have largely subsided, however outbreaks reappeared in Vietnam, Thailand and China in mid 2004 (FAO 2004e).

Populations of migratory waterbirds in East Asia include over 10 million ducks and geese, six million egrets and herons, seven million shorebirds, 20 million seabirds and substantial but un-estimated numbers of rails (Delaney & Scott 2002, Kondratyev *et al.* 2000).

The majority of seabirds remain at sea during the winter and most would be unlikely to come in to contact with domestic poultry, gulls in Asia notably being far less associated with human agricultural activities than in Europe or North America, although a case of H5N1 in a Black-headed Gull in Hong Kong in January 2003 (AFCD 2003) should not be overlooked.

<sup>1</sup> Scientific names are given in Tables 1 & 2

**Table 1.** Species of wild bird in which avian influenza has been recorded in East/Southeast Asia\*

Species		Locality
Little Grebe	<i>Tachybaptus ruficollis</i>	Thailand
Great Cormorant	<i>Phalacrocorax carbo</i>	China
Little Egret	<i>Egretta garzetta</i>	Hong Kong
Grey Heron	<i>Ardea cinerea</i>	Hong Kong
Chinese Pond Heron	<i>Ardeola bacchus</i>	Hong Kong
Black-crowned Night Heron	<i>Nycticorax nycticorax</i>	China
Asian Openbill	<i>Anastomus oscitans</i>	Thailand
Mute Swan	<i>Cygnus olor</i>	Japan
Tundra Swan	<i>Cygnus columbianus</i>	Japan
Whooper Swan	<i>Cygnus cygnus</i>	China, Mongolia
Bar-headed Goose	<i>Anser indicus</i>	China, Mongolia
Ruddy Shelduck	<i>Tadorna ferruginea</i>	China
Eurasian Wigeon	<i>Anas penelope</i>	Japan
Falcated Duck	<i>Anas falcata</i>	Russian Far East
Baikal Teal	<i>Anas formosa</i>	Russian Far East
Common Teal	<i>Anas crecca</i>	Japan, Russian Far East
Mallard	<i>Anas platyrhynchos</i>	Japan, Russian Far East
Spot-billed Duck	<i>Anas poecilorhyncha</i>	Japan
Northern Pintail	<i>Anas acuta</i>	Japan, Russian Far East
Tufted Duck	<i>Aythya fuligula</i>	Japan
Peregrine Falcon	<i>Falco peregrinus</i>	Hong Kong
Brown Crake	<i>Amauornis akool</i>	China
Bar-tailed Godwit	<i>Limosa lapponica</i>	China
Whimbrel	<i>Numenius phaeopus</i>	China
Common Snipe	<i>Gallinago gallinago</i>	Russian Far East
Curlew Sandpiper	<i>Calidris ferruginea</i>	Hong Kong
Dunlin	<i>Calidris alpina</i>	Japan
Black-tailed Gull	<i>Larus crassirostris</i>	Japan, Russian Far East
Black-headed Gull	<i>Larus ridibundus</i>	Hong Kong
Relict Gull	<i>Larus relictus</i>	China
Brown-headed Gull	<i>Larus brunnicephalus</i>	China
Great Black-headed Gull	<i>Larus ichthaetus</i>	China
Guillemot	<i>Uria aalge</i>	Russian Far East
Black/Spectacled Guillemot	<i>Cephus grylle/carbo</i>	Russian Far East
Red Turtle Dove	<i>Streptopelia tranquebarica</i>	Thailand
Little Cuckoo Dove	<i>Macropygia ruficeps</i>	Thailand
Yellow-vented Bulbul	<i>Pycnonotus goiaver</i>	Malaysia
Oriental Magpie Robin	<i>Copsychus saularis</i>	Hong Kong
Japanese White-eye	<i>Zosterops japonica</i>	Hong Kong
White-rumped Munia	<i>Lonchura striata</i>	Hong Kong
Scaly-breasted Munia	<i>Lonchura punctulata</i>	Hong Kong
Eurasian Tree Sparrow	<i>Passer montanus</i>	China, Hong Kong
Crested Mynah	<i>Acridotheres tristis</i>	Hong Kong
Black Drongo	<i>Dicrurus macrocercus</i>	Thailand
Common Magpie	<i>Pica pica</i>	South Korea, Hong Kong, China
House Crow	<i>Corvus splendens</i>	Hong Kong, Thailand
Large-billed Crow	<i>Corvus macrorhynchos</i>	Japan, Cambodia, Hong Kong

**Table 2.** Species of wild bird which occur in East/Southeast Asia and in which avian influenza has been recorded elsewhere\*

Red-throated Diver	<i>Gavia stellata</i>	Black-throated Diver	<i>Gavia arctica</i>
Great Crested Grebe	<i>Podiceps cristatus</i>	Wedge-tailed Shearwater	<i>Puffinus pacificus</i>
Little Cormorant	<i>Phalacrocorax niger</i>	Glossy Ibis	<i>Plegadis falcinellus</i>
Eurasian Spoonbill	<i>Platalea leucorodia</i>	Greater White-fronted Goose	<i>Anser albifrons</i>
Greylag Goose	<i>Anser anser</i>	Brent Goose	<i>Branta bernicla</i>
Common Shelduck	<i>Tadorna tadorna</i>	American Wigeon	<i>Anas americana</i>
Gadwall	<i>Anas strepera</i>	Garganey	<i>Anas querquedula</i>
Northern Shoveler	<i>Anas clypeata</i>	Red-crested Pochard	<i>Netta rufina</i>
Common Pochard	<i>Aythya ferina</i>	Greater Scaup	<i>Aythya marila</i>
Tufted Duck	<i>Aythya fuligula</i>	Long-tailed Duck	<i>Clangula hyemalis</i>
Velvet Scoter	<i>Melanitta fusca</i>	Common Scoter	<i>Melanitta nigra</i>
Goosander	<i>Mergus merganser</i>	Red-breasted Merganser	<i>Mergus serrator</i>
Smew	<i>Mergus albellus</i>	Saker Falcon	<i>Falco cherrug</i>
Northern Goshawk	<i>Accipiter gentilis</i>	Common Buzzard	<i>Buteo buteo</i>
Ring-necked Pheasant	<i>Phasianus colchicus</i>	Purple Swamphen	<i>Porphyrio porphyrio</i>
Common Moorhen	<i>Gallinula chloropus</i>	Common Coot	<i>Fulica atra</i>
Pied Avocet	<i>Recurvirostra avosetta</i>	Black-winged Stilt	<i>Himantopus himantopus</i>
Eurasian Oystercatcher	<i>Haematopus ostralegus</i>	River Lapwing	<i>Vanellus dauvcelii</i>
Eurasian Curlew	<i>Numenius arquata</i>	Eurasian Woodcock	<i>Scolopax rusticola</i>
Common Redshank	<i>Tringa totanus</i>	Spotted Redshank	<i>Tringa erythropus</i>
Green Sandpiper	<i>Tringa ochropus</i>	Ruddy Turnstone	<i>Arenaria interpres</i>
Sharp-tailed Sandpiper	<i>Calidris acuminata</i>	Red-necked Stint	<i>Calidris ruficollis</i>
Red Knot	<i>Calidris canutus</i>	Sanderling	<i>Calidris alba</i>
Temminck's Stint	<i>Calidris temminckii</i>	Ruff	<i>Philomachus pugnax</i>
Pomarine Skua	<i>Stercorarius pomarinus</i>	South Polar Skua	<i>Catharacta maccormicki</i>
Slender-billed Gull	<i>Larus genei</i>	Herring Gull	<i>Larus argentatus</i>
Black-legged Kittiwake	<i>Rissa tridactyla</i>	Common Tern	<i>Sterna hirundo</i>
Arctic Tern	<i>Sterna paradisaea</i>	Little Tern	<i>Sterna albifrons</i>
Sooty Tern	<i>Sterna fuscata</i>	White-winged Tern	<i>Chlidonias leucopterus</i>
Black Tern	<i>Chlidonias niger</i>	Collared Dove	<i>Streptopelia decaocto</i>
Great Spotted Woodpecker	<i>Dendrocopus major</i>	Barn Swallow	<i>Hirundo rustica</i>
Yellow Wagtail	<i>Motacilla flava</i>	White Wagtail	<i>Motacilla alba</i>
Common Whitethroat	<i>Sylvia communis</i>	Yellow-breasted Bunting	<i>Emberiza aureola</i>
Black-faced Bunting	<i>Emberiza spodocephala</i>	House Sparrow	<i>Passer domesticus</i>
Common Starling	<i>Sturnus vulgaris</i>	Carrion Crow	<i>Corvus corone</i>

\* after Stallknecht & Shane (1988) and Olsen *et al.* (2006) with additions

The large areas of rice paddy throughout much of the region (74 million ha, of which some 38% is in China; IRRI 2004) provide artificial, freshwater wetland habitats which may be used by a wide variety of waterbirds including ducks, geese, waders, storks, ardeids and rallids. All of these birds potentially could come into contact with the large numbers of domestic ducks (Shortridge & Melville 2005) which are widely used for pest control and scavenge in paddis during and immediately after harvest - there being some 19 million in the Mekong delta alone (Bui *et al.* 1998). However most poultry affected by H5N1 were chickens, not ducks, suggesting that direct transfer of virus was unlikely. Furthermore, the outbreak occurred in mid-winter, at a time when most waterfowl populations are thought to be fairly sedentary, although there is evidence of mobility in some ducks populations (Pradel *et al.* 1997), and mid-winter movements of presumed waterfowl have been recorded by radar in Hong Kong (Melville 1980). There were no particularly unusual weather events reported in East Asia which might have resulted in mass movements of waterfowl in the region.

The highest concentrations of migratory Anatidae occur in Japan, South Korea and eastern and central China, south of the 0°C January isotherm (Li & Mundkur 2004). Relatively few migratory ducks occur in Indochina and Thailand, and even less in Indonesia, which suggests that they were unlikely to be carriers of virus in these areas. Ringing data show that at least some ducks migrate from Japan through Taiwan to the Philippines (Yamashina Institute for Ornithology records) yet Taiwan alone was affected by a mildly pathogenic form of H5N2, rather than H5N1, and no avian influenza outbreaks were reported from the Philippines – a situation hard to reconcile with the suggestion that wild birds were the main means of virus transport.

It is unclear whether the 'first reported' dates really reflect the situation on the ground, especially since Vietnam had potential human cases as early as October 2003 (WHO 2004a). Thus it is possible that virus was present for some time before being reported, in which case wild birds might have assisted its spread. For example, large numbers of rails migrate from mainland Asia to Indonesia where they are trapped for food, being sold in

markets together with domestic poultry (*M. Silivius pers. comm.*) and this could have allowed for transmission of virus in the autumn of 2003. Little is known of AIV infection rates in rallids: Delogu (2003) reported 1.2% infection in Eurasian Coots in Italy. However, if waterbirds were responsible for introducing the virus to Indonesia it might be expected that at least some of the birds would also have passed through Malaysia and/or The Philippines, yet there were no reports of H5N1 from either country.

Transmission of virus by terrestrial bird species which occur around fish and duck farms, such as, in Southern China, Rufous Turtle Dove *Streptopelia orientalis*, Barn Swallow, Red-billed Starling *Sturnus sericeus* and Eurasian Tree Sparrow is a possibility (virus isolations are known from the swallow and sparrow, and from congeners of the dove and starling), and all four are to a greater or lesser extent migratory, but the timing and extent of the outbreak does not fit known movement patterns.

Most reported cases affected chickens, but domestic ducks and geese were also affected in some areas. Information on mortality in wild birds remains sketchy with a number of unconfirmed reports. The provenance of the Peregrine Falcon found dead in Hong Kong is uncertain (P.J. Leader *in litt.*) and it may have been held in captivity. Large-billed Crows and Common Magpies were reported dead in association with poultry farms in Japan and South Korea, respectively, but presence of H5N1 has not been confirmed. In Thailand several hundred Asian Openbills were reported dead and H5N1 was isolated from at least one individual (The Influenza Sequence Database 2004), while in Cambodia several birds at a wildlife rehabilitation centre were reportedly positive, including free-flying wild Large-billed Crows (FAO 2004d, D.W. Geale *in litt.* 2004). It is noteworthy that no wild waterfowl were recovered anywhere, and extensive surveillance in Hong Kong failed to find any H5N1 virus in wild waterfowl faeces (L. Young *in litt.* 2004).

There are no known wild bird reservoirs of HPAI (Swayne and Suarez 2000). Although there are some instances of HPAI virus isolation from wild birds associated with outbreaks in poultry (as apparently in 2003–2004), the fact that such birds have been found dead suggests that HPAI causes mortality in at least some wild birds, in which case they are unlikely to be effective carriers of infection (Capua *et al.* 2000).

It is noteworthy that despite fears that migratory birds might carry H5N1 northwards in the spring of 2004, there is no evidence that this occurred – although it was suggested that migratory birds and wild waterfowl could have transmitted the disease to a poultry farm near Chau Hu, Anhui, China (OIE 2004), the timing of the outbreak in early July makes this unlikely and the lake apparently supports relatively few waterfowl even in winter (M. Barter, *in litt.*). A reported die-off of wild birds in Mongolia in mid-March (FAO 2004c) was apparently the result of another cause.

It remains unclear why the 2003–2004 outbreak occurred in such an explosive manner. It seems likely that human activity resulted in at least some of the spread, as in the case of an outbreak in Lhasa, Tibet which appears to have resulted from the introduction of chickens from Lanzhou, Gansu – some 1 500 km away (FAO 2004b). The trade in wild song birds, for example, laughingthrushes *Garrulax* spp. from China to Indonesia (Melville & Lau 1993), also might have provided an avenue for dissemination of virus, while the Buddhist practise of ‘merit release’ of caged birds might have resulted in local transmission as birds joined local wild populations. It seems more likely

however, that the virus had been ‘smouldering’ for some time, possibly partly masked due to vaccination programmes in some countries (MacKenzie 2004) and that most of the spread was human mediated, aided by poor hygiene standards and biosecurity protocols (Melville and Shortridge 2004).

The 2003–2004 outbreak has highlighted how little we know of both birds and avian influenza in East Asia.

## INTER-FLYWAY CONNECTIONS

Whilst migrant waterfowl may not have played a significant role in the spread of H5N1 in 2003–2004, their potential role in the spread of viruses should not be overlooked. Not only is there potential for North–South spread along the East Asian–Australasian Flyway but also for East–West spread. Although the differing Eurasian and North American influenza A virus lineages are thought to have arisen as a result of the general lack of interchange between birds in these land masses there is mixing of some populations. Wrangel Island, for example, is used as a post-breeding moulting ground by Brent Geese from both Siberian and Alaskan breeding areas (Ward *et al.* 1993), and ~2% of recoveries of Pintail ringed wintering in Japan have been in North America (Yamashina Institute for Ornithology records). Dunlin winter in large numbers along the coast of eastern China and inland, and DNA analysis indicates that at least some of these birds are from the Alaskan breeding population (Wenink & Baker 1996), and thus may mix with those that winter along the west coast of the USA south to California (Warnock & Gill 1996).

Webby *et al.* (2002) postulated that an outbreak of H6N2 influenza in California which had genetic similarities to viruses from chickens in Eurasia might indicate convergent evolution in which common mutations arose as viruses adapted to the chicken host, but there remains the possibility of importation of Eurasian genes via migratory waterfowl.

Our knowledge of the East and Central Asian Flyways is limited, but they appear to overlap extensively in western China, Mongolia and central Siberia allowing for interchange between them. Thus Bar-headed Geese *Anser indicus* migrate from the Tibetan plateau to winter in India or southwest China (Zhang & Yang 1997) and Great Cormorants from the same area also winter in India (Kumar 2003). In view of the fact that the Thai breeding population of Asian Openbills migrates to Bangladesh (McClure 1974), isolation of H5N1 from at least one of these birds highlights the potential for spread of this virus to the Indian subcontinent. Such movements potentially could provide a route for the westward spread of novel virus forms from South China, the hypothetical epicentre for the emergence of pandemic influenza viruses (Shortridge & Stuart-Harris 1982).

## THE FUTURE

Avian influenza is asymptomatic in wild birds, and the only record of significant mortality was of 1 300 Common Terns in South Africa (Becker 1966). This pales to insignificance in comparison with some other pathogens such as fowl cholera which killed over ten thousand Baikal Teal in Korea in 2000 (Kwon & Kang 2002), and botulism which resulted in the death of four to five million wild waterfowl in the western USA in 1952 (Locke & Friend 1987). This may help explain the scant attention that avian influenza has received from most ornithologists to date – it did not even feature in a review of avian related zoonoses (Cooper 1990). With the potential for a new pandemic

there is an urgent need for ornithologists to work with influenza virologists to implement widespread surveillance in wild birds, as well as promoting migration studies, to help elucidate the role of wild birds in the ecology of avian influenza.

## ACKNOWLEDGEMENTS

We are grateful to M. Barter, D.W. Geale, P.J. Leader, M. Silvius and L. Young for providing information.

#### Update June 2006

Avian influenza is now endemic in poultry in Southeast Asia and, as of 20 June 2006, there have been 228 human cases with 130 deaths (WHO 2006). Whilst there is currently little evidence of human-to-human transfer of virus (Williamson 2006), there remains concern that a readily transmissible form may emerge and start a pandemic (WHO 2005).

In April/May 2005 some 6,000 waterfowl were reported dead at Qinghai Hu, China, including Great Cormorant, Bar-headed Goose, Ruddy Shelduck, Great Black-headed Gull and Brown-headed Gull. H5N1 virus taken from these birds was closely related to viruses circulating in poultry and wild birds in southern China (Chen *et al.* 2005, Liu *et al.* 2005). In early August H5N1 was recovered from a Bar-headed Goose and three Whooper Swans found dead in Mongolia (OIE 2005), and H5N1 was reported from poultry and wildfowl in Russia and Kazakhstan in August.

Throughout late 2005 and early 2006, H5N1 apparently spread westwards across parts of Central Asia and Europe, reaching

Africa in February 2006, infecting both domestic poultry and a variety of wild birds - Mute Swans in particular appeared to suffer high mortality in Europe. A virus from birds in Western Siberia and Europe is very similar to that from Qinghai (Brown *et al.* 2006.), however, the role of wild birds in spreading the virus remains uncertain and trade in live poultry and products has been implicated in some cases (Melville & Shortridge 2006). Highly pathogenic H5N1 virus has been isolated from apparently healthy ducks and Eurasian Tree Sparrows in China (Chen *et al.* 2006, Kou *et al.* 2005) and H5N1 virus seems to be moving between domestic and wild birds and back again (Chen *et al.* 2006). In April/May 2006 there were further outbreaks in wild waterfowl in both China and Mongolia (FAO 2006), but the situation in Bar-headed Geese has become further complicated with the discovery that these are being artificially reared in Qinghai (Butler 2006).

Cole, R.A. & Franson, J.C. 2006. Recurring waterbird mortalities of unusual etiologies. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 439-440.

### ABSTRACT

Over the last decade, the National Wildlife Health Center of the United States Geological Survey has documented various large-scale mortalities of birds caused by infectious and non-infectious disease agents. Some of these mortality events have unusual or unidentified etiologies and have been recurring. While some of the causes of mortalities have been elucidated, others remain in various stages of investigation and identification. Two examples are discussed: 1) *Leyogonimus polyoon* (Class: Trematoda), not found in the New World until 1999, causes severe enteritis and has killed over 15 000 American Coot *Fulica americana* in the upper mid-western United States. The geographic range of this parasite within North America is predicted to be limited to the Great Lakes Basin. 2) In the early 1990s, estimates of up to 6% of the North American population of the Eared Grebe *Podiceps nigricollis* died at Salton Sea, California, with smaller mortalities occurring throughout the 1990s. Birds were observed to have unusual preening behaviour, and to congregate at freshwater drains and move onto land. Suggested etiologies included interactions of contaminants, immuno-suppression, an unusual form of a bacterial disease, and an unknown biotoxin. During studies carried out from 2000 to 2003, Eared Grebe mortality did not approach the level seen in the early 1990s and, although bacteria were identified as minor factors, the principal cause of mortality remains undetermined. The potential population impact of these emerging and novel disease agents is currently unknown.

### INTRODUCTION

Causes of avian mortality events are often difficult to identify. As birds are highly mobile and can travel great distances during their migrations, the identification of disease agents, often in concert with temporal or seasonal factors, can be elusive. The two events discussed herein were recurring, which facilitated multi-year investigations and research. The disease agents in these events have never previously been identified in North America and/or were agents that caused signs of disease which were unusual or unconventional for that disease agent.

#### *Leyogonimus polyoon* (Class: Trematoda) infection of American Coot *Fulica americana* in Shawano Lake, Wisconsin

Shawano Lake is the headwater drainage lake for the Wolf River and has a surface area of 6 063 acres (2 452 ha) with an average depth of 6 ft (1.83 m) and maximum depth of 42 ft (12.8 m). The lake is covered in ice for approximately six months of the year. In 1997, a large mortality event involving primarily American Coot and some waterfowl, mostly Lesser Scaup *Aythya affinis*, occurred. By the end of the 1997 mortality event, over 11 000 American Coot and 800 Lesser Scaup had been

American Coot *Fulica americana*. Photo: Gary Kramer, USFWS.

collected. In subsequent years, mortality events have waned, with the last documented mortality event occurring in 2002. Post mortem examinations of American Coots in 1997 revealed that a trematode *Leyogonimus polyoon*, previously only found in the Eurasian Coot *Fulica atra* and Common Moorhen *Gallinula chloropus* in Europe and Russia, was the cause of mortality in the American Coot. Ten American Coots, six males, one female and three of unknown sex, were submitted for necropsy. Body condition of birds was as follows: five poor, three moderate, one good and one not recorded. Those birds in poor flesh had no subcutaneous fat and a very prominent keel. The duodenum and jejunum had multi-focal areas approximately 1-1.5 cm in length which were distended and firm upon palpation. The intestines contained fibrinous to caseous cores of necrotic debris which occluded the lumen. All other organs were unremarkable. Cultures for *Salmonella* spp. and fungi were negative. Microscopic examination of intestinal sections from the coots revealed a general enteritis characterized by mucosal sloughing in areas where cores of necrotic debris were found with trematodes embedded into the tunica muscularis with occasional multinucleated giant cells surrounding the parasites. In one bird, over 40 000 trematodes were removed from the intestine. This is a conservative count, given that many worms were embedded in the intestinal tissue and not available for enumeration.

The life cycle of this trematode was not documented in the literature; neither was it reported to cause mortality in birds. We found that the snail *Bithynia tentaculata* was infected with *L. polyoon* cercariae (first larval stage). This snail was introduced into the United States in the 1870s (Mills *et al.* 1993). Various insect larvae from Shawano Lake were infected with the metacercariae (second larval stage, infectious for birds) of the parasite. Laboratory reared American Coots that were fed insects infected with metacercariae passed parasite eggs in their feces approximately 10-13 days after feeding, and were found to have adult worms in the small intestine upon necropsy.

Two other pathogenic trematodes, *Sphaeridiotrema globulus* and *Cyathocotyle bushiensis*, which also use *B. tentaculata* as an intermediate host, were found in Lesser Scaup and some American Coot in the latter stages of the mortality event. These parasites were first recorded in North America in the early 1900s, and have been reported as causes of mortality in Lesser Scaup and other waterfowl in Canada and the United States. *C. bushiensis* and *S. globulus* are also reported to infect waterbirds in Europe, but do not cause mortality events.

Ongoing research has indicated that *B. tentaculata* has moved west into the Mississippi River and has carried *S. globulus* and *C. bushiensis* into that waterway (National Wildlife Health Center, unpubl. results). At this point, control activities would most likely be focused on the snail, with the intention of decreasing the number of snails in certain water bodies where snails gather to overwinter. Various molluscicides are being tested for their effectiveness in killing snails in the early spring months.

#### **Eared Grebe (Black-necked Grebe) *Podiceps nigricollis* mortality at the Salton Sea, California**

The Salton Sea in southern California is the state's largest lake, at approximately 375 square miles (97 000 ha) in surface area. The Sea is below sea level and its salinity is greater than that of the Pacific Ocean. From January to March, during staging for spring migration, more than one million Eared Grebes may congregate at the Salton Sea (Jehl & McKernan 2002). In late 1991 and early 1992, an undiagnosed disease event at the Sea killed an estimated 150 000 Eared Grebes, representing about 6% of the North American population (Meteyer *et al.* 2004). During the die-off, feathers of affected grebes often appeared disheveled or wet, and the birds exhibited unusual preening behaviour, congregated at freshwater drains where they were observed to gulp fresh water, moved onto the shore, and allowed people to approach and capture them (Meteyer *et al.* 2004). Trace elements, organochlorine contaminants, salt toxicosis, and botulism were ruled out, and, although avian cholera was diagnosed in some grebes collected along the north and west shorelines of the Sea, it was not found in grebes that died on the south shore and was not determined to be the major cause of mortality. Potential causes for the 1991-1992 die-off were suggested to include interactions of contaminants, immuno-suppression, an unknown biotoxin or pathogen present at the Sea, or a unique form of avian cholera (Meteyer *et al.* 2004). Previous Eared Grebe die-offs have been noted at the Salton Sea, and one in 1989, in particular, was of large magnitude (Jehl 1996).

Eared Grebe mortality continued to occur through the 1990s, but none of the die-offs approached the magnitude of the 1992 event. From early 2000 to early 2003, the Salton Sea Authority

Wildlife Disease Surveillance Program reported that the number of Eared Grebe carcasses picked up ranged from a low of 37 in 2002 to 2 973 in 2003, with a total of 5 094 during the four-year period. As in previous years, most of the Eared Grebe mortality occurred from January to May. Of the carcasses picked up from 2000 to 2003, 214 were recovered that were in suitable post mortem condition for full or partial diagnostic evaluation at the National Wildlife Health Center. About 28% of the carcasses were described as having wet plumage, compared with 19% in the 1992 die-off (Meteyer *et al.* 2004). The weights of Eared Grebes found sick or dead in 2000-2003 were similar to the weights reported by Meteyer *et al.* (2004) for grebes that were emaciated or in poor to fair condition in the 1992 die-off. Carcass weights did not differ between grebes found sick or dead, but weights of dead grebes decreased as the spring season progressed. This finding suggests a chronic process and may indicate that grebes can tolerate a greater loss of body mass as the temperature increases. In other words, it could be expected that grebes should be able to thermoregulate with a lower body mass in warm weather than in cold weather. *Pasteurella multocida* (the bacterial agent of avian cholera) was a minor factor in the Eared Grebe mortality that occurred at the Salton Sea in 2000 and 2001, but none of the grebes tested in 2002 and 2003, when mortality was highest, was positive for *P. multocida*. Most of the *P. multocida* isolates were from grebes collected on the north and north-west shorelines of the Sea. Similarly, in the 1992 mortality event, most of the avian cholera cases were found in Eared Grebes collected on the north and west shorelines of the Sea (Meteyer *et al.* 2004).

*Salmonella* sp. was also associated to a relatively low degree with Eared Grebe mortalities in 2000 to 2002, but none of the grebes tested in 2003 was positive for *Salmonella* sp. and no isolates were found in the 1992 mortality event (Meteyer *et al.* 2004). No viruses were isolated from Eared Grebes from 2000 to 2003. Enveloped RNA viruses were isolated from two Eared Grebes in the 1992 die-off, but they were not lethal to embryos and were not characterized further (Meteyer *et al.* 2004). Botulism toxins were not detected in any of the Eared Grebes that were tested during 2000-2003, and there was no evidence to attribute Eared Grebe mortality at the Salton Sea during this period to avian botulism. In summary, despite investigative efforts over the years, no single responsible etiology has been identified as the cause of the Eared Grebe mortality events occurring at the Salton Sea between the early 1990s and 2003.

## Consequences of an unforeseen event: effects of foot-and-mouth disease on the Barnacle Goose *Branta leucopsis* population wintering on the Solway Firth

Griffin, L., O'Brien, M. & Rees, E.C. 2006. Consequences of an unforeseen event: effects of foot-and-mouth disease on the Barnacle Goose *Branta leucopsis* population wintering on the Solway Firth. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 441-442.

The outbreak of foot-and-mouth disease (FMD) in Britain in February 2001 had a major impact on farming activity around the Solway Firth the following summer, with many farmers losing their cattle and sheep. The changes in farming practices associated with FMD were considered likely to have consequences for the Svalbard Barnacle Goose *Branta leucopsis* population (which winters almost exclusively on the Solway Firth), because the geese generally feed on short, well fertilised pastures which have been grazed by sheep and cattle, and/or cut for hay or silage. They also spend time feeding on grazed merse (Owen *et al.* 1987). Longer or unfertilised swards, fields being put to arable crops, or an increase in set-aside in some parts of their wintering range could have caused shifts in goose feeding distribution in winter 2001/02. Moreover, variation in feeding opportunities could have led to a detrimental effect on body condition in winter 2001/02, which in turn might have influenced breeding success in summer 2002 and survival to the 2002/03 season.

Goose distribution before and after FMD was analysed to determine whether the reduction in livestock grazing rendered traditional feeding sites less attractive to the birds. Sward characteristics were measured to describe variation in food quality and quantity, and thus explain any changes in distribution. Demographic parameters recorded since the 1970s were used to determine whether a post-FMD change in food supply had longer-term effects on the population, by influencing survival and breeding success. This short note presents a summary of the results of the study. They are presented in full in Griffin *et al.* (2004).

To quantify the effects of FMD on farming activity, farmers were asked to complete questionnaires describing, for both 2000 and 2001, the main crop in each field, the number and timing of cuts for hay/silage, type of livestock and duration of grazing, fertiliser application, the year in which the field was last reseeded (if <10 years ago), and whether the farmer lost sheep, cattle, or both types of livestock due to FMD. In 2001-2002, more detailed monthly habitat assessments were also undertaken, to provide data to investigate causal links between farming activity and goose feeding site selection. Mean sward length was recorded for 177 fields, and sward biomass and protein content for a stratified sample of 64 fields (Griffin *et al.* 2004).

Changes in goose distribution across the Solway was monitored by: (i) weekly counts of numbers present in each field along a fixed route on the north side of the estuary, and (ii) coordinated weekly total population censuses covering all the main areas used by the geese. Fixed route counts recorded in 2001/02

were compared with similar route counts made each winter since 1993/94 so as to determine any local changes in feeding site selection. The latest total population counts were compared with population counts undertaken at least once a winter since 1993/94, and monthly since winter 1999/2000 (Phillips *et al.* 2000, Griffin & Coath 2001), to determine whether there was a more major shift in distribution across the Solway.

The potential of longer-term effects of FMD to affect goose survival and breeding success was assessed by comparing abdominal profile (body condition) scores for the geese in 2001/02 with those recorded in previous winters, using the method described by Owen (1981). Breeding success in summer 2002 (post-FMD) was assessed subjectively by considering the proportion of juveniles recorded in winter 2002/03 with observations made in the previous nine winters. Resightings of Barnacle Geese marked with plastic leg-rings were analysed using the MARK programme (White & Burnham 1999), to determine whether post-FMD survival (i.e., from winter 2001/02 to winter 2002/03) differed from annual survival rates recorded since the colour-ringing programme commenced in 1973.

The questionnaire interviews with farmers revealed that those affected by FMD reduced their fertiliser application in summer 2001, and switched grassland management from grazing to mowing. There was no significant change in the proportion of land that was tilled and cropped, rather than left as grass, in comparison with earlier years. Sward height on 'FMD affected farms' (those that lost both cattle and sheep) was taller than on 'unaffected farms' (those that lost sheep but not cattle) in October, but not from December onwards. At the Wildfowl and Wetlands Trust (WWT) Caerlaverock Reserve (FMD affected) the sward was taller in autumn 2001 than any previous autumn for which data had been collected (1997 to 2000 inclusive; Fig. 1). Otherwise, there was little variation in the sward variables (i.e., live biomass, forage quality and protein content) between FMD affected and unaffected sites in winter 2001/02.

The total population censuses found no evidence for a major shift in goose distribution between the southern (English) and northern (Scottish) sides of the Solway Firth in the winter immediately following FMD, in comparison with earlier and subsequent years, nor for a major movement to feeding sites outside the traditional wintering area. Individual flock sizes were smaller in 2001/02, and the geese used a greater number of fields in comparison with previous winters and with 2002/03, suggesting that the birds were more widely dispersed across their traditional feeding areas in 2001/02.

**Fig. 1.** Variation in winter sward height in a typical pasture field at WWT Caerlaverock, for three winters before FMD (solid lines) and one winter after FMD (dashed line).

Changes in field management between 2000 and 2001 had some effect on goose distribution in the early part of winter 2001/02: fewer geese were recorded in fields in October 2001 where cattle grazing was lower during summer 2001 than the previous year, and fewer geese were recorded in November 2001 where a post-FMD reduction in sheep grazing had occurred. This supports earlier studies indicating that livestock grazing regimes can prepare the optimal sward for geese in autumn (Owen *et al.* 1987). However, there was little evidence that changes in field management influenced goose usage of fields from December onwards, or that the sward parameters measured influenced goose distribution in a substantial manner. Moreover, it seemed that the geese would feed on longer swards than had previously been considered optimal.

Modelled factors that affected goose distribution prior to FMD (for winters 1997/98–1999/2000 inclusive) were that, the disturbance regime for each field (fields having been classified as reserve, feeding, buffer and scaring zones each year, as part of the Solway Goose Management Scheme) was more closely associated with distribution than other variables. This is likely to have been due to the scheme reflecting feeding site fidelity in previous years, since previous use of a field by the geese is taken into account on determining the zone to which a field is assigned. Crop type was also significantly associated with goose distribution, with young pasture more frequently used by the geese than old pasture in early winter, while merse was used more frequently from February to April inclusive (Griffin *et al.* 2004).

A model of goose distribution in winters 1997/98 to 1999/2000 appeared better able to predict distribution in the winter immediately after FMD (2001/02) than in the previous ‘control’ year (2000/01) (Table 1). This confirmed the analyses of changes in goose distribution, which indicated that there was no major shift in feeding site selection in the winter following FMD.

Low goose body condition in 2001/02 reflected a long-term decline, associated with poorer condition on arrival in October. Thus, there was no evidence for FMD-related changes in food

**Table 1.** The ability of the model to predict the frequency of occurrence of Barnacle Geese on a field-by-field basis in 2000/01 compared with 2001/02. The Chi-squared values given are the goodness of fit of the model.

	2000/01 winter	2001/02 winter
October	4.78*	57.53***
November	41.24***	64.67***
December	102.61***	42.17***
January	67.10***	94.77***
February	71.15***	96.22***
March		59.89***
April		29.31***

\*  $P < 0.05$ ; \*\*\*  $P < 0.001$

supply affecting the birds’ condition in 2001/02. Similarly, low survival to winter 2002/03 reflected an ongoing trend, which may be related to other factors, such as density-dependent effects on the breeding grounds. Breeding success in 2002, recorded during winter 2002/03, was better than in the previous two years, and approached the ten-year mean of 10.8%.

Overall, the study found no evidence for FMD having a major effect on the Svalbard Barnacle Goose population. This may perhaps reflect the lack of variation in sward quantity and quality between FMD affected and unaffected sites, which in turn may be due to the farmers switching from grazing to mowing, and to the short time period involved. Further experimental work is needed to confirm whether sward condition and large-scale goose distribution are affected if changes in grazing and fertiliser regimes are maintained.

Samuel, M.D. 2006. Snow Goose *Chen caerulescens caerulescens* overabundance increases avian cholera mortality in other species. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 443-445.

### ABSTRACT

Avian cholera is a highly infectious disease caused by the bacterium *Pasteurella multocida* that affects >100 species of waterbirds worldwide. Current information on avian cholera indicates Lesser Snow Goose *Chen caerulescens caerulescens* to be a likely reservoir of the disease, though more birds survive outbreaks than was previously believed, and many of the birds that survive infection could be carriers of the disease agent. North American snow geese have increased dramatically, they are frequently involved in larger avian cholera outbreaks, they associate in dense winter aggregations that can enhance disease transmission, and these birds nest in colonies that facilitate continuation of the disease cycle during the summer. In the Rainwater Basin, an internationally recognized migration area for waterbirds, increasing populations of snow geese are associated with increasing avian cholera mortality, especially in other waterfowl species using the area each spring. High avian cholera in snow geese increases the risk of disease transmission and the magnitude of disease outbreaks in the community of waterfowl hosts using this area.

### INTRODUCTION

Avian cholera is a highly infectious disease caused by the bacterium *Pasteurella multocida* and is the most important infectious disease affecting waterfowl in North America (Wobeser 1997). The bacteria are primarily transmitted by ingesting or inhaling contaminated water from wetlands where birds die from the disease and from bird-to-bird contact. Wetlands with high densities of waterfowl can increase the risk of disease transmission and potentially the magnitude of disease outbreaks. Because the bacterium affects >100 species of waterbirds (Botzler 1991) factors such as bird density, disease transmission, and species mortality rates may depend on the community of waterfowl hosts using an area. Although much remains unknown about the ecology of avian cholera, recent evidence indicates that Lesser Snow Geese *Chen caerulescens caerulescens*, and possibly other waterbirds, are probable carriers of this disease agent (Samuel *et al.* 2005). Although avian cholera has killed >100 000 birds during single outbreaks the disease also appears to cause ongoing, low-level mortality within waterfowl populations (Botzler 1991, Wobeser 1992, Samuel *et al.* 1999b). Current management strategies to control avian cholera losses in waterfowl have been reactive, consisting primarily of collecting and disposing of carcasses when outbreaks occur (Wobeser 1992).

The Rainwater Basin (RWB) in Central Nebraska is internationally recognized as a key focal point in the spring migration of millions of ducks, geese, shorebirds, and cranes. However, large scale habitat changes in the RWB have produced at least

two notable effects on migratory waterfowl. First, the dramatic reduction in habitat has produced extremely high concentrations (>500 000) of birds on many of the remaining wetlands. These crowded conditions can enhance transmission and spread of infectious diseases (Friend 1992). Since the 1970s avian cholera has been a recurrent disease problem in the RWB (Windingstad *et al.* 1984, 1988) where mortality occurs annually and in some years (e.g. 1998) estimated losses exceeded 100 000 birds. Risk and severity of diseases like avian cholera may have been further exacerbated by concurrent reductions in wetland quality (Friend 1981). Secondly, over the past decade, the skyrocketing population of mid-continent Lesser Snow Geese has shifted its principal spring migration corridor from eastern to central Nebraska. These birds have apparently been attracted to the abundance of nutrient and energy subsidy provided to waterfowl feeding on waste agricultural crops in the RWB.

### METHODS

The RWB encompasses >10 000 km<sup>2</sup> in south-central Nebraska with <10% of the pre-settlement wetland basins remaining (Smith & Higgins 1990). Because the vast majority of wetlands have been destroyed, the remaining basins exist in an intensive agricultural environment. The RWB is also recognized as the focal passageway for 7-9 million ducks and 5-7 million geese migrating from their wintering grounds in the southern United States and Mexico to their breeding grounds in Canada and the Arctic (Gersib *et al.* 1992). Avian cholera was first reported in the RWB in 1975 when an estimated 25 000 birds died (Zinkl *et al.* 1977). Since that time, avian cholera has occurred almost annually with most losses during spring migration, but fall outbreaks have occasionally occurred. Estimated losses have varied each year with peak mortality reported in 1980 (Brand 1984) and again in 1998.

We used data on carcasses collected by U.S. Fish and Wildlife Service and Nebraska Game and Parks Commission staff during spring avian cholera mortality events in the RWB from 1984-1999 to evaluate species composition of mortality and the relation between Lesser Snow Goose mortality and mortality in four of the predominate species of waterfowl: White-fronted Geese *Anser albifrons*, Canada Geese *Branta canadensis*, Mallard *Anas platyrhynchos*, and Northern Pintail *Anas acuta*. Carcass collection for remaining waterfowl species were considered as "other waterfowl" mortality. We used regression methods to evaluate the relation between the number of Snow Goose carcasses collected during outbreaks and those of other species collected during the same outbreaks. A separate regression analysis was conducted to compare Snow Geese to each of the waterfowl species collected.

**Table 1.** Carcasses collected during spring (February-April) avian cholera outbreaks in the Rainwater Basin, Nebraska, 1984-99 and reported to the National Wildlife Health Center. No avian cholera losses were reported during spring 1993 and 1994.

## RESULTS

The severity of avian cholera losses among waterfowl populations has varied annually from endemic to epizootic wherever this disease has become established (Windingstad *et al.* 1998). Mortality levels may be influenced by a number of factors including species susceptibility, waterfowl density, age/sex of birds, stress, and weather (Rosen 1969, McLandress 1983, Botzler 1991, Samuel *et al.* 1999b, Windingstad *et al.* 1998). From 1984 to 1999, >56 000 carcasses of known species composition were collected during spring avian cholera outbreaks in Nebraska's RWB (Table 1). Lesser Snow Geese comprised the majority of carcasses (70.5%), followed in frequency by Northern Pintail (9.0%), White-fronted Geese (8.6%), other waterfowl species (4.3%), Mallard (4.1%), and Canada Geese (3.5%). The number of carcasses collected in the RWB varied annually, generally reflecting severity of avian cholera losses. However, the number of carcasses collected typically was much smaller than estimated mortality during the outbreak. For example, in 1998 <25 000 carcasses were collected and identified to species compared with an estimated total mortality >100 000 birds. The number of Snow Goose carcasses collected was positively related to the number of White-fronted Geese (slope = 0.040,  $t_{12} = 3.80$ ,  $P = 0.003$ ), Northern Pintail (slope = 0.127,  $t_{13} = 17.1$ ,  $P < 0.0001$ ), Mallard (slope = 0.060,  $t_{13} = 20.9$ ,  $P < 0.0001$ ), and other waterfowl species (slope = 0.046,  $t_{13} = 9.83$ ,  $P < 0.0001$ ) collected. However, there was no relationship between Snow Goose carcasses and the number of Canada Geese collected (slope = 0.004,  $t_{12} = 0.56$ ,  $P = 0.58$ ).

## DISCUSSION

The RWB appears to provide nearly ideal conditions for regular outbreaks of avian cholera (Wobeser 1992: 678), increasing Lesser Snow Geese, and crowding on a markedly reduced wetland base further contribute to the increased risk of avian cholera (Friend 1992). Current information indicates that Snow Geese are a likely reservoir of the disease (Samuel *et al.* 2005)

and may be particularly important in the ecology of avian cholera because populations have increased dramatically, they are frequently involved in larger avian cholera outbreaks, they associate in dense winter aggregations that can enhance disease transmission, and they nest in colonies which facilitate continuation of the disease cycle during the summer (Samuel *et al.* 1999a). In the RWB, Snow Geese are associated with increasing avian cholera mortality in other waterfowl species using the area each spring. Thus, there appears to be considerable potential for overabundant Snow Goose populations to adversely impact other species of birds by increasing the risk of disease transmission and outbreaks. Clearly a better understanding of the ecology of avian cholera is needed, including factors that promote and terminate outbreaks; the frequency of carrier birds and their role in the disease cycle; and how bird density, species composition, carcass density, and wetland conditions affect transmission of the disease. In the RWB and other areas with endemic avian cholera mortality it appears that management actions that reduce bird density, increase habitat available to waterfowl, reduce stress on birds, and provide habitat that encourages separation of ducks and geese would be beneficial.

Rusev, I. & Korzuykov, A. 2006. Ukraine as an ecological corridor for the transcontinental migration of birds in the Afro-Eurasian region and questions of epidemiological safety. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 446.

Ukraine acts as an ecological corridor for the transcontinental migration of birds in the Afro-Eurasian region. This paper suggests that migrating birds may carry potentially dangerous viruses from Africa to Europe via the Ukraine.

A total of 416 species of birds reside in Ukraine for at least some part of the year (Fesenko & Bokotej 2002); of these, 19 are listed on the IUCN Red List and 67 in the Red Book of Ukraine. These include a number of important migratory birds. Over 100 of the 170 birds listed in the African-Eurasian Migratory Waterbird Agreement either nest in Ukraine or stop during migration: the Azov-Black sea coastal area is therefore a very important migration ecological corridor for many species of birds from Europe, Asia and Africa. Snake Island in the Black Sea is a key point for migrating non-passerine birds (Korzuykov *et al.* 1998).

The wetlands in the coastal areas of the Azov- Black Sea, particularly in the deltas of the Danube and Dniester, and along the Azov-Black Sea corridor provide habitat or resting sites for over then 200 species of waterfowl many of which migrate to Africa and some to Asia (Shegolev & Rusev 1993; Rusev & Barker 1995). For example, the well-known Night Heron *Nycticorax nycticorax* nesting population which in the Dniester delta consists of only 2 500 pairs, migrates to Mali, Chad and Niger (Rusev 1999). Some birds have also been found in Russia to the east, and to the west in France, Germany, Spain and Italy (Fig. 1).

It is known that Africa has many natural foci of arboviruses – West Nile Fever, Sindbis fever and others (Lvov & Ilichev 1979), and this natural migration root could be a possible transmission route for viruses and infection of people. Our previous serological and virology investigations of ticks, mosquitoes and birds in the Azov-Black Sea region during 1986-2002 showed that they are significant factors in the potential spread of infection to human populations, and a practical system of monitoring and managing the epidemiological situation is needed (Rusev & Boshenko 1977; Rusev *et al.* 1998). This is particularly relevant given the need to monitor avian influenza in Europe and elsewhere.

Monitoring waterbirds in Sudan. Photo: Niels Gilissen - MIRATIO.

Counts of migratory waterbirds in their breeding, staging and non-breeding areas have taken place for many decades. For non-breeding birds, the International Waterbird Census (IWC) organised by Wetlands International, has developed into a systematic global programme since its introduction in the 1960s. Summaries of national monitoring programmes were presented for a number of countries, including for North America (Blohm *et al.*), Sweden (Nilsson), the Netherlands (van Roomen *et al.*), the Czech Republic (Musilova *et al.*), and Slovakia (Ridzon). Long-term monitoring of breeding birds is also well-established at particular sites (such as the Bulgarian Bourgas wetlands reported by Profirov *et al.*) as well as for single species. However, it is clear that many gaps remain and there are many challenges in obtaining and using the data needed for more effective flyway management.

At a flyway scale, the symposium aimed to provide an overview of present monitoring approaches and programmes, identifying important gaps, and discussing ways to improve coverage and effectiveness. It suggested ways to link monitoring and results more closely to waterbird conservation and management.

It concluded that monitoring under the IWC is a strong contribution to the current knowledge of the status and trends of waterbird flyway populations; and also that there are many

challenges ahead to improve monitoring so as to effectively address data needs in relation to flyway management.

The following five recommendations were made:-

1. The expansion of spatial and temporal coverage of the IWC, and improvement in the quality of data obtained, through capacity building and the training of observers in data deficient regions, as well as the monitoring of sites during migration and breeding seasons.
2. Strengthening the monitoring of demographic parameters. An integrated approach to the monitoring of waterbirds gives cost-effective identification of the reasons for waterbird population changes. There are good examples of the collection of demographic information and its integration with census data. Further such national and especially international schemes should be strongly encouraged and funded.
3. Incorporating data obtained by various methods including hunting bag statistics, ringing and other marking methods.
4. Development of monitoring site characteristics and threats to sites using methods including remote sensing.
5. Improvement in co-operation between Wetlands International, BirdLife International and other organisations so as to ensure optimum efficiency.

## Monitoring North America's waterfowl resource

### ABSTRACT

Monitoring programs are an essential component of successful waterfowl management in North America. Five major categories of waterfowl monitoring efforts are conducted annually: population surveys; production surveys; habitat surveys; banding and marking programs; and harvest surveys. These surveys and programs are cooperative in nature, and rely on integrated partnerships between federal, state, and provincial agencies, as well as private organizations throughout the continent. Results from these surveys provide estimates of waterfowl population size, recruitment, survival rates, and harvest, as well as a means of evaluating habitat quality. Quantitative assessments of these key parameters provide the foundation for understanding waterfowl population dynamics and making and evaluating harvest management decisions.

### INTRODUCTION

One of the primary goals of waterfowl harvest management is to provide equitable hunting opportunity while ensuring the long-term sustainability of the hunted populations. Monitoring bird populations is an essential element in facilitating this task, and is the common basis for regulating hunting activities in all three countries in North America. The signatories of the various migratory bird treaties (United States, Canada, Mexico, Russia, and Japan) share responsibility for conducting the monitoring efforts that are needed to ensure sustainability.

In this paper, we provide an overview of the monitoring programs in North America, which are critical components of successful waterfowl management. There are five major categories of waterfowl monitoring efforts that are conducted annually: population surveys, production surveys, habitat surveys, banding and marking programs, and harvest surveys. These surveys and programs are cooperative in nature, involving biologists and other personnel from federal, state, and provincial agencies, as well as some non-governmental organizations. Information collected in these surveys results in estimates of waterfowl population size, recruitment, survival rates, and harvest, and also provides a means of appraising habitat quality. Together, these estimates provide the foundation for understanding waterfowl population dynamics and making and evaluating harvest management decisions.

### POPULATION SURVEYS

Each year, waterfowl population surveys are conducted on breeding and wintering grounds, and during migration. Most of these surveys are broad-scale in nature, wherein pilot-biologists count many species simultaneously, but some are designed to be species- or population-specific. These are primarily aerial surveys, and the data they provide are used independently or in conjunction

with other information to derive annual estimates or indices of abundance for most species of ducks and populations of geese.

### Breeding Ground Surveys

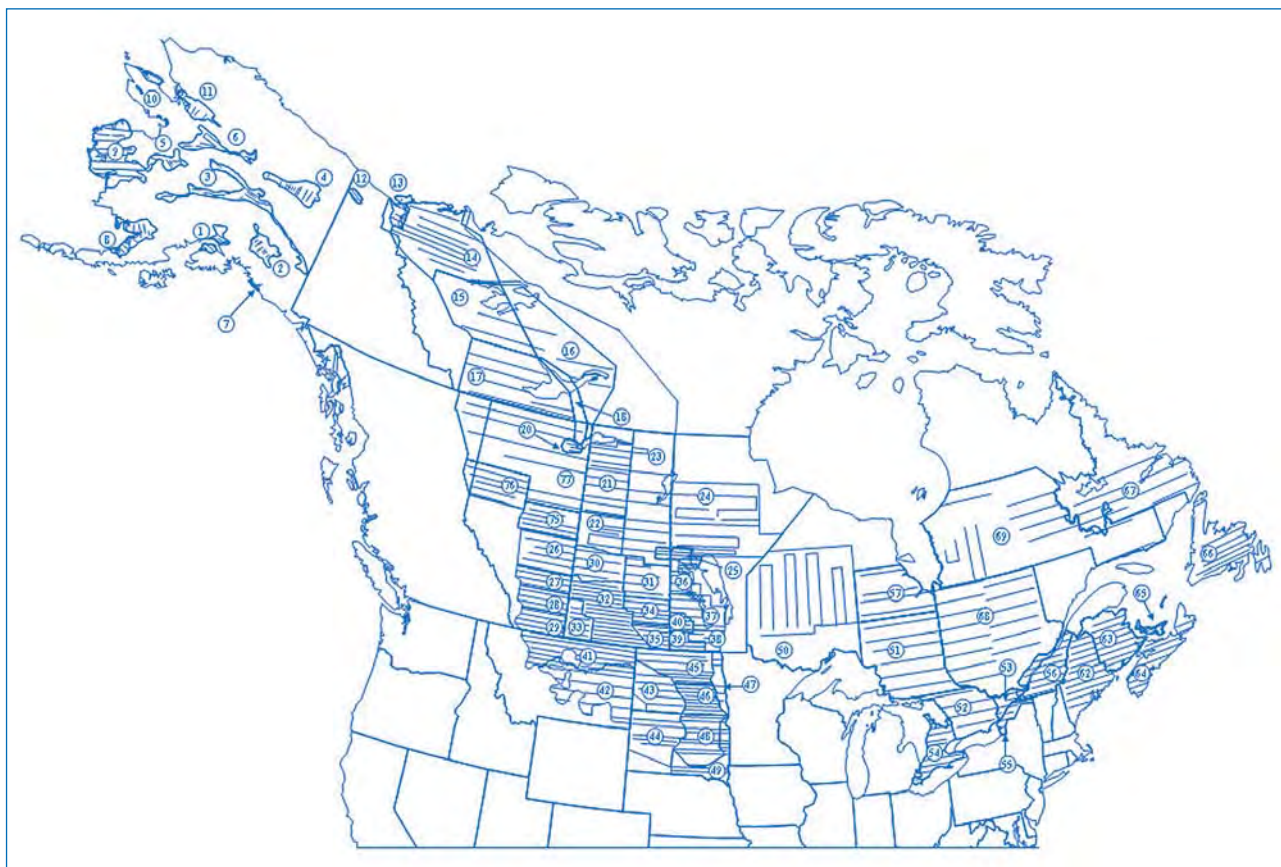

The May breeding population and habitat survey is the most extensive and most important of North America's waterfowl population surveys. This survey was initiated on an experimental basis in 1947, became fully operational in 1955 (Martin *et al.* 1979), and has since been conducted annually. This survey is a cooperative effort of the United States Fish and Wildlife Service (USFWS), the Canadian Wildlife Service (CWS), and state, provincial, and tribal agencies. From 1955 to 1995, the May breeding population and habitat survey annually sampled more than 3.6 million square km of waterfowl breeding habitat throughout central Canada, north-central United States, and Alaska (Smith 1995). In 1996, the survey area was expanded to include an additional 1.8 million square km in the north-eastern United States and eastern Canada. In its entirety, this area represents a large portion of the primary duck nesting areas in North America.

The methodology for the May breeding population and habitat survey is described in detail in manuals of standard operating procedures (CWS & USFWS 1977, 1987) and elsewhere (e.g. Reynolds 1987); therefore we will only outline it briefly here. To sample the North American waterfowl breeding habitat efficiently, the area is divided up into 65 strata or areas of similar waterfowl habitat and waterfowl densities. Within each stratum are transect lines that were established to sample the stratum from the air (Fig. 1). Different strata are sampled at different intensities depending on waterfowl densities within the strata. Each transect is further divided into a series of 28.8 km segments (25.6 km in Alaska). In total, over 85 000 km of transects are flown each year using 13 fixed-wing aircraft.

Air crews, each of which consists of a pilot-biologist and an observer, fly along each transect line at an altitude of 30-45 m and a speed of 145-170 km per hour. The pilot-biologist identifies and counts all ducks and geese within 200 m of the transect line on the left side of the aircraft, while the observer is responsible for identifying and counting waterfowl within 200 m on the right side. Observed birds are identified as singles, pairs, flocks, or groups (CWS & USFWS 1977, 1987). Until recently, pilot-biologists and observers recorded their observations on tape recorders, and later transcribed and summarized the data onto paper forms or into a computer. Today, observations are recorded directly in a computer, and each observation is geo-referenced with point locations from the aircraft's Global Positioning System (GPS, see Hodges & Thorpe 2002).

When the survey was first established, population estimates derived from the aerial counts were not adjusted for birds that

**Fig. 1.** Strata and transect lines of the May waterfowl breeding population and habitat survey that is flown annually in North America.

could not be seen from the air. To correct for this bias, a sub-sample of segments was chosen for more intensive scrutiny by biologists on the ground. Ground crews consisting of two to four people coordinate with the air crews and conduct their waterfowl counts on sample segments within three days after the air crew has flown the segment. The ground crew uses GPSs, aerial maps, and past experience to check every wetland and count and identify each duck or goose observed on the sample segments. The use of these “air-ground comparison segments” was first tested in 1959, and the system became fully operational in 1961 in Canada and in 1974 in the United States. Currently, in the United States and Canadian prairies there are 163 air-ground comparison segments. The ground counts provide the basis for developing visibility correction factors to account for the fact that not all birds within 200 m of the transect can be seen from the air. In some northern and eastern strata, where ground access is problematic due to lack of roads, helicopters are used instead of ground crews (e.g. Malecki *et al.* 1981). In these areas, transects are flown by the fixed-wing aircraft and then followed up by a helicopter crew using procedures similar to those used by the ground crews in the prairie areas.

Species-specific estimates of breeding populations are derived by taking the counts obtained from fixed-wing aircraft, adjusting them based on the visibility correction factors, and expanding them over the survey area in each stratum. Martin *et al.* (1979) provided a detailed explanation of the statistical analyses used to derive population estimates and the associated variances.

Although the May breeding population and habitat survey covers a large portion of North America’s primary waterfowl

breeding areas, it is not all-encompassing. Many populations of geese nest in the arctic or sub-arctic regions of Alaska and Canada, and the remoteness and extensive distribution of their habitats make it difficult to acquire population estimates at this season. Therefore, biologists must rely on other surveys to obtain indices of abundance for many populations of geese, including Snow Geese *Chen (Anser) caerulescens*, Ross’s Geese *C. (A.) rossii*, Greater White-fronted Geese *Anser albifrons*, and Canada Geese *Branta canadensis*. One such survey is the arctic-nesting goose survey, where biologists from federal, state, and provincial agencies, and universities, count geese at various locations on the nesting grounds. These surveys are usually conducted from helicopters over historical goose nesting areas (e.g. Reed & Chanton 1987), and they are used in conjunction with other population surveys conducted during autumn and winter to provide annual goose population estimates.

### Wintering Ground Surveys

The mid-winter survey is another survey of continental waterfowl populations that includes most species of ducks and geese. Conducted annually since 1935, this survey provides estimates of waterfowl on major wintering areas throughout the United States. It is a cooperative effort between federal and state personnel that is usually conducted in January. Unlike the transect-based May survey, the mid-winter survey is primarily a cruise survey during which pilot-biologists and their observers attempt to census birds in the areas they survey. Unfortunately, survey methodology has varied among states, and coverage has varied over years. This lack of standardization, coupled with the cost of conducting the survey, has been the origin of some

criticism (e.g. Eggeman & Johnson 1989). However, although the mid-winter survey only yields general information for most waterfowl species, such as relative abundance and distribution on wintering habitats, it does provide the best population data available for some species, including Tundra Swan *Cygnus columbianus*, Black Brant *Branta bernicla nigricans*, and some other goose populations (Trost *et al.* 1990).

The Mexican waterfowl survey is another winter aerial survey that is conducted cooperatively by biologists from Canada, Mexico, and the United States. Starting in the mid-1930s, this cruise survey covers the major waterfowl wintering grounds of Mexico, including the east coast from Laguna Madre to Tampico, the west coast including the Baja Peninsula, and the interior highlands (Saunders 1952). Parts of the survey are conducted annually, but the entire survey is now carried out at three-year intervals. The Mexican waterfowl survey is not part of the mid-winter survey; however, it augments the winter surveys conducted in the United States by providing additional coverage of waterfowl species that winter extensively in Mexico. For example, species such as Mallard *Anas platyrhynchos* are well covered by the mid-winter survey, but a large proportion of some species such as Blue-winged Teal *A. discors*, Northern Pintail *A. acuta* and Redhead *Aythya americana* winter far into Mexico.

### Migration Surveys

In addition to surveys on the breeding and wintering grounds, some population surveys are also conducted during the spring and autumn migrations. An example of a migration survey is the mid-continent Sandhill Crane *Grus canadensis* survey, which is conducted in late March. Nearly the entire population gathers in Nebraska's Platte River Valley at that time, during the northward spring migration. The survey consists of a pilot-biologist and his observer counting birds along established transect lines. It also uses aerial photography of a sub-sample of crane flocks to quantify errors made by the pilot-biologist and observer in the estimation of flock sizes, thereby enabling the development of correction factors to obtain a more accurate estimate of the population size (Benning & Johnson 1987). Another example is the September survey of mid-continent Greater White-fronted Geese that is conducted in the Canadian prairie, where the population gathers during the southward autumn migration.

### PRODUCTIVITY SURVEYS

The July duck production survey is very similar to the May breeding population and habitat survey, but instead of counting breeding pairs, pilot-biologists count duck broods, and, whenever possible, identify the broods by age class. They also count pairs and lone males to obtain an index of the late nesting effort, an important component of overall productivity for some species (Reynolds 1987). The survey area is a subset of the May survey area, and fewer transects are sampled. Ducklings cannot be identified to species from the air, and brood counts are not corrected for pilot/observer visibility because broods are difficult to count from the ground. As a result, this survey provides an index of annual production for all ducks in the survey area, but not species-specific estimates.

The wintering grounds are another place for biologists to estimate productivity, especially for Tundra Swans and some species of geese. Adult Tundra Swans and their young of the year are easily distinguishable from the air, because the adults

are white and the young birds have dull gray plumage. The winter productivity counts are generally conducted with the mid-winter surveys, and consist of both transect and cruise surveys.

### HABITAT SURVEYS

Knowledge of habitat conditions is an important component in any attempt to predict changes in the size of duck populations. The two major operational surveys used for this purpose are the May breeding population and habitat survey and the July duck production survey. In addition to counting ducks and geese during these surveys, pilot-biologists and their observers also count ponds and assess habitat conditions over the key breeding areas in North America. Pond counts and the changes in pond numbers between May and July have been critical components of the process that predicts annual duck production in the Prairie Pothole Region of the United States and Canada. Furthermore, annual pond counts obtained during the May survey serve as major inputs into the models used to determine annual hunting seasons and regulations (Johnson *et al.* 1997).

Satellite imagery and remote sensing are also two techniques currently being used and/or evaluated to monitor and estimate habitat conditions. For example, biologists can access LANDSAT satellite imagery to determine the amount and distribution of upland and wetland habitat available for breeding waterfowl (Koeln *et al.* 1988). Such imagery is important for targeting where habitat management projects should be undertaken. In addition, Advanced Very High Resolution Radiometry (AVHRR) has recently been used to monitor the timing of snow melt in some of the arctic habitats used by nesting geese (Strong & Trost 1994). In the arctic and sub-arctic regions, the phenology of snow melt and timing of the spring break-up are important variables used for predicting the timing of nest initiation by geese, and ultimately annual goose productivity. Production is usually poor if nesting is delayed much beyond 15 June. These approaches to quantifying and qualifying habitat not only hold promise for improving our estimates of available habitat, but will allow pilot-biologists and observers to concentrate their efforts on counting ducks (Smith *et al.* 1989).

### BANDING AND MARKING PROGRAMS

Banding is another important source of information for waterfowl managers. The first large-scale North American banding program was established in 1922 (USFWS & CWS 1989), but it was not until 1946 that an international banding effort was organized to address specific management objectives for ducks (Smith *et al.* 1989).

One of the first uses of banding and recovery location data was to help biologists determine migration routes (Lincoln 1935). Determining the four major migratory pathways, or flyways, in North America led to the establishment of the Flyway System in 1948; Flyways are still the administrative units by which we manage waterfowl today. Understanding migration routes for various species gives biologists insight into the distribution and derivation of the harvest, which allows us to better manage individual populations.

Biologists can also estimate both annual harvest rates and annual survival rates for some waterfowl species from band recovery data. The annual variation in harvest and survival rates has helped biologists understand how breeding habitat conditions and harvest regulations affect survival (e.g. Burnham *et al.* 1984).

Thus, these harvest and survival rates are critical pieces of information that are used to help determine appropriate hunting regulations each year, i.e. the regulations that will result in sustainable harvest levels (Williams *et al.* 1996). Estimating harvest rates from band recoveries requires a thorough understanding of band reporting rates. Reporting rates reflect the willingness of people who recover bands to report this information to the Bird Banding Laboratory. In recent years, use of a toll-free telephone number imprinted on bands has raised reporting rates significantly from the levels that Nichols *et al.* (1995) estimated for the late 1980s. We are currently conducting a comprehensive multi-year investigation to determine what the reporting rates are now, and whether they vary by region, species, and sex.

Currently, biologists band more than 200 000 ducks and nearly 150 000 geese and swans in North America each year. To date, we have concentrated most of our duck banding efforts on Mallards. The Mallard is the most commonly harvested duck in the United States and Canada (USFWS 2003), and much of what we know regarding waterfowl population dynamics and harvest management is due to the continued success of the banding effort devoted to this species.

## HARVEST SURVEYS

National surveys of sport hunters have been conducted annually since 1952 in the United States and since 1967 in Canada. Although they have undergone significant changes since their inception, these surveys are still conducted by mail, and consist of asking samples of waterfowl hunters to report the number of ducks and geese they harvest during the hunting season (Martin & Carney 1977, Cooch *et al.* 1978). The surveys provide annual information that allows biologists to evaluate long-term trends in harvest, hunter numbers, hunting pressure, and waterfowl population demographics (Trost *et al.* 1987). This information, coupled with data from other surveys, allows biologists to generate population models that are used to help determine harvest management prescriptions for several species, such as Mallard, Northern Pintail, and Canvasback *Aythya valisineria*.

Both countries currently require all hunters of migratory birds to provide their name and address, either through a migratory bird hunter registration system (United States) or a special migratory bird hunting permit (Canada). This yields sample universes from which the USFWS and CWS select samples of hunters for their "harvest diary" surveys. Each sampled hunter is asked to report the date, location, and the number of ducks and geese taken for each day of waterfowl hunting. Hunters' responses are used to estimate the mean number of ducks and geese harvested per hunter for each state or province. The total number of ducks and geese harvested in each state or province is then estimated by expanding these means by the number of hunters in each state or province.

Both countries also select another sample of hunters annually, and ask them to participate in "parts collection" surveys. Hunters who agree to participate are mailed postage-paid wing envelopes and are asked to send back a wing from every duck and the tail feathers of every goose that they shoot throughout the hunting season. Biologists identify the species, age, and sex of each duck wing in the sample and the species and age of each goose tail. Thus, these surveys yield estimates of the species, sex, and age composition of the harvest. Results of the parts collection surveys are combined with the results of hunting diary

surveys to provide species-specific harvest estimates (Martin & Carney 1977, Cooch *et al.* 1978).

Additionally, a survey of the annual harvest of subsistence hunters has been conducted in Alaska since 1985. For this survey, a sample of households is selected in the parts of Alaska where subsistence harvesting of birds and eggs is legal. Survey forms that show pictures of the various species of birds are hand-delivered to the sample households, and participants are asked to record how many birds and eggs of each species they take over the entire subsistence harvest period (April-October). Harvest estimates are derived in a similar fashion as sport harvest in the United States and Canada, except that species-specific estimates are derived directly from the household reports rather than from a wing survey.

## CONCLUSION

Monitoring programs are integral components of migratory bird management in North America. Together, results from these surveys and programs comprise the largest data set on any wildlife species group in the world. Results from these surveys serve as crucial inputs for many waterfowl population models, and are used to help guide biologists in setting and evaluating harvest management and habitat management programs. Furthermore, the success of North America's monitoring efforts is entirely dependent upon cooperation at all levels among the agencies and organizations that are charged with managing this important wildlife resource.

### ABSTRACT

The African Waterbird Census (AfWC) is one of several co-ordinated international waterbird censuses carried out under the umbrella of the International Waterbird Census (IWC). The census was initiated in 1991, and since 1998 has been managed from the Wetlands International office in Dakar, Senegal. To date, over 900 sites in 36 countries have been counted at least once during the census, and thousands of volunteers and professionals have participated in the counts. Over 9.2 million waterbirds were counted in the census of January 2000. This paper provides a brief history of the AfWC, and reviews some of the problems and challenges that it faces. A strategy for the development of the AfWC during the period 2004-2006 is discussed, and a number of priorities are identified.

### INTRODUCTION

The African Waterbird Census (AfWC) runs parallel to other international waterbird censuses in Asia, the Western Palearctic and the Neotropics under the umbrella of the International Waterbird Census (IWC). The AfWC, which concerns sub-Saharan Africa, was initiated in 1991, when 15 countries participated. Gradually, the AfWC has extended its coverage to reach most parts of the continent and Africa's outlying islands, particularly in the Indian Ocean, such as Madagascar. The main objectives of the AfWC are to:

- establish a monitoring programme for African wetlands;
- determine distribution and migratory strategies of waterbirds in Africa;
- develop estimates of the populations of waterbirds in Africa;
- create a network grouping persons involved in the survey, management and use of waterbirds and wetlands; and
- promote education and public awareness concerning wetlands and waterbirds.

During its implementation, Wetlands International has benefited from the financial support of several partners for the AfWC, including the Government of The Netherlands, the Swiss Agency for Environment and Forests, the Ramsar Convention Bureau, and the Secretariat of the African-Eurasian Migratory Waterbird Agreement (AEWA), whilst other partners have contributed to the programme directly through parallel initiatives, including the Office National de la Chasse et de la Faune Sauvage (ONCFS) in West Africa and the Wildfowl and Wetlands Trust (WWT) in Eastern Africa.

### Participation, coverage and national co-ordination

After the opening of Wetlands International's Africa Programme Office in Dakar, Senegal, in 1998, the database was transferred

to Dakar and is managed there, whilst regular contact is maintained with the IWC database at the headquarters of Wetlands International in The Netherlands. To date, the database holds data from more than 900 sites in 36 countries, and thousands of volunteers and professionals have participated in the waterbird census in one way or another.

There is an on-going effort to strengthen national co-ordination of the AfWC, especially through the nomination of National Co-ordinators; so far 38 have been nominated. There are also voluntary Regional Co-ordinators for the five identified sub-regions of West Africa, Central Africa, Eastern Africa, Southern Africa, and Madagascar and the Indian Ocean islands.

### Network development

In 1997, *A Preliminary Waterbird Monitoring Strategy for Africa* (Dodman 1997) was published. This used the results of an international workshop, questionnaires and other sources to propose a strategy for applied programmes of waterbird monitoring in Africa. An African Waterbird Census Steering Committee was formed on the recommendation of the AfWC network, and this met for the first time in November 1998, when a number of action points were developed. Just before the 10th Pan-African Ornithological Congress in Kampala Uganda, in 2000, Wetlands International organized an AfWC development workshop. The main theme "from census to conservation" translates the desire to link the AfWC closely to the conservation of waterbirds and wetlands in Africa. About fifty resource persons attended the workshop including many AfWC National Co-ordinators. This provided a good basis for the development of the AfWC in the coming years. Regional recommendations were formulated, lending a new dynamism to this pioneering conservation network.

### Some results from the AfWC programme

The results of the census from 1991 to 2001 demonstrate that tremendous efforts have been made by the network to cover a wide range of sites. The total counts have varied considerably from year to year (Fig. 1), often reflecting the coverage more than actual decreases or increases in birds at individual sites. The high count in 2000 can be explained by the coverage of some sites of high productivity where birds concentrate, such as the Banc d'Arguin (Mauritania), Lake Bogoria (Kenya), and some large breeding colonies such as Bird Island (Seychelles). Indeed, these sites alone accounted for more than 50% of the numbers of birds counted in January 2000.

The number of participating countries has generally increased since the initiation of the census, with around 30 countries now regularly participating in the programme (Fig. 2). However, there are often difficulties in maintaining the census in certain countries,

**Fig. 1.** Number of waterbirds counted under the African Waterbird Census: 1991-2001.

**Fig. 2.** Number of countries counted under the African Waterbird Census: 1991-2001.

**Fig. 3.** Number of sites participating in the African Waterbird Census: 1992-2001.

due to insecurity, lack of financial resources, lack of commitment, changes in national co-ordination and other reasons. The availability of a small grants programme for the AfWC managed by Wetlands International has assisted greatly in assuring the participation of a number of countries, and extending the census to new countries. In addition, the inclusion of AfWC surveys within some regional projects has significantly helped to strengthen networks, especially in West and Eastern Africa.

The number of sites covered by the programme increased significantly from 1991 to 1999, a period which saw many new

countries joining the AfWC network, but this has tailed off since then (Fig. 3). This is to be expected, and a key challenge for the AfWC, if it is to function as a monitoring programme, is to maintain the regular coverage of key sites.

The outputs of the AfWC are multiple. Of particular significance, the AfWC has provided an excellent platform for capacity building of national networks, through training, exchanges, provision of equipment and by simply enabling people to get involved in fieldwork on a regular basis. The census also benefits from participation of a wide range of partners at all levels. This has helped strengthen partnerships between organizations.

### Use of AfWC information

The main data collected under the AfWC are the numbers of birds counted at different wetlands. However, additional information is requested through the compilation of census forms, which include sections for site condition, weather and other variables. Site forms are also requested to be completed for each site, where standard information may be recorded and a site map provided. However, the quality of these additional data are often poor, and the level of data inadequate. Another challenge for the census is to improve the site data and the regular monitoring of site conditions, including threats. These may help, in the long run, to improve analysis and thereby usefulness of the data.

Some of the main current uses of the AfWC data are:-

- Increasing knowledge of waterbird populations, their migratory strategies and conservation status. Data have been used extensively in the development of Waterbird Population Estimates (Rose & Scott 1994, Rose & Scott 1997, Wetlands International 2002) and waterbird atlases (Scott & Rose 1996, Delany *et al.* in prep.), and in developing strategic analyses of waterbirds (e.g. Perennou 1991, Scott 1999, Dodman 2002). Data have been used for the identification of Important Bird Areas (IBAs) in Africa (Fishpool & Evans 2001). Data are also used for assessments of the status of particular species, such as the Cape Teal *Anas capensis* (Baker 2005).
- Development of Species Action Plans. AfWC data were used in particular for developing a conservation action plan for the Black Crowned Crane *Balearica pavonina* (Williams *et al.* 2002).

Long-toed Lapwing *Vanellus crassirostris*, Lake Naivasha, Kenya. Photo: Ian Francis

- Monitoring the ecological character and productivity of wetlands. Regular repeated surveys can contribute to quantifying changes in wetland character and measuring the impacts of developments. This is achieved through measuring basic site characteristics as well as through recording waterbirds numbers and distribution.
- Provide baseline data that may be referred to if a wetland is threatened by land use developments, such as draining or conversion to irrigation. Data may thus be used in contributing to Environmental Impact Assessments (EIAs) and in highlighting important and/or sensitive areas.
- Support development and implementation of the Convention on Wetlands (Ramsar, Iran 1971) and the AEWA in Africa. Data have been used in particular for the identification of new and potential Sites of International Importance under the Ramsar Convention (Ramsar sites) and of key site networks under the AEWA.

### Constraints for the development of the AfWC

There are many and diverse challenges facing the AfWC at different levels. Some of the common constraints are given below:

#### Weak financial and organizational support for the AfWC.

Surveys cost money, and many African organizations lack the financial means to execute surveys on a regular basis. Wetlands International does provide small grants and sometimes more substantial funds for surveys and related activities, but such funds are generally limited, whilst provision of external funds on a regular basis cannot be seen as a sustainable means of support. Countries are encouraged to build the AfWC into more regular conservation or monitoring programmes, but this is often difficult to achieve, and most nature management organizations in Africa depend to a large extent on external funds for specific short-term projects. National Co-ordinators themselves are often not in a position to dedicate much time to the AfWC, and the material means at their disposal are derisory for achieving good results on a regular basis.

#### Inadequate communication and commitment.

Good communication is an essential component of an effective functioning network. Whilst recent technological developments have facilitated communication in Africa, there is still limited communication between most members of the network. This is partly due to the fact that the network is rather dynamic, outputs are irregular and there have been no means of late to permit National Co-ordinators to meet together at a regional or continental level. Poor communication generally leads to lowered commitment to the census, especially if feedback is not provided often enough.

#### Limited expertise and data quality control.

At the national level, there is generally only limited expertise in the AfWC, from planning surveys to identification of waders to collection and input of data. There is also a limited ability to check data carefully and thoroughly, for instance, before submission to Wetlands International. This situation can result in errors in the database, published reports and resulting analyses.

Goliath Heron *Ardea goliath* at Lake Baringo, Kenya. Photo: Colin Galbraith.

### Priorities for the future

Although the AfWC remains one of the few regional monitoring schemes in Africa and enjoys a wide participation of countries and network members, constant attention needs to be paid to its execution and development. Five key practical requirements for the coming years are as follows:

#### Enhance communication within the AfWC network.

National Co-ordinators in particular need time and resources (availability of computers, e-mail etc.) for effective communication within the network. Organization of regular workshops, creation and regular updating of an AfWC web-site and production of a biannual newsletter would also be useful. These and other actions could be included in an AfWC communication strategy.

#### Institutional strengthening of the AfWC network.

To help build the census into national planning schemes, National and Regional Co-ordinators need organizational support to enable them to carry out census activities, and in particular, for national co-ordination and data collation. They and managers of key sites also need field equipment to enable their national networks to carry out wetland surveys, including binoculars, telescopes, identification guides, GPS, digital cameras etc.

#### Develop a fundraising strategy for operation and development of the AfWC.

There are requirements to meet the core running costs of the AfWC, such as network support, data entry, regular reporting and database management. Additional funds are needed so that action can be taken on the basis of the results of the AfWC, for instance conservation of species that are (or appear to be) in decline.

### Improve the data quality of the AfWC.

The quality of the data needs to be improved at site, national and international levels. There is scope for involving the Wetlands International Specialist Group network in checking data and reports.

### Develop a training and public awareness programme.

The AfWC network is large and dynamic, with many new recruits each year. Training is needed widely at different levels, whilst awareness needs to be raised, especially concerning the value and application of the AfWC, linked to the importance of conservation of wetlands.

## Ten years of continuous waterbird monitoring at Lutembe Bay, Lake Victoria, Uganda

Achilles Byaruhanga & Dianah Nalwanga

Nature Uganda, East Africa Natural History Society, PO Box 2703, 4 Kampala, Uganda.  
(email: achilles.byaruhanga@natureuganda.org)

Byaruhanga, A. & Nalwanga, D. 2006. Ten years of continuous waterbird monitoring at Lutembe Bay, Lake Victoria, Uganda. *Waterbirds around the world* (Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud). The Stationery Office, UK. pp. 457-458.

Lutembe Bay lies on the northern shores of Lake Victoria at the mouth of Murchison Bay between Entebbe and Kampala, at an altitude of 1 130 m, covering an area of 500 ha. It is shallow, papyrus-fringed, and almost completely cut off from the main body of Lake Victoria by two papyrus islands. The dominant vegetation is a mosaic of papyrus on the main open waterside of the lake, with *Miscanthus* and *Vossia* species towards dry land (Langdale-Brown *et al.* 1964). The bay extends into a *Miscanthus* swamp and merges with forest remnants to the north and horticultural farms to the northwest on the landward side, with shallow waters and scattered islets of mud in the open area of the bay.

*Nature Uganda* has carried out waterbird counts at least twice a year since 1994, and monthly since 1998. Total counts were made of all birds seen or heard from a slow moving canoe. In addition, birds such as crakes, coucals or fish eagles *Haliaeetus vocifer* heard calling from fringing habitats were recorded. Species abundance was calculated as encounter rates (number of individual birds per field hour).

Lutembe Bay is one of 30 Important Bird Areas (IBAs) in Uganda due to its globally, regionally, nationally and locally important biodiversity (Byaruhanga *et al.* 2001, Birdlife International 2001). The bay regularly supports 20 000 – 50 000 roosting and feeding waterbirds and seven globally threatened species occur: Papyrus Yellow Warbler *Chloropeta gracilirostris*, Papyrus Gonolek *Laniarius mufumbiri*, Shoebill *Balaeniceps rex*, African Skimmer *Rhynchops flavirostris*, Pallid Harrier *Circus macrourus*, Great Snipe *Gallinago media* and Madagascar Squacco Heron *Ardeola idea*. There are 24 species of regional concern. As well as supporting a large diversity of African species it is an important non-breeding area for huge congregations of Palearctic migrants. It regularly holds over 70% of the global population of White-winged Black Terns *Chlidonias leucopterus* (Byaruhanga *et al.* 2002, Byaruhanga 2003), and there are often large numbers of Grey-headed Gulls *Larus cirrocephalus*, Black-headed Gulls *Larus ridibundus* and Gull-billed Terns *Sterna nilotica*.

A total of 207 species were recorded during 63 counts between January 1994 and July 2003 (Dodman & Taylor 1993, 1994, 1995, 1997, Scott *et al.* 1994, Omoding *et al.* 1996, Wetlands International 2002). Of these, 76 were waterbirds, with the others being associated with fringing wetland habitats or remnant forests, bushes and gardens. The largest number of species (82) was recorded December 2000, and the smallest number (13) in May 1998. Species diversity varied seasonally, with more species present during the boreal winter when Palearctic migrant species are present: monthly averages were 34.5-51.7 species between September and March, and 22.5-36.0 species between April and August.

Fig. 1. Monthly average counts of birds in Lutembe Bay, Uganda between 1994-2003. Numbers in parentheses are the number of counts in each month.

Similarly, the numbers of birds counted were lowest in June and July (average 2 449 birds; n=9 counts), and variable but often much higher between August and April, with the highest monthly average being in December (1 237 769 birds; n=4 counts) (Fig. 1). The highest count was 2 639 567 birds in December 1999, with counts exceeding 1 million birds on five other occasions (March and August 2000, April and October 2002, and March 2003).

The great variations in the number of birds counted was largely a consequence of the frequent but not consistent presence of very large numbers of White-winged Black Terns. Averaged over the 63 counts, this species formed >95% of all birds present. The largest numbers were present in December 1999 (2 567 540 birds), with other high counts being 2 056 000 (March 2000), 1 238 723 (October 2002) and 1 041 700 (March 2003).

Only three other species (all Palearctic migrants) occurred in large numbers: Whiskered Tern *Chlidonias hybridus*, with its largest number (102 800 birds) in March 2000; Gull-billed Tern (largest count 12 640 birds in February 1997); and Black-headed Gull (largest count 16 460 birds in January 2002. Black-headed Gull numbers appear to have increased considerably since 2000. The site also hosts hundreds of Palearctic ducks, notably Garganey *Anas querquedula* (Byaruhanga & Arinaitwe 1996). Gulls and terns roost on muddy islets when the water level is low, especially between September to March. The exceptionally low count (308 birds) in January 1998 was probably due to "El Nino" rains which raised water levels that flooded most of the islets in the bay on which many birds breed or roost.

Among Afro-tropical migrants, the Open-billed Stork *Anastomus lamelligerus* was the most abundant (encounter rate five birds per hour). The most common resident waterbirds were

Long-toed Plover *Vanellus crasirostris* (encounter rate 94 birds per hour), Long-tailed Cormorant *Phalacrocorax africanus*, Yellow-billed Duck *Anas undulata* and African Jacana *Actophilornis africanus*.

Of globally threatened species, the Madagascar Squacco Heron was recorded twice (one in July 1994 and two in January 2002); Shoebill was recorded four times (March 1995, July 1997, August 2000 and January 2002); and a pair of African Skimmer was seen in January 2001. The near-threatened Papyrus Gonolek was regularly recorded calling. Other notable species included the Black Heron *Egretta ardesiaca*, recorded in 18 counts, with a maximum of 15 birds in December 2000.

Whilst Lutembe Bay is of major importance for waterbirds, including globally and regionally threatened species (Arinaitwe 1997), it is also very important in supporting local community livelihoods as a source of raw materials for building, local crafts, water for domestic use and, probably more importantly, fish as food and income. Since it is also close to Uganda's capital, Kampala, it also has high potential for income-generation through eco-tourism. However, Lutembe Bay faces degradation in its ecological character: agro-chemicals used by five flower farms close to the Bay have been detected in its waters. Monitoring needs to be put in place to assess the potentially adverse impacts from these and other developments such as sand mining and stone quarrying.

## Priority needs for co-ordinated research at flyway level to improve monitoring and management of waterbird populations, as identified by the French National Observatory of Wildlife

Michel Vallance & Yves Ferrand

ONCFS Base administrative St Benoist, 78610 AUFFARGIS, France. (email: m.vallance@oncfs.gouv.fr)

Vallance, M. & Ferrand, Y. 2006. Priority needs for co-ordinated research at flyway level to improve monitoring and management of waterbird populations, as identified by the French National Observatory of Wildlife. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 459-462.

### ABSTRACT

The National Observatory of Wildlife was created by the French Government in 2003 to provide high scientific standards to underpin for the implementation of regulations and government decisions relating to game management, with special reference to enforcement of the European Union (EU) Birds Directive. The main priority is to set up integrated monitoring schemes for waterbird populations at flyway level, starting with the more vulnerable species. One illustration of the methods to be developed is the monitoring scheme for Eurasian Woodcock *Scolopax rusticola* run for the last 20 years by the Office National de la Chasse et de la Faune Sauvage (ONCFS). This comprises intensive ringing programmes, monitoring of breeding areas, and analysis of hunting bags. The priorities for research have now been identified more clearly, and have highlighted the need for co-operative research programmes at flyway level. Two such programmes include stable isotope analysis to infer population origins, and improved interpretation of data through modelling.

### INTRODUCTION

In ensuring that we make the right decisions in migratory bird management, integrated population monitoring is an appropriate and useful management tool. However, initial studies have highlighted that some key data are missing for a good understanding of the status of migratory bird populations. The situation can be improved through the application of new research techniques and better international co-operation. This leads us from a national point of view towards an international flyway approach.

### THE NATIONAL OBSERVATORY OF WILDLIFE (FRANCE)

The National Observatory of Wildlife was created by the French Government in February 2003 to provide high scientific standards for the implementation of statutory regulations and government decisions relating to game management, especially the national implementation of the European Union (EU) Directive on the conservation of wild birds. It comprises a scientific council of 11 experts whose expertise must be based on the best information and scientific data available. Material for the meetings of the council is prepared by the national wildlife agency, the Office National de la Chasse et de la Faune Sauvage (ONCFS).

The Government has asked the question: are we making good rules? Neither the hunters nor the conservation associations think that this is the case. Obviously, not all questions have a clear answer. Serious problems can arise in the interpretation of data and scientific discussion. For example:

- a) Different sub-populations of the same species can confuse the situation (long-distance migrants, short-distance migrants, residents, birds that migrate east, birds that migrate west, etc.). They may be exposed to different habitat conditions and may differ in conservation status, requiring different management decisions;
- b) Huge variations in the raw data sets – from one year to another, and from one site to another – are also confusing. It is necessary to separate out environmental variation and census errors (statistical variation) from demographic variation as far as possible;
- c) Turnover among wintering birds can cause problems. The birds that we count on 15 December are not always the same as those that we count on 15 January. At some large sites, it would be informative to have an estimate of turnover, e.g. by determining the mean duration of stay; and
- d) Finally, difficulties can arise as a result of different sampling bases (breeding or wintering populations). These two sampling bases do not overlap, causing discrepancies and uncertainties.

Not all these problems can be resolved at the present time.

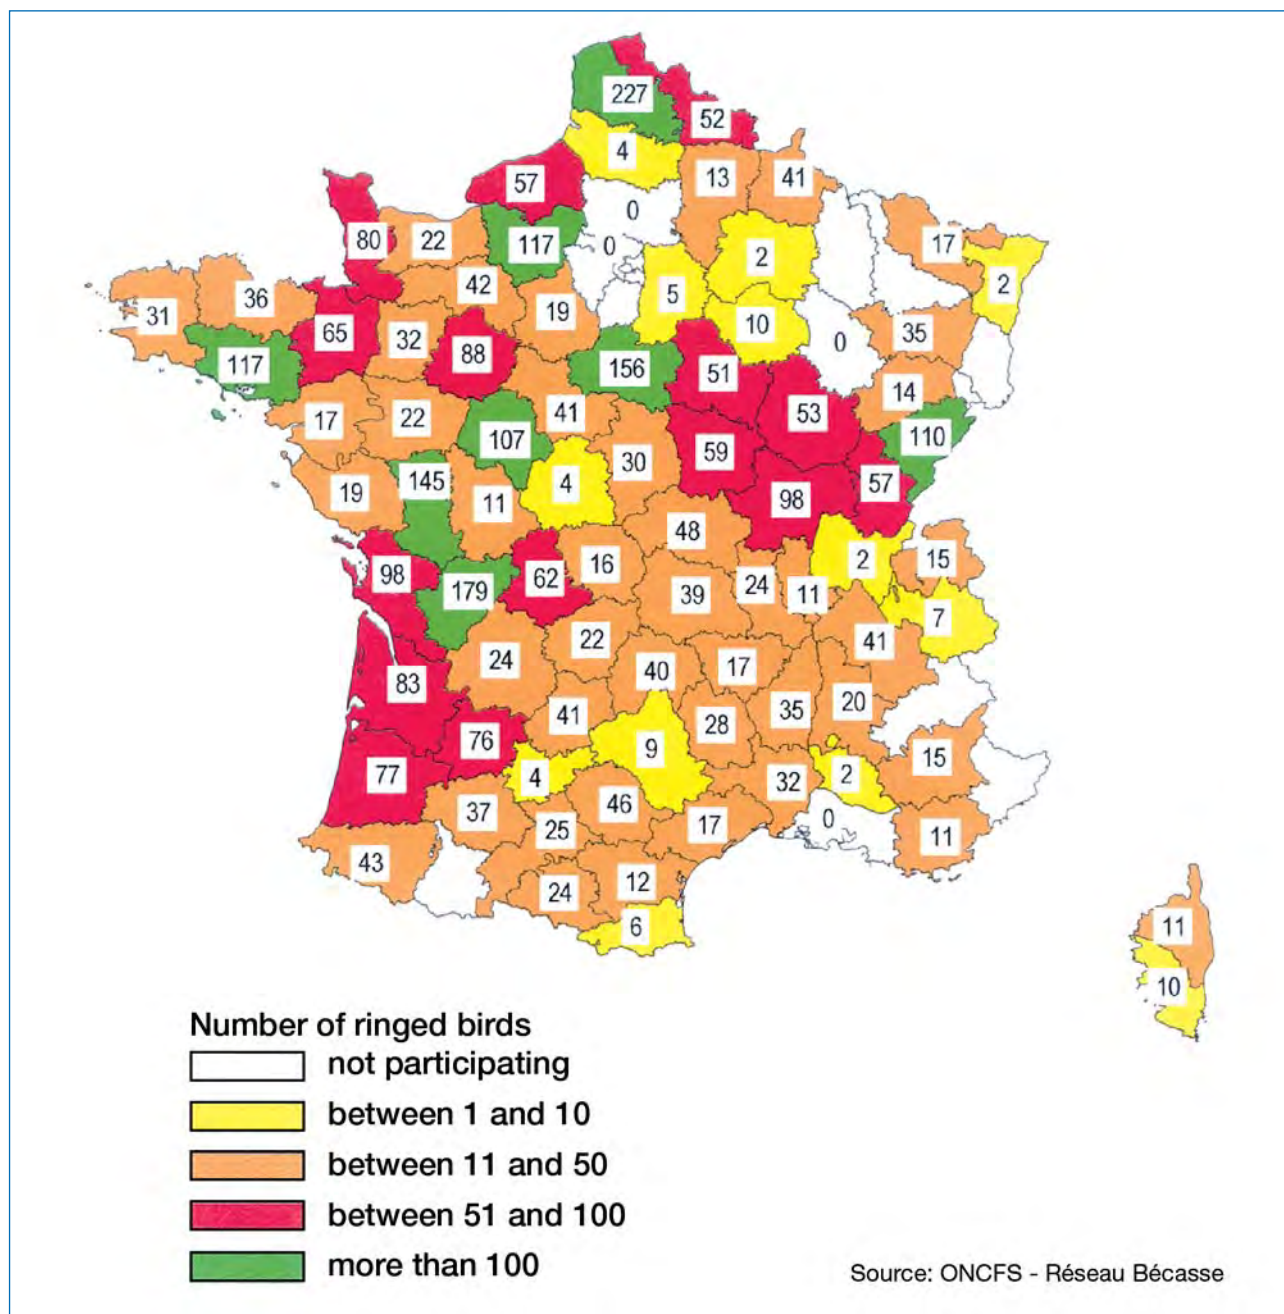

### INTEGRATED MONITORING

In the best cases, all of the existing knowledge and data sets can be organized in a management tool known as “integrated monitoring”. This requires the following:

- a) Intensive data collection over long time periods;
- b) Data analysis to provide estimates of key demographic and other parameters; and
- c) Modelling to give an understanding of the real situation, to facilitate adaptive management, and to forecast the results.

As an example of an integrated monitoring scheme, we give a short account of the monitoring scheme for Eurasian Woodcock *Scolopax rusticola* in France. One important factor is the statistical quality of the sampling (geographical coverage). At present, statistical methods give indices of relative abundance, and not estimates of absolute population numbers. Ringing has been an important aspect of the work on Woodcock, and has been carried out continuously and intensively since the 1980s in close co-operation with hunting associations, which has ensured good recovery rates of rings (Fig. 1). Wing examination (for ageing) and national hunting bag statistics have been used in the analyses of hunting bags.

This fieldwork has given us a very long time-series of data to analyse. The long-term trend in Woodcock populations wintering in France has been stable (Ferrand *et al.* 2003), but shows some important annual fluctuations (Fig. 2). It is impor-

**Fig. 1.** Numbers of Eurasian Woodcocks *Scolopax rusticola* ringed in France during the winter of 2002/03, by department. A total of 3 417 Woodcocks were ringed. Colours indicate the numbers ringed in each district.

**Fig. 2.** Population trends in Eurasian Woodcocks *Scolopax rusticola* wintering in France. ICA = hunting abundance index; IAN = contact index during night ringing sessions. All figures are national averages.

**Fig. 3.** Survival rates of Eurasian Woodcocks *Scolopax rusticola* wintering in France (Tavecchia *et al.* 2002).

**Fig. 4.** Demographic trends of wintering Common Teal *Anas crecca* in France (average of numbers counted in December, January and February).

tant to bear in mind, however, that these variations are also linked to the precision of the estimates. With respect to survival rates (Fig. 3), we see that the curve has good precision because of the large number of ringing recoveries (over 4 000 Woodcocks have been ringed every winter for ten years). When we consider our attempts to obtain an indirect estimation of breeding success, we see the importance of a flyway approach: our French data on age ratios (from wing examinations) are combined with Danish data, which are collected earlier in the year along the migration route.

As a management tool, this monitoring scheme is already rather useful (Ferrand & Gossman 2001). It will become fully effective when we can integrate more data from Russia (breeding area, breeding density, reproduction rate). Ultimately, we will be able to construct a demographic model to inform hunting management decisions and adapt measures and rules in response to demographic trends in woodcock populations.

In many cases, however, we need more sophisticated research to make progress in our understanding of populations of migratory birds. Possible ways to achieve this are illustrated by two international research programmes making use of new scientific methods in a global flyway approach: stable isotope tracking to infer population origins, and improved interpretation of data through modelling.

#### STABLE ISOTOPE TRACKING TO INFER POPULATION ORIGINS

The wintering population of a migratory bird species often comprises a mixture of individuals from several sub-populations which cannot be separated on the basis of phenotypic differences. The idea behind stable isotope tracking is to track birds by means of the isotope signatures of their feathers. This technique is being used by ONCFS in co-operation with the Canadian Wildlife Service. We first verified that there was a correlation between Deuterium isotope ratios in feathers and in rainwater samples (Hobson *et al.* 2004). This correlation had already been used in North America, but had not yet been veri-

fied and used in Europe. A map showing the geographical variation in stable isotope ratios gives a clear geographic pattern that can be used to determine whether birds have originated from northern Europe, central Europe or southern Europe. Important progress can now be made in the identification of birds' origins, and this will allow more information to be derived from the analyses of European hunting bags and ringing data sets.

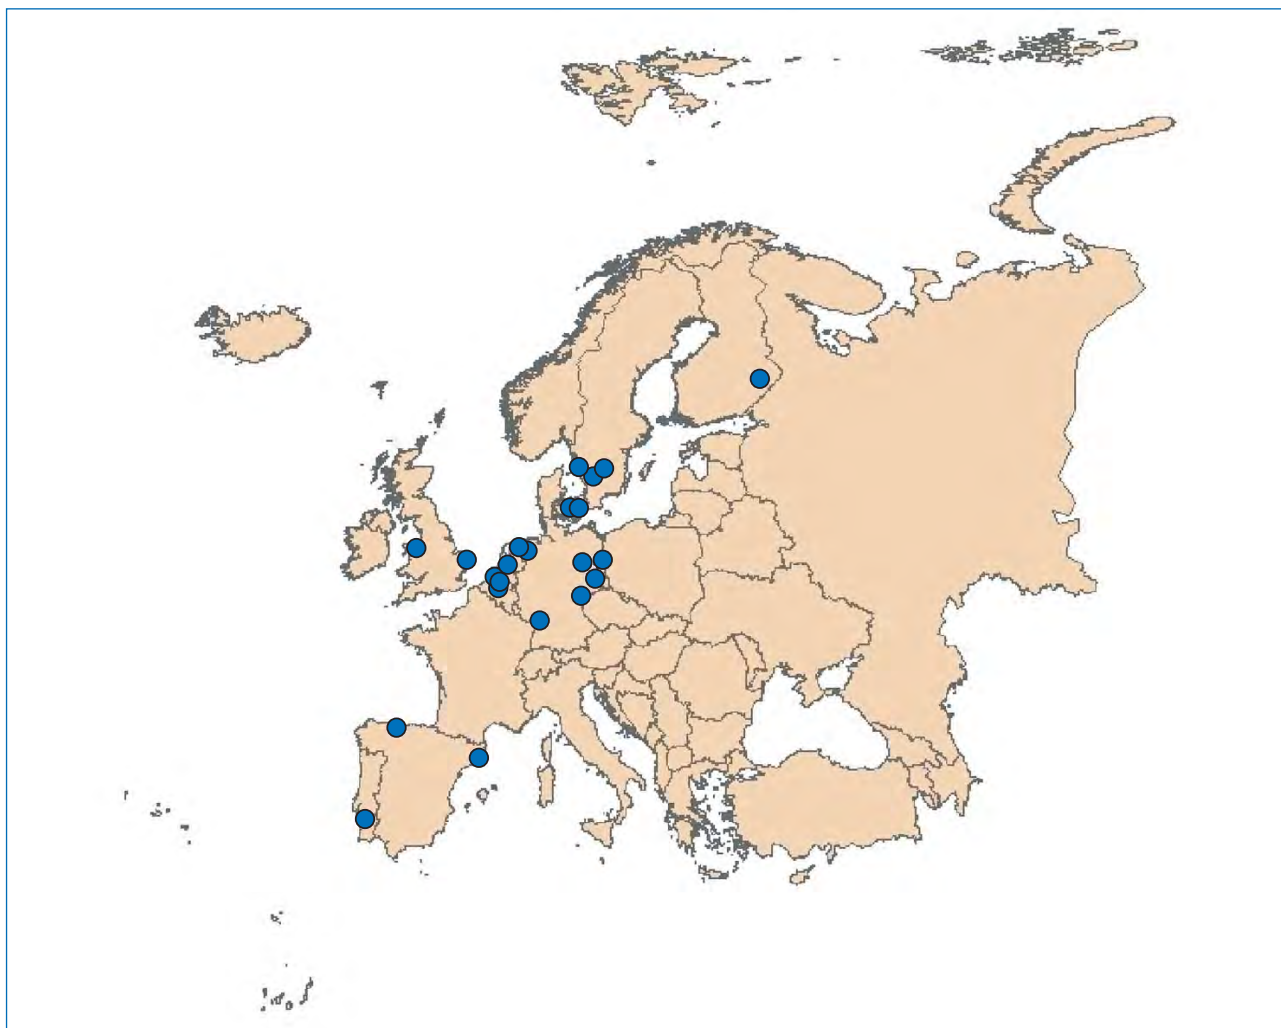

#### DATA INTERPRETATION: THE HELP OF MODELS

The direct and simplistic interpretation of raw data may be misleading, as highlighted by Common Teal *Anas crecca* (Fig. 4). The conservation status of this species in France is a priority issue for policy makers, since only 70 000-90 000 birds are counted in midwinter, while over 330 000 are harvested by hunters. In addition to the analysis of existing ringing data, a new ringing and marking programme has been launched at six sites scattered around France. As well as being ringed, some birds are fitted with nasal saddles, allowing long-distance recognition of individuals. This marking activity is being co-ordinated with scientists in Portugal and Sweden, and has already resulted in a number of international re-sightings (Fig. 5). To date, 1 356 Common Teal have been ringed, of which 708 have also been fitted with nasal saddles. There have

**Table 1.** Preliminary results of Common Teal *Anas crecca* ringing and marking programme (ONCFS, France; Kristianstad University, Sweden; Coimbra University, Portugal).

	Metal ring only	Metal ring & nasal saddle
Marked	648	708
Recoveries (dead birds)	28	33
Recaptures & re-sightings	207	1 455
At least one report (% of birds)	19.8%	49.9%

**Fig. 5.** Each dot represents a wetland at which one or more birds have been observed. In total, there were 87 observations of 26 different birds outside France between November 2002 and June 2004.

been 1 195 observations of birds with nasal saddles, involving 298 different individuals. In all, 42% of marked individuals have been recaptured or re-sighted at least once during the first two years of the programme (Table 1). Nasal saddles have therefore proved to be much more efficient than metal rings in building up a large data set quickly. The results are also more rewarding, since in addition to providing useful information on residence times at sites, survival rates, etc., the use of individually marked birds provides a scientific basis for the determination of parameters for a behaviour-based model of population dynamics.

Modelling at a flyway scale will hopefully give us, in the near future, a better understanding of fluctuations in populations and turnover of individuals, and allow us to predict the potential outcome of human activities on population trends, thus helping us to make the right decisions for policy-making. This type of model has already been developed and successfully validated for Eurasian Wigeon *Anas penelope* (Guillemain *et al.* 2002).

#### ACKNOWLEDGEMENTS

We would like to give our special thanks to the hunters' federations, the French Woodcock clubs and the field staff of ONCFS, as well as the Station Biologique de la Tour du Valat, for their

participation in the collection of field data and valuable help in the acquisition of this scientific knowledge.

### ABSTRACT

The monitoring of waterbirds in The Netherlands has a long tradition. It has evolved from various regional, seasonal and species-specific projects into an integrated monitoring scheme which aims to assess waterbird trends at site and national level, and operates within the framework of a governmental network of ecological monitoring. It is also incorporated in international monitoring programmes such as the International Waterbird Census (IWC) and the Wadden Sea Trilateral Monitoring and Assessment Programme (TMAP). The backbone of the scheme comprises monthly counts at all sites supporting large numbers of non-breeding waterbirds. This paper provides an overview of the monitoring scheme, starting with its aims and targets. It describes the census scheme, and discusses the sites that are covered and the methods used to calculate indices and trends. It also shows how data are used for policy and management issues, taking the EU Birds Directive as an example. Data from the waterbird monitoring project have been used extensively to designate Special Protection Areas in The Netherlands. Population trends in individual species are used to assess conservation status which is then translated into the aims of future management plans. Monitoring will gain importance by assessing the numbers and trends against targets and a system of alerts. As waterbirds are highly dependent on their food supplies and often respond quickly to changes in food availability, they are cost-effective indicators of changes in the broader ecological quality of their habitats.

### INTRODUCTION

The Netherlands are of outstanding importance for many waterbirds. The country's position along the East Atlantic Flyway, the large amount of wetland habitat and the prevailing mild winters attract internationally important numbers of waterbirds during all stages of their life cycle. The monitoring of waterbirds in The Netherlands has a long tradition. As early as the 1950s and 1960s, waterbird counts were being carried out regularly. The start of the International Waterbird Census (IWC) in the late 1960s further improved the network and stimulated many volunteer and professional bird-watchers to participate. In addition to the international midwinter counts, several regional (often monthly) censuses were established in important wetlands, e.g. in the Wadden Sea, along the River Rhine and its tributaries, at Lake IJsselmeer, and in the Delta area in the south-west of the country. Counts of geese and swans had already started in the 1960s, both in wetlands and in agricultural areas. In response to the growing need for comprehensive national monitoring data, all these surveys have recently been combined in a national waterbird

monitoring scheme (Koffijberg *et al.* 2000). This scheme is part of the so-called Network Ecological Monitoring, a governmental instrument to collect monitoring data for various groups of species including, for example, plants, dragonflies and mammals (van Strien 2005). Through this scheme, data required for international treaties and conventions, such as the European Union (EU) Birds and Habitats Directives, Ramsar Convention on Wetlands, and African-Eurasian Migratory Waterbird Agreement (AEWA) of the Bonn Convention, also become available.

Waterbird monitoring in The Netherlands is currently a joint scheme of the Ministry of Agriculture, Nature and Food Quality, the Ministry of Transport, Public Works and Water Management, BirdLife The Netherlands and Statistics Netherlands, and is co-ordinated by the SOVON Dutch Centre for Field Ornithology. At present about 1 500 observers, of whom a large proportion are dedicated volunteers, participate in the scheme each year. This paper provides an overview of the monitoring programme, and gives examples of results and their role in the development of environmental policies and management plans.

### WHY WATERBIRDS?

Statistics on the status and trends in numbers of waterbirds are required for the conservation of bird populations and biodiversity, as well as for the conservation of their (wetland) habitats. This acknowledges the role of waterbirds as indicator species. Waterbird numbers can be assessed rather accurately by counts, and since they often respond quickly to changes in their environment, their status can be a powerful indicator of changes in other organisms in the ecosystem, which are often more difficult to measure or for which only recent data are available. At Lake Veluwemeer, for instance, a close relationship was found between the numbers of some waterbird species and the amount of submerged macrophytes (Fig. 1). In the 1970s and 1980s, submerged vegetation was very limited because of eutrophication. As a consequence, the numbers of waterbirds were low. However, an improvement in water quality led to an increase in aquatic vegetation, which was followed by an increase in waterbird numbers. By using this relationship, it was possible to reconstruct the ups and downs in the abundance of submerged vegetation and other aspects of the ecosystem before the 1970s, when only bird numbers were being surveyed. In this way, qualitative descriptions of the lake could be underpinned with (modelled) data. Several additional relationships exist between waterbird numbers, food supply, water quality parameters, and policy and management issues in which waterbirds might act as effective indicators of underlying processes at lower trophic levels (Noordhuis & Koffijberg 2004).

**Fig. 1.** Trends in biomass of herbivores and stonewort in Lake Veluwemeer, The Netherlands. A strong correlation is found between waterbird numbers (expressed in biomass to account for consumption by species of different size) and stonewort biomass ( $r = 0.96$ ,  $df = 29$ ).

#### AIMS OF THE MONITORING PROGRAMME

A clear definition of the aims and targets of a monitoring scheme will help to direct efforts to improve the programme and provide the information that is required. This includes selection of the target species which are to be covered and a definition of the geographical scale for which data are required. Fortunately, waterbirds are relatively easy to count, and it is often the case that numbers of all species can be assessed when visiting a site. All species of divers, grebes, cormorants, herons and allies, swans, geese, ducks, rails, coots, waders, gulls and terns occurring in The Netherlands are included in the counts. Non-native species which have been introduced or escaped are also covered. In addition, a few species of raptors and passerines, which are specific to wetlands and easy to cover while counting other waterbirds, are included. For analyses and trend calculations (see below), priority is given to species which are important in

**Fig. 3.** Trends in the numbers of Great Crested Grebe *Podiceps cristatus* at Lake Veluwemeer, The Netherlands, based on numbers from January counts (dashed line) and on bird-days calculated from monthly counts in September-April (solid line).

**Fig. 2.** Trends in the numbers of Gadwall *Anas strepera* in The Netherlands and in North-west Europe. The trend in North-west Europe is taken from Delany *et al.* (1999). Numbers in The Netherlands have grown faster than those in North-west Europe ( $t = -12.4$ ;  $df = 12$ ,  $p < 0.001$ , based on a non-linear regression analysis).

**Fig. 4.** Phenology of the number of target species of waterbirds (Annex I of the EU Birds Directive and indicator species in national freshwater bodies) occurring in The Netherlands. Species are only included for a given month if their numbers in that month are equal to at least 80% of the peak count during the 12-month period.

relation to the EU Birds Directive. This aims to safeguard bird species and their habitats within the EU, and obliges member states to carry out regular monitoring at important sites (Special Protection Areas, SPAs).

At present, indices and trends are calculated for 53 species (van Roomen *et al.* 2004). These are calculated at three different geographical scales: individual sites, regions and the country as a whole (national trends). Priorities for trend analyses at site level are SPAs designated under the EU Birds Directive (in most cases these sites have also been designated as Ramsar sites under

the Ramsar Convention on Wetlands), national freshwater bodies (water bodies managed by the government and overlapping to a large extent with SPAs), and agricultural sites important for geese and swans (these often lack any protection status).

In addition to these national aims, the counts also contribute to international monitoring programmes, including the International Waterbird Census (IWC) co-ordinated by Wetlands International and the Trilateral Monitoring and Assessment Programme (TMAP) for the international Wadden Sea. The latter is a trilateral co-operation between The Netherlands,

**Fig. 5.** Monitoring sites in The Netherlands used for the calculation of national trends in populations of waterbirds (except for swans, geese and seaducks).

**Fig. 6.** The proportions of the national January totals of 28 species of waterbirds that occur within the monitoring sites shown in Fig. 5.

Germany and Denmark for monitoring and management policies in the Wadden Sea. International population estimates and trends are important references for national monitoring. They are necessary for separating trends at national or site level from trends at flyway level (Fig. 2).

## OUTLINE OF THE MONITORING PROGRAMME

### Several counts a year

A single count in January is the best strategy for an international monitoring scheme, since the distribution of waterbirds at this time of year is rather stable, and in many countries a large survey effort can only be achieved once a year. However, for monitoring at national level and at the level of individual sites, more counts are required per year, since a single count in January covers only a tiny part of the annual cycle of waterbirds. For example, species occurring on migration in spring and autumn and those occurring in moulting concentrations in late summer are not covered at all in January, but might be the most important species at many sites. Moreover, as phenology patterns or wintering strategies might change in time (e.g. a switch in distribution as a result of global warming), national monitoring of waterbirds benefits from counts which are carried out at all times of the year. Thus, trends in January may give a very misleading picture of the overall abundance of a species, as shown in Fig. 3 for the Great Crested Grebe *Podiceps cristatus* at Lake Veluwemeer. When only the January counts are considered, it appears that Great Crested Grebes were very scarce in the 1960s and 1970s, and increased after the mid-1980s. However, it is known that the species did occur in substantial numbers in the 1960s and 1970s, but mainly in spring and autumn, with only a few birds remaining in January. This only becomes apparent when one takes into account all monthly counts between September and April. It then becomes clear that the current use of the site is rather similar to that in the 1960s and 1970s. The recent increase in January is simply the result of an increase in the numbers of wintering birds (i.e. a prolonged stay of birds in autumn).

Since most countries will have a mixture of resident species, passage migrants and winter visitors, waterbird counts should ideally cover all months of the year. In The Netherlands, each month of the year appears to be of some importance as regards the number of target species occurring in important numbers

(Fig. 4). The main reason for this is the large variation in phenology of the species involved. In freshwater lakes and other inland sites, the period September–April has the highest abundance of waterbirds. Some large lakes are also used in other months, e.g. when moulting concentrations occur in late summer. In estuaries, however, all months of the year are important. Based on these patterns, it was decided to use monthly counts between September and April to cover inland sites and monthly counts throughout the year to cover coastal estuaries (e.g. the Wadden Sea and Delta area) and some large freshwater lakes (e.g. Lake IJsselmeer). In the Wadden Sea, monthly counts are achieved through a combination of monthly counts at a sample of sites and five total counts throughout the year. This area is so large that monthly total counts would be beyond the capability of the volunteer counters.

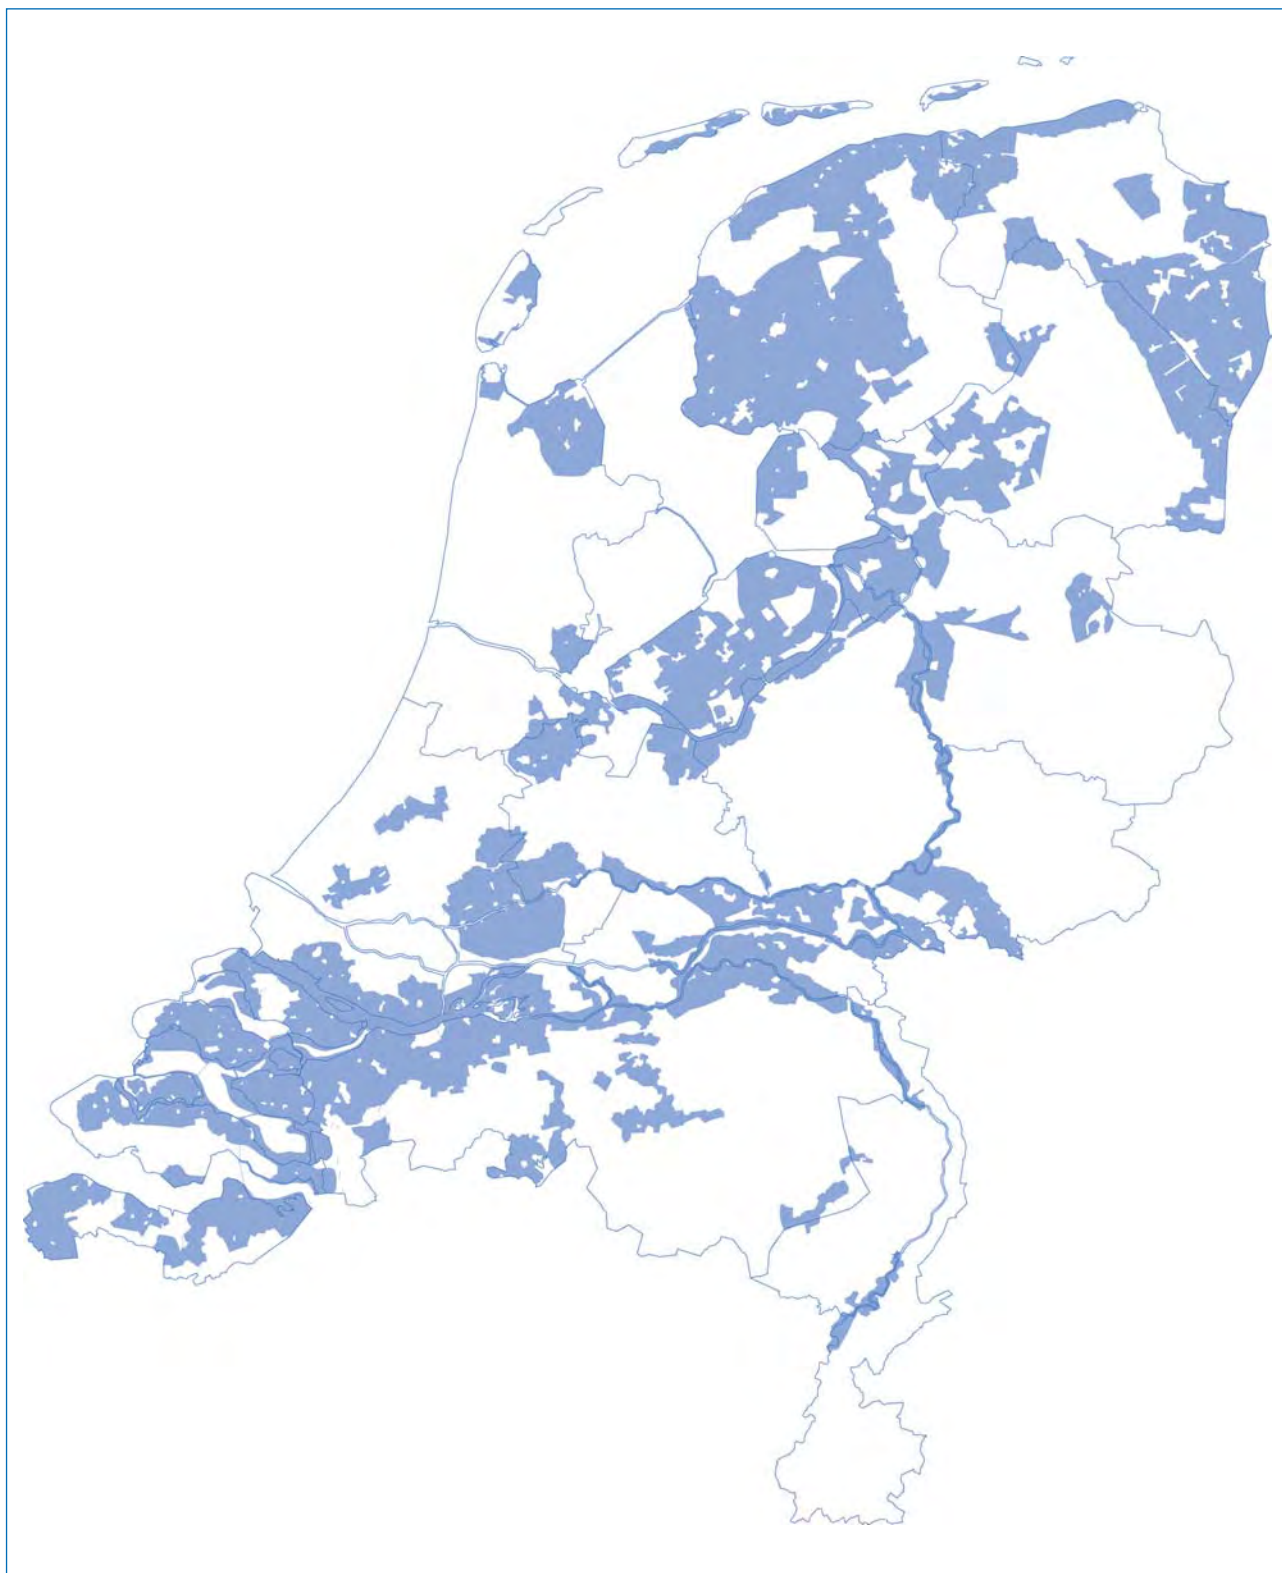

### Selection of sites for monitoring

Because of the large amount of wetland habitat in The Netherlands and large part of the year in which important numbers of waterbirds are present, it would be a considerable task to include all water bodies in the monitoring scheme. Therefore, a selection of sites has been identified which covers all important waterbird concentrations (Fig. 5). This selection includes all SPAs and national freshwater bodies, and thus all priorities for site monitoring. For most waterbird species except geese, swans and seaducks, these sites together support a high proportion of the national populations (Fig. 6). The core areas for geese and swans are in agricultural areas, and additional counts are carried out for these species in these areas (Fig. 7). Seaducks occur in large numbers only in the coastal zone of the North Sea and open waters of the Wadden Sea. Both of these areas are not covered by monthly land-based counts, but are counted once a year (in January) by an aerial survey. Additional waterbird counts are made in January at less important sites as part of the International Waterbird Census.

### Missing counts and trend analysis

Due to the different history of the various census projects, not all sites have similar and comparable series of data. Some sites have monthly counts dating back to 1975, while others have counts starting in the 1980s or lack counts in important months. Even though coverage has increased over the decades (Fig. 8), some counts are still missed because of poor weather conditions (e.g. fog), absence of the observer or other reasons. Thus, when compiling uniform data sets for trend analyses, consideration has to be given to the missing counts. Standardized methods have been developed to estimate numbers at the sites not counted (imputing). In The Netherlands, we have adopted the method used in the Wetland Bird Survey in the British Isles (for background, see Underhill & Prys-Jones 1994). Species-specific models are used to account for site, month and year factors. This imputing is performed by using the U-index package (Bell 1995). Missing counts are imputed on the basis of the smallest count units, and count units are stratified according to their seasonal and annual patterns (Soldaat *et al.* 2004).

Trend analyses are based on annual estimates of occurrence per species for a certain geographical area (either site, regional or national level). This annual estimate of occurrence is defined as the seasonal sum of the counted and estimated (imputed) numbers throughout the year (or in September–April, depending

**Fig. 7.** Staging sites of swans and geese in The Netherlands used for the calculation of national trends.

on the site; see above). Trends are calculated by using a linear regression of the log-transformed seasonal sums, and are assessed for different periods (e.g. since the start of monitoring or over the last 10 years). The output is classified according to certain definitions, including definitions of stable and fluctuating trends. In the near future, trend calculations will be extended by incorporating flexible trends (Visser 2004) which are better able to deal with strong fluctuations.

#### **USE OF WATERBIRD DATA IN RELATION TO THE EU BIRDS DIRECTIVE**

The EU Birds Directive has become increasingly important for nature conservation policy and management in The Netherlands (and other EU countries). Together with the EU Habitats Directive, a network of sites, the so-called Natura 2000 sites, has been set up within the EU for the conservation of biodiversity. Special Protection Areas (SPAs) are a part of this Natura 2000

**Fig. 8.** The availability of count data for freshwater monitoring sites in The Netherlands since 1975/76. Coverage is expressed as a percentage of all possible main count unit/month combinations. Column C indicates complete coverage of all sites.

network. As a first step, national waterbird counts (and breeding bird surveys) were used to identify SPAs on the basis of the list of target species (species listed in Annex I of the Birds Directive) and 1% threshold values of the Ramsar Convention (van Roomen *et al.* 2000). To date, 79 sites have been designated as SPAs in The Netherlands. These include all important wetland sites but do not cover many agricultural sites important for populations of geese and swans.

Designation of important sites is only a first step towards better protection of the species involved. The conservation status of the species needs to be assessed regularly, both at national and site level, and monitoring plays an important role in evaluating trends in abundance. A methodology for assessing the conservation status of species against the formulated targets is currently being developed. Overviews of the trends in waterbird species listed in the EU Birds Directive are already available at site level (Fig. 9). However, judgements on the favourable or unfavourable conservation status of a species (and thus the direction of the observed trends) are not always easy to make. EU environmental policies not only cover biodiversity, but also deal, for example, with improved environmental conditions in water bodies. The Water Framework Directive (WFD), for instance, aims to tackle the problem of eutrophication. A decline in the nutrients in water bodies, however, might change the food web and thus have a (negative) effect on the abundance of some waterbirds. An example of this paradox is the relationship between the numbers of Tufted Ducks *Aythya fuligula* and stocks of the Zebra Mussel *Dreissena polymorpha* at Late Markermeer. As the levels of eutrophication were reduced, mussel stocks declined and the water became more turbid. The numbers of Tufted Ducks responded negatively and declined (Fig. 10). From the viewpoint of the Water Framework Directive, the lower eutrophication levels can be regarded as a success, but according to the EU Birds Directive, site management should undertake action to halt the decline in Tufted Ducks. Therefore, definitions of favourable conservation status should not simply refer to bird numbers, but should also take into account the ecological potential of a site.

## DISCUSSION

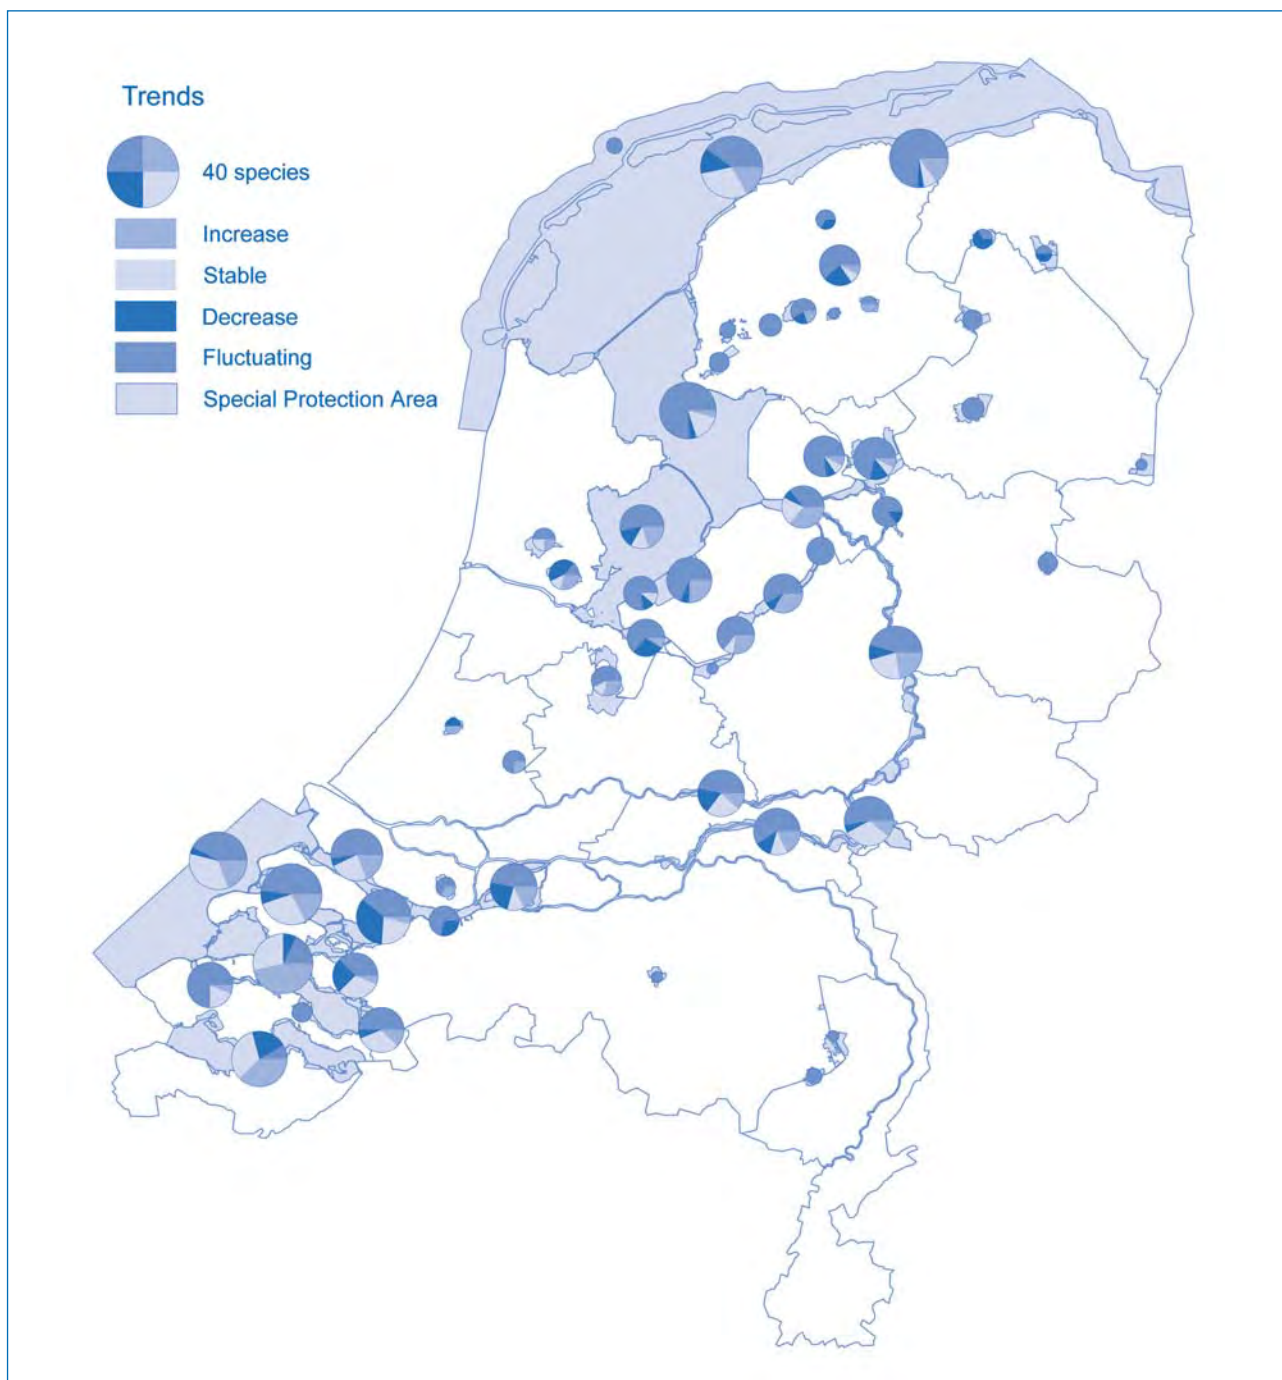

### The monitoring programme

The monitoring of waterbirds in The Netherlands is only possible at the present time because of the high interest and co-operation of many volunteer bird-watchers. The participation and commitment of many site managers and institutions are also essential. We are very fortunate that as early as the 1970s monthly censuses had started in several important wetland systems. These censuses provided a firm basis for the current monitoring scheme. Although we now have a smooth-running and well-used scheme, a number of compromises had to be made while re-designing the programme.

Firstly, because of the limitations to observer effort, we work with a selection of monitoring sites, e.g. SPAs, national freshwater bodies and internationally important goose and swan staging areas (Figs. 5 & 7). One could argue that these sites only represent optimal sites and do not take into account dynamics in site use. As is known from studies of individual species (e.g. of Dark-bellied Brent Goose *Branta bernicla bernicla*, Ebbingse 1992), optimal sites are often the first to become saturated when a population increases, and less optimal sites are abandoned as soon as a population experiences a downward trend. The impact of such processes is thought to be very small in our monitoring scheme. For many species, 50% or more of the national population is included within the selection of sites. For some goose species, nearly the entire national (or even international) population is covered by the current selection of monitoring sites. Thus, the dynamics in site use are well taken into account, as a large number of sub-optimal sites are already part of the network of monitoring sites. The January census, which covers many more sites, might eventually indicate sites that are becoming increasingly important, at least in winter.

Secondly, underestimation of bird abundance might occur, since the monthly counts will not always cover all the migration peaks of a species, especially when these occur during a period of only a few days or always between the mid-monthly counts. Therefore, monitoring in the Wadden Sea within the framework of the Trilateral Monitoring and Assessment Programme was initially set up with twice-monthly counts in sample census areas (Rösner 1994, Günther 2003). However, in the Dutch Wadden Sea, no representative sample of sites could be established. Hence, the errors in estimates of bird abundance caused by the non-representative sample of sites were larger than in the less accurate numbers derived from monthly counts in the entire area (van Roomen *et al.* 2002). Monthly counts represent reliable estimates of the abundance of birds, especially for the purposes of long-term trend analysis. Only in the case of very small sites, or to derive numbers for qualification purposes (e.g. when designating SPAs), are additional counts needed to arrive at a more reliable estimate of numbers or to assess peak counts.

Thirdly, we use imputing techniques to arrive at estimates for sites not covered by the counts. In recent years, this has involved only a few sites, but when using the older data, the amount of imputed data increases and this might result in erroneous trend estimates. Moreover, the calculation of standard errors is theoretically questionable because we are not dealing with a sample of sites but with more or less complete counts. The results from a recent experiment with “artificial” gaps in a complete data set have shown that trend estimates might be fairly reliable even with a high proportion of imputed data

**Fig. 9.** The proportion of decreasing, increasing, stable and fluctuating trends in non-breeding populations of waterbird species listed in the EU Birds Directive, for each of the relevant Special Protection Areas in The Netherlands (SPAs that only support terrestrial species are not taken into account). The size of the circles represents the number of species per site.

(Soldaat *et al.* 2004). The results of this study are now being used to fine-tune the imputing technique.

#### Data for policy and management

The need for monitoring data has increased substantially in the last decade. While the first waterbird counts focussed on estimates of total population size and identification of key sites, the monitoring of individual key sites has become increasingly important and is an obligation in the implementation of the EU Birds and Habitats Directives. As a consequence, periodical assessment of the conservation status of species is required, and management plans have to be written to formulate conservation objectives.

Developing alert limits will be an essential tool to judge the observed trends and to point at detrimental or negative impacts at the designated sites (de Nobel *et al.* 2002, Austin *et al.* 2003).

Furthermore, in the case of negative trends it will be important to separate between local (site) trends, national trends and international (flyway) trends. Comparing site trends with international trends will help policy makers and site managers to make the right decisions regarding the underlying causes. If the trends at a particular site seem to be caused by local factors, the relationship between the waterbirds and their food supply needs to be investigated. The numbers of waterbirds are often regulated by their food supply or their possibilities to exploit this

**Fig. 10.** Trends in the numbers of Tufted Duck *Aythya fuligula* and levels of eutrophication (expressed as mg/l of phosphorus) at Lake Markermeer, The Netherlands.

supply (carrying capacity theory). As waterbirds can be readily divided into guilds according to their food preferences (herbivores, fish-eating birds, etc.), and as long time-series of count data exist, re-constructions of the development in numbers (monitoring) will be of great help in unravelling the causes of any unfavourable development. The same relationships will help to formulate effective measures to restore a favourable conservation status.

#### ACKNOWLEDGEMENTS

First of all, we would like to thank all observers participating in the waterbird monitoring project in The Netherlands. The waterbird monitoring scheme is financially supported by the Ministry of Agriculture, Nature and Food Quality, the Ministry of Transport, Public Works and Water Management, and BirdLife The Netherlands (Vogelbescherming Nederland). Jeroen Nienhuis and Erik van Winden (SOVON) transformed the first drafts of the figures into more presentable versions.

## Monitoring geese in the Vinogradovo floodplain - the core stop-over site in Moscow region

Alexander L. Mischenko, Olga V. Sukhanova & Sergej P. Kharitonov

Russian Bird Conservation Union, Shosse Entuziastov, 60, bld.1, Moscow 111123, Russia. (email: almos@redro.msk.ru)

Mischenko, A.L., Sukhanova, O.V. & Kharitonov, S.P. 2006. Monitoring geese in the Vinogradovo floodplain - the core stop-over site in Moscow region. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 471-472.

The Vinogradovo floodplain is particularly valuable as a spring stop over station for large geese flocks: this paper presents the results of monitoring migrating goose numbers there from 1979 to 2003.

The Vinogradovo floodplain of the Moskva River (c. 50 sq km) is included in the Ramsar Shadow List of the Russian Federation, and is important as a spring stopover for large flocks of geese. It is an "island ecosystem", wedged in a ring of settlements of cottages and fields on terraces. The floodplain is characterized by a mosaic of habitats, including meadows (c. 30 sq km), small lakes, fens, abandoned pastures and small forage fields, drainage ditches and bushes, and is one of the few well-preserved floodplain sites in the densely populated Moscow Region. In 1986 a regional state nature reserve (Zakaznik) was established in the most important part of this area (c. 20 sq km). Monitoring of migrating goose numbers has been conducted there since the late 1970s.

In the Vinogradovo floodplain counts of geese were conducted using two methods: observation of feeding geese from raised viewpoints using a telescope, and observation of geese flying to the floodplain (morning) or to surrounding fields for feeding (evening) using binoculars. The maximum numbers of staging geese during the period of monitoring are shown in the Table 1, from which it can be seen that there is no obvious dependence of geese numbers upon a level of spring flood.

The White-fronted Goose *Anser albifrons* formed the majority of migrating geese in Vinogradovo in all years except

**Table 1.** Dynamics of geese numbers on spring stop-over in Vinogradovo.

Years	Maximum quantity of staging geese	Level of spring flood
1979-1983	12 000 - 15 000	
1984-1990	13 000 -16 000	
1995	5 000-6 000	Low
1997	10 000	Low
2000	8 000-10 000	High
2002	12 000	Very low
2003	7 000	Medium

See Zubakin *et al.* 1988, Kontorschikov *et al.* 1991, and Zubakin 2000 for more detailed information on these geese.

for 2002, when peak numbers (just over 3 000 birds) were much lower than in other years. In 2003 the maximum number of staging White-fronted Geese (c. 7 000) was also considerably lower than in 1980-1990. The maximum numbers of staging Bean Goose *Anser fabalis* were no more than 350 geese in the early and mid-1980s, 870-1 000 in 1997 and 2000, and about 120 individuals in 2003. In 2002 there was a very early, dry spring and very low spring flood, and very high numbers of migrating Bean Geese were recorded: at the peak of migration (4 April 2002) - the number of Bean Geese exceeded 8 700 individuals – about 80% of all goose numbers in that year.

The Vinogradovo floodplain is an important spring staging area for nominate race of White-fronted Goose *Anser albifrons*. Photo: Paul Marshall.

The maximum number of the migrating Greylag Goose *Anser anser* did not exceed 50 birds annually, while no more than four Lesser White-fronted Goose *Anser erythropus* were observed at one time in any year. In springs with low floods (e.g. 2002) resting goose flocks concentrated in swamps and flooded areas in the southern and north-eastern sectors of the floodplain, while in springs with normal floods (2003) geese dispersed throughout the floodplain.

Migrating geese fed on plants of meadow grass on the floodplain and fields beyond the river valley. Usually White-fronted Geese passed over to forage in fields far further away, but in 2002 foraging Bean Geese concentrated in the corn fields and perennial crops on the terrace of Moskva River, close to the floodplain and 4-5 km from the main resting sites. In early May 2002 Geese also used the floodplain for roosting: before dawn, they left the floodplain for the fields and returned after 9:00; between 17:30 and 21:00, they flew out to forage and returned to roost in complete darkness.

It is impossible to estimate the total number of geese migrating across the Vinogradovo floodplain without large-scale colour marking, but on the basis of a comparison between changes in the number and species composition in different migration waves, no fewer than 22 000 geese stopped over in the area, and the actual number could approach 30 000. Large flocks of resting Bean Geese can be observed in the Vinogradovo floodplain only in years with extremely early springs, as most Bean Geese normally fly through the floodplain without stopping.

Within last decade recreation pressures in the floodplain have sharply increased, resulting in illegal shooting and disturbance to geese, while the areas of corn fields and perennial crops used by geese for feeding near the floodplain have greatly

decreased. For all of those reasons, the general numbers of White-fronted Geese in Vinogradovo floodplain has been decreasing.

Development of a management plan for the Vinogradovo floodplain has started, and will include guidelines on more efficient protection, agricultural management, expansion of the reserved area and establishment of the protected zone with spring hunting banned.

#### ACKNOWLEDGEMENTS:

We express sincere gratitude to the Administration of Voskresensk District (Moscow Region) for financial support of our research in 2002-2003. Also we thank Dr. Victor Zubakin and Dr. Sergej Volkov for assistance with goose counts in 2002 and 2003.

## Estuarine waterbirds at low tide: the WeBS low tide counts 1992-93 to 1998-99

Andy Musgrove

British Trust for Ornithology, The Nunnery, Thetford, Norfolk, IP24 2PU, UK. (email: webs@bto.org)

Musgrove, A. 2006. Estuarine waterbirds at low tide: the WeBS low tide counts 1992-93 to 1998-99. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 473.

UK estuaries are of key international importance for non-breeding waterbirds. Whilst the numbers of birds frequenting these estuaries have been well monitored by a large team of experienced volunteers for many years, notably through the Wetland Bird Survey (WeBS), the UK has shown a further commitment to the conservation of estuarine waterbirds by undertaking a national "Low Tide Counts" scheme from the winter of 1992-93 onwards. The WeBS Low Tide Counts Scheme aims to investigate the within-site distribution of estuarine waterbirds at low tide, in order to improve understanding of site usage and thus to focus conservation efforts to greater effect. The data arising from the first seven winters have now been summarised for a book, *Estuarine Waterbirds at Low Tide* (Musgrove *et al.* 2003). The introduction to the book includes background information about estuarine habitats, estuarine wildlife, human influences on estuaries and the monitoring of estuarine waterbirds. There then follows a detailed account and discussion of the methods used during the WeBS Low Tide Counts, both for the survey itself and for subsequent data processing and presentation. The coverage achieved by the scheme during the seven winters 1992-93 to 1998-99 is detailed, with 62 UK estuaries being included during that period.

The main bulk of the book is a set of 62 site accounts. For each of these, background information about the site is given, along with the coverage of the site achieved by the scheme, including a discussion of the degree of overlap with the boundaries of designated Special Protection Areas and Ramsar Sites.

The waterbird distribution at the site is then discussed in a broad sense, and the distribution of all key waterbirds at each site is also mapped. Following the site accounts, the data are discussed by species, with fuller accounts for 29 key species, reduced accounts for 32 species and brief notes on a further 47 species. The book is completed by a discussion of the use of Low Tide Counts for the purposes of nature conservation casework, along with a broad discussion of the findings of the survey and aims for the future.

The Wetland Bird Survey is a partnership between the British Trust for Ornithology, The Wildfowl & Wetlands Trust (WWT), Royal Society for the Protection of Birds (RSPB) and the Joint Nature Conservation Committee (JNCC, on behalf of English Nature, Scottish Natural Heritage, the Countryside Council for Wales and the Environment and Heritage Service in Northern Ireland). However, although *Estuarine Waterbirds at Low Tide* was a joint production between these partners, it could not have been produced without the hard work of hundreds of dedicated volunteer fieldworkers who contributed data to the scheme. The International Wader Study Group (WSG) is also thanked for its hard work in the final production of the book.

Rodrigues, D.J.C., Figueiredo, M.E., Fabião, A. & Tenreiro, P. 2006. Waterfowl marking in Portugal: main results and future perspectives. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 474-475.

The recent integrated monitoring of some Portuguese waterfowl populations has allowed several studies of their ecology, biology and management (Figueiredo 2003, Rodrigues 2001, Rodrigues & Fabião 1997, Rodrigues & Tenreiro 1996, Rodrigues *et al.* in press). This paper reports and discusses some results related to capture and marking processes used with waterfowl in Portugal.

We started the regular capture of waterfowl in Portugal in June 1993, and by the end of March 2004 we had marked 7 519 ducks and 1 047 rails. We also nasal-saddled ducks and obtained more than 21 000 resightings. The use of nasal saddles on ducks improved the results obtained (e.g. information on Mallard international movements increased 225%) and allowed new data analyses.

Ducks and Rails were captured on baited swim-in and walk-in traps, and marked with metal rings. Ducks were also nasal marked with flexible PVC, rubber (Rodrigues *et al.* 2001) or Polyurethane saddles (D. Rodrigues, unpubl. data). Nasal saddling started in 1993 with *Anas platyrhynchos* and continued with Wigeon *Anas penelope*, Gadwall *A. strepera*, Pintail *A. acuta* and Shoueler *A. clypeata* (from 1998), Teal *A. crecca* and Garganey *A. querquedula* (from 1999), and Tufted Duck *Aythya fuligula* (from 2003). Different colours and alphanumeric

codes on the nasal saddles allowed individual identification. Capture took place from July 1993 to the end of March 2004.

Capture totals, recoveries and resightings are summarised in Table 1. Most captured duck species have higher International resighting rates than recovery rates. Teal and Wigeon moulting primaries were captured between September and early December.

Nasal marks proved to be an efficient tool in the study of duck movements and migration. They increased the amount of information obtained from marked birds, allowed the estimate of survival rates (Rodrigues 2001), and will allow the assessment of returning rates of migratory ducks. The study has become less dependent on hunter reports, which gave a recovery rate of only 2.6%.

According to Rodrigues *et al.* (2000), Mallard populations from Central and Northern Portugal (from Mondego River basin to the north) are more related to Galicia and North Atlantic populations (Atlantic flyway) than to the Southern Portuguese populations (from Tagus basin to south). The latter should be more related to the southern Spanish and Mediterranean populations. This separation should probably also be applied to migratory species since ducks wintering in central and north Portugal prefer to use the Atlantic flyway, and birds wintering in south

**Table 1.** Total birds ringed and nasal marked within the study, recovered and resighted in Portugal, and recovered and resighted abroad.

Species	N (N marked)	Recoveries in Portugal	Resightings in Portugal	International recoveries	International resightings (N birds)
<i>Anas acuta</i>	8 (2)	0	0	1 (12.5%)	0
<i>Anas clypeata</i>	44 (33)	0	>80	2 (4.7%)	8 (4-12.1%)
<i>Anas crecca</i>	1 502 (847)	1 (0.1%)	>1000	61* (4.1%)	26 (14-1.7%)
<i>Anas carolinensis</i>	2 (=)	0	>25	0	0
<i>Anas penelope</i>	157 (138)	1 (0.6%)	>210	4 (2.5%)	10 (5-3.6%)
<i>Anas platyrhynchos</i>	5 739 (5 689)	216 (3.8%)	>20 000	20 (0.4%)	80 (54-0.9%)
<i>Anas querquedula</i>	3 (2)	0	11	0	0
<i>Anas strepera</i>	21 (18)	0	>35	1 (4.8%)	0
Hybrid of <i>Anas</i>	1 (=)	0	7	0	0
<i>Aythya collaris</i>	1 (=)	0	>20	0	0
<i>Aythya ferina</i>	5 (0)	0	0	1 (20%)	0
<i>Aythya fuligula</i>	36 (10)	1 (2.8%)	>55	1* (2.8%)	3 (1-10.0%)
<i>Fulica atra</i>	104 (-)	4 (3.9%)	-	0	-
<i>Gallinula chloropus</i>	846 (-)	5 (0.6%)	-	0	-
<i>Porphyrio porphyrio</i>	2 (-)	0	-	0	-
<i>Porzana porzana</i>	1 (-)	0	-	0	-
<i>Rallus aquaticus</i>	94 (-)	0	-	0	-
Total	8 566 (6 739)	228 (2.6%)	>21 000	91 (1.2%)	127 (78-1.2%)

\* includes one recapture

Portugal have a higher component of the Central European and Mediterranean flyway, but this must be confirmed with more captures in the south.

The capture of Teal and Wigeon moulting primaries reinforced the importance of the Iberian wetlands as both wintering areas and as moulting grounds for those species that do not nest in Portugal (Rufino 1989)

## Britain's first Winter River Bird Survey: a new approach to surveying waterbirds on linear waterways

James A. Robinson, Melanie Kershaw, Jenny Worden & Peter Cranswick

The Wildfowl & Wetlands Trust, Slimbridge, Gloucestershire, GL2 7BT, UK. (email: jenny.worden@wwt.org.uk)

Robinson, J.A., Kershaw, M., Worden, J. & Cranswick, P.A. 2006. Britain's first Winter River Bird Survey: a new approach to surveying waterbirds on linear waterways. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 476-477.

Rivers are essential to large numbers of wetland birds that visit the UK during the winter. The distribution and numbers of waterbirds using rivers need to be monitored so that correct and effective conservation action can be triggered if numbers decline. Currently, linear waterways such as rivers and canals are poorly covered by existing surveys compared with other wetland habitats. The aim of a national Winter River Bird Survey would

be to increase the coverage of linear waterways to improve the accuracy of national population estimates for relevant species and to evaluate the extent to which current surveys underestimate these populations.

A pilot survey was undertaken in January and February 2000 and 2001 to investigate methods for a full national survey (Robinson *et al.* 2003). Since a full survey could not hope to

**Fig. 1.** A plot of the scores of the first and second axes of the CCA ordination of the environmental variables and bird scores (Abbreviations used: canad = Canada Goose *Branta canadensis*, corm = Cormorant *Phalacrocorax carbo*, dip = Dipper *Cinclus cinclus*, gad = Gadwall *Anas strepera*, gold = Goldeneye *Bucephala clangula*, goos = Goosander *Mergus mergus*, greyl = Greylag Goose *Anser anser*, gsand = Green Sandpiper *Tringa ochropus*, gwag = Grey Wagtail *Motacilla cinerea*, heron = Grey Heron *Ardea cinerea*, king = Kingfisher *Alcedo atthis*, lg = Little Grebe *Tachybaptus ruficollis*, mall = Mallard *Anas platyrhynchos*, moor = Moorhen *Gallinula chloropus*, mute = Mute Swan *Cygnus olor*, oyst = Oystercatcher *Haematopus ostralegus*, redsh = Redshank *Tringa totanus*, tuft = Tufted Duck *Aythya fuligula*, wig = Wigeon *Anas penelope*; Alakl = Alkalinity, Alt = Altitude, DissO2 = Dissolved O2, DistS = Distance from source, Phos = Phosphate).

cover all river lengths in the UK, a randomised sampling approach would be used to derive population estimates. Stratified random sampling gives more accurate results than unstratified sampling, since bird density is predicted to vary according to factors such as region, river width, flow rate etc. The pilot survey identified the most suitable strata for a national survey, allowed selection of the most appropriate length of river to use as a count unit, and assessed the level of coverage required to generate estimates with a given confidence interval.

During the pilot, 30 rivers and canals were surveyed, representing a wide range of geographical, physical and environmental waterway types. Each river and canal was divided into 500 m sections and each stretch was visited once to record the numbers of each species present. Over 27 400 birds were counted, and data analysed for 22 species. The following environmental variables had been measured by the Environment Agency for each stretch in England and Wales and were used in statistical analyses: width; depth; alkalinity; % silt or clay; % sand; % pebbles or gravel; % boulders or cobbles; altitude; distance from source; slope; mean phosphate; mean nitrate; BOD; dissolved oxygen; ammonia; easting; northing; flow category; and General Quality Assessment biology grade.

Count data were used to identify suitable strata for the national survey, based on bird densities in river channels, so as to minimise the within-stratum variance in bird density. Multivariate analyses were used to identify major patterns of distribution for different species and the relationships between density, and the various environmental variables were quantified using Canonical Correspondence Analysis (CCA), a form of direct gradient analysis which attempts to explain species distribution patterns.

An indirect gradient analysis technique was used to test whether the measured environmental variables were adequate to explain the major variation in species composition. Unlike CCA, this technique does not attempt to constrain the species

responses to any environmental variables. It therefore represents major patterns in the species data without making any assumptions about the factors associated with these gradients.

A biplot of the first and second axes of the CCA ordination of the river and bird scores is shown in Fig. 1. The first axis is primarily a width/flow axis separating stretches that are wide with high flow rates from narrower stretches with lower flows. Having run the CCA analysis with all variables included, forward selection was then used to rank environmental variables in terms of their importance for determining the species data. Automatic selection was used to sequentially select the best five variables on the basis of maximum extra fit. The five environmental variables most important in explaining the species data were: water flow, northing, easting, dissolved oxygen and % silt or clay.

A nine-level stratification was identified based on region and flow combinations. The full survey will aim to cover 8 000 x 500 m stretches of river across nine strata, based on low and high flows and regions within England and Wales, to produce population estimates with +/-10% precision for a variety of species. Means for stratifying coverage in Scotland are being pursued.

## ACKNOWLEDGEMENTS

We thank Ron Thomas, Graeme Storey and Emily Orr for providing large amounts of environmental data from the Environment Agency's databases. This work was funded by a partnership between the British Trust for Ornithology, The Wildfowl & Wetlands Trust, the Royal Society for the Protection of Birds and the Joint Nature Conservation Committee.

## Fluctuations and trends in Swedish waterfowl populations during the last four decades

Leif Nilsson

Department of Animal Ecology, University of Lund, Ecology Building S-223 62 Lund, Sweden. (email: leif.nilsson@zoekol.lu.se)

Nilsson, L. 2006. Fluctuations and trends in Swedish waterfowl populations during the last four decades. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 478-479.

Regular waterfowl counts have been undertaken in Sweden since 1959/60, and Sweden has participated in the international midwinter counts of the International Waterbird Census since their start in January 1967. The counts aimed at the fullest

possible coverage during the years 1969-78, after which a standardized net of sites were counted each year for the calculation of annual indices. In addition, country-wide surveys of south Sweden were undertaken in 1971-73, 1987-89 (partial - no aerial

**Fig. 6.** Red-breasted Merganser *Mergus serrator*

**Figs. 1–6.** Annual indices for some common species based on pair-wise comparisons of counts on sites for two consecutive years. The values so obtained have been recalculated so that the mean for the series =100 (January data for the period 1987–2003).

**Table 1.** Totals for some species from country-wide surveys in Sweden 1971- 73 and 2004. All inshore coastal areas and the majority of inland sites were covered.

Species	1971-73	2004
<i>Anas platyrhynchos</i>	86 000	11 000
<i>Anas penelope</i>	40	5 000
<i>Aythya fuligula</i>	65 000	201 000
<i>Bucephala clangula</i>	24 000	69 000
<i>Somateria mollissima</i>	9 000	43 000
<i>Mergus serrator</i>	3 400	4 400
<i>Mergus merganser</i>	11 000	17 000
<i>Cygnus olor</i>	10 000	30 000
<i>Fulica atra</i>	15 000	17 500
<i>Phalacrocorax carbo</i>	1 900	8 100

surveys in Baltic archipelagos) and 2004. Areas further north are normally ice-covered in January and thus not important for waterfowl numbers. Midwinter indices are presented here for six species out of ten which were analysed (Figs. 1-6). Significantly increasing trends were found for seven species, whereas there were no long-term trends in the indices for the other three species. The index for the Eider, being representative only for

the southern part of the winter area on the Swedish west coast, showed a peak in the 1970s, then very low numbers followed by an increase in the 1990s. In the Coot *Fulica atra* there was a marked peak in the late 1970s after the previous mild winters, and then the population crashed after the cold 1979 winter, remaining at a low level until it once again increased during the 1990s. In most cases the increasing trends in the Swedish International Waterfowl Census (IWC) indices reflect changes in the winter distribution of the different species in relation to the milder winters in recent years. In some cases the increase can be a combination of distribution changes and a real population change. These questions can only be answered by the coming international analysis of the IWC data gathered in several countries in the flyway. Almost complete aerial surveys were undertaken in the Baltic archipelagos and the west coast in 1971-73 and 2004, with complete land-based coverage along the open coasts and on all important inland sites. Preliminary totals for 2004 are compared with country-wide surveys in 1971-73 in Table 1, and trends for individual species are shown in Fig. 1-6. Updates of the results from the Swedish mid-winter counts are found on the homepage of the project: [www.biol.lu.se/zooekologi/waterfowl/index.htm](http://www.biol.lu.se/zooekologi/waterfowl/index.htm). A major analysis of the data from the Swedish midwinter counts has started and will be finished in late 2005.

Numbers of Swedish Mute Swans *Cygnus olor* have stabilised in the last decade after an earlier period of increase. Photo: Chris Wilson.

## Conflicting trends in Ruddy Shelduck *Tadorna ferruginea* populations: a myth or reality?

Anastasia B. Popovkina

Goose, Swan and Duck Study Group of Northern Eurasia

Dept. Vertebrate Zoology, Biol. Faculty, Moscow State University, Moscow 119992, Russia. (email: nastya@soil.msu.ru)

Popovkina, A.B. 2006. Conflicting trends in Ruddy Shelduck *Tadorna ferruginea* populations: a myth or reality? *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 480-481.

This paper discusses changes in the numbers of different populations of the Ruddy Shelduck *Tadorna ferruginea* in Europe and Asia, changes which are not well understood, and describes a new initiative to assist in collecting and analysing population data.

Six populations (Ethiopian, Northwest African, Black Sea–East Mediterranean, Southwest and Central Asian, Central–Southern–Southeast Asian, and East Asian) of the Ruddy Shelduck are presently recognised (Penennou *et al.* 1994, Scott & Rose 1996). Noticeable fluctuations in numbers and certain shifts of the range of the species have been observed over the last three centuries. Mid-winter counts have indicated a dramatic decline in the western populations between the 1980s and mid-1990s, while at the same time the population numbers of Ruddy Shelducks in the Asian part of the range have undergone no noticeable changes over the past century and, moreover, seem to increase there. The recent influx of the Ruddy Shelducks in Western Europe cannot be explained by the dispersal of the escapes from captivity and still puzzles the experts. These facts have led some experts to assume that the species is being gradually driven out of the western parts of its range and that the range is shifting eastwards.

Ruddy Shelduck is listed as a species of European Conservation Concern (SPEC3: unfavorable – Europe). Its threat status in Europe is Vulnerable. The species is listed in the EU Wild Birds Directive (Annex I), Bern Convention (Appendix II), and Bonn Convention (Appendix II).

Different experts suggest the following reasons for the decline of the Ruddy Shelduck populations:

- habitat changes due to agricultural development (drainage of shallow marshland, subterranean water extraction for irrigation, over-grazing, etc.);
- coastal housing development;
- dramatic decline of marmot populations in steppe habitats;
- excessive shooting, particularly at the wintering grounds;
- nest-site disturbance; and
- natural causes (global and local climate changes, degradation of habitats, etc.).

The future of the species in Europe seems greatly dependent on the implementation of conservation measures, particularly prevention of shooting at its wintering grounds. However, increases of Ruddy Shelduck populations have been reported in the last decades for Bulgaria and European Russia. An increase in numbers from the early 1970s to the late 1980s has been reported for Kazakhstan and the Caspian region. Along with a noticeable (about 96%) decline in Pakistan, the population wintering in Iran has increased dramatically in the last 20 years,

the mid-winter counts suggesting that a five- or six-fold increase has occurred (Penennou *et al.* 1994).

In some experts' opinion, the recent increase in Ruddy Shelduck numbers in particular areas was caused by:

- direct conservation measures (Red Listings, banning of hunting, etc.);
- expansion of favourable habitats (dispersal and increase in numbers of marmots due to conservation measures; construction of dams and water reservoirs; depression in agriculture due to stagnation of economic development, etc.);
- reintroduction; and
- natural causes (global and local climate changes; improvement of habitats).

We have reviewed whether re-distribution of birds between the western and eastern populations has occurred, or are we witnessing the extinction of certain populations and the increase of others? The question could be answered if the existence of isolated populations is confirmed and if boundaries between populations (if any) are determined. Ringing recovery data would be of great help although very few Ruddy Shelducks have been ringed so far. For population studies, DNA-analysis would also help. Global censuses (primarily those conducted by Wetlands International) provide data on the species numbers on wintering grounds, while those for the breeding areas are of great value.

With a view to understanding population trends and providing valuable information for international conservation efforts, a few years ago the Goose, Swan, and Duck Study Group of Northern Eurasia launched a Project to study recent changes in numbers and

Ruddy Shelducks *Tadorna ferruginea*. Photo: Anastasia Popovkina.

range. Questionnaires containing questions on the numbers and local distribution of Ruddy Shelducks and status of their populations in particular areas were compiled and distributed primarily in the regions inhabited by the species, and information from many European and Asian regions of Russia and other countries was obtained. Data provided by numerous respondents have been entered into a database and regularly updated. Analysis of published data provides an understanding of the long-term population trends.

Data on recent Ruddy Shelduck numbers were reported by more than 130 respondents from 49 countries.

We encourage people to support this project by filling in the questionnaire available from the Project Coordinator at [nastya@soil.msu.ru](mailto:nastya@soil.msu.ru). Joint international efforts could facilitate

both better understanding of the Ruddy Shelduck population dynamics at a global level and implementation of the necessary conservation measures.

## The Swan Goose *Anser cygnoides* research and conservation programme in Russia

Nikolay D. Poyarkov

Lomonosov Moscow State University; Goose, Swan and Duck Study Group of Northern Palearctic, Russia.  
(email: Poyarkov@soil.msu.ru)

Poyarkov, N.D. 2006. The Swan Goose *Anser cygnoides* research and conservation programme in Russia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 482-483.

Up to the middle of the 20th century, Swan Geese *Anser cygnoides* were quite common in Russia, from Predbaikalie to the Lower Amur (Nizhneye Priamurie), Priamorie region, and northern Sakhalin. Since the 1950s, the range of this species has been progressively shrinking and its numbers declining under increasing anthropogenic impacts.

The Swan Goose is the most vulnerable goose species in East Asia, due to its nesting in densely populated and easily accessible flood plains, and intensive and uncontrolled hunting at its wintering grounds.

In 2000, a Russian-Japanese joint program of Swan Goose research and conservation was initiated with financial support from the Keidanren Science Foundation (Japan), with the goal of developing conservation measures at national and international levels. The main objectives were to: census Swan Geese in

known nesting sites and to study the peculiarities of their biology; mark geese of different populations; establish the need for specially protected areas; raise awareness in local communities about the need for protecting Swan Geese; adjust hunting regulations to avoid accidental shooting of Swan Geese; and develop procedures for restoration of the species within its range.

During the pilot phase (2000-2003) achievements included:

- the establishment, in 2002, of an International Task Force for Swan Geese with the participation of China, Japan, Korea, Mongolia and Russia;
- the publication of all available original and published data on numbers and biology of Swan Geese (Poyarkov, 2001, 2003);
- the survey of all known and potential nesting sites of Swan Geese in the Russian Far East, with the discovery of some

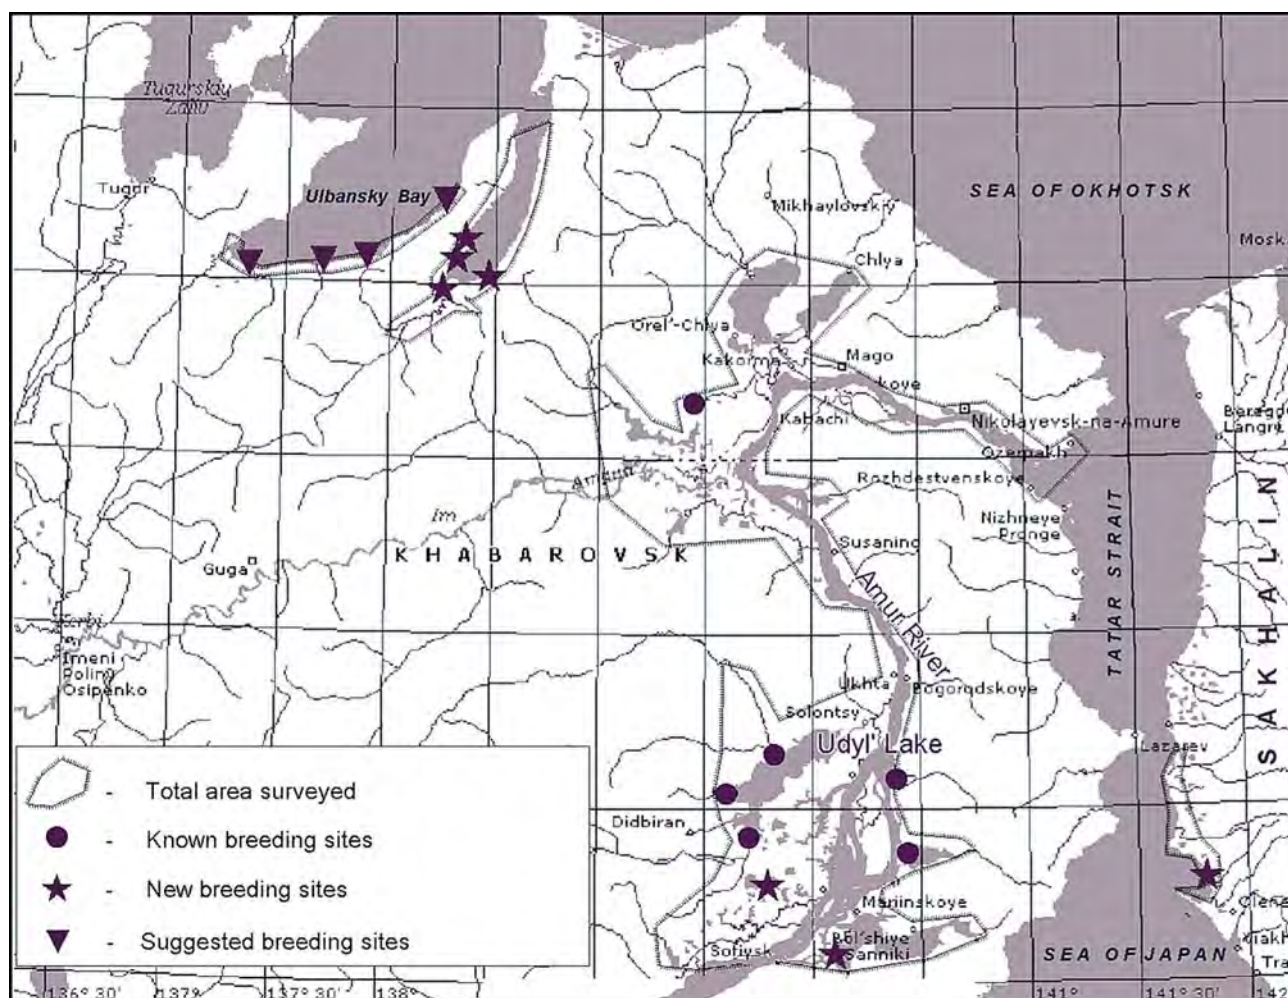

Fig. 1. Total area surveyed and the breeding sites of Swan Geese *Anser cygnoides* in the Priamurie, the Far East.

previously unknown nesting sites (Fig. 1) as well as obviously vacant and poorly occupied sites;

- recognising an increase in goose numbers in Udyl' Zakaznik (refuge), identified through the monitoring of Swan Geese population on Udyl' lake (Russian Far East), as a result of raising public awareness and education;
- coordination of an Swan Geese research program in the transboundary region of Transbaikalia with Dr. Oleg Goroshko (Dauriskiy State Nature Reserve), who undertook research and compiled all available published data and original materials on the status and biology of Swan Geese in the region (Goroshko 2001, 2003a, Goroshko & Liu Sangtao 2003);
- the discovery of some characteristics of the species, including; nesting in different types of habitats, the mobility of populations and brood amalgamations, the relationship between population condition in Dauria and long-term climatic cycles, and the extremely high proportion of non-breeding birds during a drought period (Goroshko 2003b);
- marking of Swan Geese with neck collars at Udyl' (139°48'E, 52°10'N) and Torey (115°41'E, 50°00'N) lakes;
- indications that a Korean stopover area is very important for Far Eastern Swan Geese breeding populations from recoveries made at Han River estuary (126°41'E, 37°48'N);
- the establishment of the Zakaznik "Kholan" for the protection of the nesting Swan Geese in the Russian Far East, in 2001;
- implementation of large-scale public awareness and education campaigns targeting local communities with hundreds of stickers, posters, and booklets printed and distributed, radio clips recorded and played as advertisement on radio, and lectures for students;
- the confiscation of nine young Swan Geese from local people, which were taken to Moscow Zoo to be used as basic stock for a captive breeding program of Swan Geese populations; and
- the collection of sample feathers for population structure studies by molecular genetic methods.

Unfortunately, proposals for changing some hunting regulations in the Far East were not supported by the Khabarovsk Department of Game Management.

Besides activities in Russia, the Task Force members have started work in other regions with a review of general information on the status of Swan Geese in Mongolia (Gombobaatar *et al.*, 2003), and China (Liu, 2004), the monitoring of Swan Geese, marking with neck collars and obtaining new data on Swan Geese feeding ecology at its Korean stopover site (Lee, 2004). Based on this data, it appears that the Swan Geese breeding range is divided into two parts: Far Eastern and Daurian. Questions regarding their degree of separation should be the focus of future studies.

Further work on Swan Geese research and protection is planned under the framework of the Task Force:

- monitoring of Swan Geese populations, research into the "bottlenecks" in species ecology and GIS-analysis of the areas inhabited by Swan Geese to reveal and examine potential nesting sites;
- banding of geese and fitting radio and satellite transmitters;
- molecular-genetic analyses of different populations to understand the population structure;
- supporting existing special protected areas and establishing new ones to enhance Swan Goose conservation;
- developing further public awareness and education programmes;
- developing and implementing a restoration program for a Swan Goose population in its former range to guarantee the survival of the species in the winter period; and
- developing a monitoring system of the Russian populations at the wintering grounds in China.

## Current status of the International Waterbird Census in the Czech Republic

Zuzana Musilová & Petr Musil

Department of Zoology, Faculty of Science, Charles University, Vinicna 7, CZ-128 44 Praha 2, Czech Republic.  
(email: iwccz@post.cz)

Musilová, Z. & Musil, P. 2006. Current status of the International Waterbird Census in the Czech Republic. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 484-486.

Monitoring of wintering waterbirds has a long tradition in the Czech Republic. The International Waterbird Census (IWC) was established (in former Czechoslovakia) in the winter of 1965/66 and has been carried out annually ever since, with results regularly published in national journals and bulletins (Pellantová 1995, 1996, 1997, 1998). Up to 2003, monitoring and counts were undertaken on 35 to 199 wetlands located in various parts of Bohemia and Moravia. However, this initial IWC monitoring scheme was designed in the 1970s, and no longer corresponds to the current distribution of wintering waterfowl in the Czech Republic.

In order to optimize coverage of the IWC, the “*Complete Wintering Waterbird Census*” project was undertaken from 2004 - 2006 to assess the current distribution and numbers of wintering waterbirds. The results of this project will be analysed to update the IWC in the Czech Republic, with the aim of

**Fig. 1.** Distribution of wetland sites covered in the “*Complete Wintering Waterbird Census*” in January 2004.

**Fig. 2.** Relationship between total number of counted individuals and variability in numbers (standard deviation of numbers of individuals per number of occupied sites). Species which show non-equal pattern of distribution, i.e. those which were counted in only a few places in high numbers are located in upper part of figure. For species abbreviations see Table 1.

**Table 1.** List of species recorded by mid-January International Waterbird Census on 478 wetland sites in the Czech Republic in January 2004. The abbreviations of species names listed in the second column are those used in Fig. 2.

Species	Abbreviated name for Fig. 2	no of sites	Number of birds counted

achieving almost complete coverage of suitable wetlands (Musilová *et al.* 2003, Musilová & Musil 2004).

In January 2004, 300 volunteers recorded 133 183 individuals of 50 waterbird species on 478 wetland sites. Sites included small rivers, sections of larger rivers, reservoirs, the most important fishpond areas, gravel and sand pit lakes, industrial wetlands and also flooded riverine habitats in south Moravia (Fig. 1). A web site [www.iwccz.wz.cz](http://www.iwccz.wz.cz) was established to assist volunteers involved in this monitoring programme.

Mallard *Anas platyrhynchos* was by far the most abundant bird species, followed by Great Cormorant *Phalacrocorax carbo*, Coot *Fulica atra*, Tufted Duck *Aythya fuligula* and Black-headed Gull *Larus ridibundus*. Mallard was also the most frequent waterbird species recorded, followed by Grey Heron *Ardea cinerea*, Great Cormorant *Phalacrocorax carbo*, Mute Swan *Cygnus olor* and Coot *Fulica atra* (see Table 1, Fig. 2).

White-fronted Goose *Anser albifrons* and Greylag Goose *Anser anser* occurred mainly in South Moravia, and Bean Goose *Anser fabalis* in Central Bohemia and South Moravia. Little Grebe *Tachybaptus ruficollis*, Pochard *Aythya ferina*, Tufted Duck *Aythya fuligula*, Goosander *Mergus merganser* and Coot *Fulica atra* were most abundant in North and Central Bohemia, but Black-headed Gull *Larus ridibundus* and Moorhen *Gallinula chloropus* were the most abundant in Central Bohemia and Goldeneye *Bucephala clangula* occurred mainly in Central Bohemia and South Moravia. Teal *Anas crecca*, Great White Egret *Egretta alba*, Smew *Mergus albellus* and White-tailed Eagle *Haliaeetus albicilla* were recorded mainly in South Moravia. Large numbers of Common Gulls *Larus canus* were recorded in North Moravia. Yellow-legged Gull *Larus cachinnans* and Herring Gull *Larus argentatus* were most abundant in North and Central Bohemia and in South Moravia. High

numbers of Dippers *Cinclus cinclus* occurred mostly in the highland regions of East Bohemia and North Moravia. Grey Heron *Ardea cinerea*, Mute Swan *Cygnus olor* and Kingfisher *Alcedo atthis* were distributed widely across the whole country (Table 1, Fig. 2).

The following species which are endangered and/or rare in the Czech Republic were recorded: Pygmy Cormorant *Phalacrocorax pygmeus*, Bittern *Botaurus stellaris*, Whooper Swan *Cygnus cygnus*, Barnacle Goose *Branta leucopsis*, Pintail *Anas acuta*, Shoveler *Anas clypeata*, Ferruginous Ducks *Aythya nyroca*, Scaup *Aythya marila* and Velvet Scoter *Melanitta fusca*.

## Waterbird censuses in Slovakia

Jozef Ridzoň

Spoločnosť pre ochranu vtáctva na Slovensku, Mlynské nivy 41, 82109 Bratislava, Slovakia. (email: ridzon@sovs.sk)

Ridzoň, J. 2006. Waterbird census in Slovakia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 487.

The first International Waterbird Census in Slovakia took place in 1967. Initially only the most important sites, such as the Danube River, the Southslovak lowland and some water reservoirs, were counted. These sites were divided into 20 - 40 sections, e.g. such that the length of one section of the Danube River being approximately 8 km.

In 1993 a winter waterbird census was inaugurated in the mountainous region of Orava North Slovakia. From 1994 to 2003, regular waterbird counts were conducted at rivers and brooks covering a total length of 373 km. The streams were divided into between 33 and 59 counting sections (Karaska 1998, 1999, 2000). Nearly all sites with a possible occurrence of waterbirds were counted – even those where only one White-throated Dipper *Cinclus cinclus* wintered. This census in the Orava region provided precise and valuable information about the wintering of rare and dispersed species, such as Jack Snipe *Lymnocyrtus minimus*, Common Snipe *Gallinago gallinago*, White-throated Dipper, Green Sandpiper *Tringa ochropus*, and Water Rail *Rallus aquaticus*. The only way to obtain data on such species in Slovakia is to achieve a complete count of streams and lakes.

In 1999 only two regions in Slovakia were counted thoroughly, the Danube River near Bratislava, the most important region for the occurrence of waterbirds and Orava, one of the least important regions for wintering waterbirds. Only a small amount of data concerning the occurrence of waterbirds was available from the other regions in Slovakia. Therefore, in 2000 counts according to the model used in Orava began in all regions of Slovakia where there were enough willing ornithologists and birdwatchers to make counts. In November, December, February and March monthly counts were added, as most sites in Slovakia are frozen in January and at that time of year it is impossible to determine their importance for the migration of waterbirds. The number of counted sites rose from 90 in January 1999, to 377 in January 2003.

The increased extent of the census significantly influenced total numbers counted. In January 1999, a total of 69 220 individuals of 42 species, was counted. In January 2003, after the introduction of the wider census, 101 070 individuals of 51 species were counted. In the other months of the 2002/2003 winter season, only half of the count sections in Slovakia were covered, and consequently the numbers of waterbirds were lower: 57 989 individuals of 51 species in November 2002; 121 257 individuals of 49 species in December 2002; 64 785 individuals of 45 species in February 2003; and 53 698 individuals of 52 species in March 2003.

The most numerous species in all the winter months of 2002/2003 was Mallard *Anas platyrhynchos*. In January, it reached its highest dominance, 46%, although a large number of

census sites were rivers, where Mallard is a monodominant species. The second most numerous species for all months was Tufted Duck *Aythya fuligula*, with its dominance fluctuating between 11% and 23%. The third most numerous species from November until January was Pochard *Aythya ferina* with dominance from 8% to 13%, but in February the third most dominant was Goldeneye *Bucephala clangula* (8% dominance), and in March Lapwing *Vanellus vanellus* (14% dominance).

In January 2003, due to the more detailed coverage compared with January 1999, significantly higher numbers of wintering individuals representing more species were recorded, representing an estimated 86% of all waterbirds wintering in Slovakia. The increase in recorded numbers of different species was (number of individuals in January 1999/number in January 2003): Cormorant *Phalacrocorax carbo* 989/5 934; Great Egret *Ardea alba* 35/205, Grey Heron *Ardea cinerea* 158/689, Mute Swan *Cygnus olor* 445 /1 755, Teal *Anas crecca* 273 /727, Mallard *A. platyrhynchos* 22 780 /47 732, Goosander *Mergus merganser* 99 /439, Green Sandpiper *Tringa ochropus* 7 /16, Kingfisher *Alcedo atthis* 10 /84, Dipper *Cinclus cinclus* 317 /453.

The most important site for wintering waterbirds in Slovakia was in Hrušovská. zdrž. In December 2002, 74 395 birds were counted there. In January 2003, the most numerous species at this site was the Tufted Duck *Aythya fuligula*, representing 86% of its Slovak population.

The increased number of count sites has provided much improved information about the importance of sites. Along the Váh river, 16 136 wintering waterbirds were recorded, which makes it the second most important river for waterbirds after the Danube river. The Malý Dunaj river was counted along all its entire length for the first time from 2000 – 2003, and in January 2003 a total of 6 064 waterbirds wintered there, representing 6% of the Slovak population of wintering birds.

The counts undertaken from 2000 to 2003 were a near complete census of the most important Slovak rivers, numerous tributaries and the biggest water reservoirs. Such a census has considerably improved the information on the distribution of waterbirds in different winters.

## Measuring wader recruitment

Jacquie A. Clark, Robert A. Robinson, Nigel A. Clark & Philip W. Atkinson

British Trust for Ornithology, The Nunnery, Thetford, Norfolk, IP24 2PU, UK. (email: Jacquie.Clark@bto.org)

Clark, J.A., Robinson, R.A., Clark, N.A. & Atkinson, P.W. 2006. Measuring wader recruitment. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 488-489.

This paper describes methods of measuring wader recruitment from catches of waders in winter. We show how best to analyse the data by using generalized linear models that allow us to account for the nature of the data. We produce national indices for two species and show that breeding populations may differ in their patterns of recruitment.

Counts of waders in the non-breeding season allow us to measure population change, but any changes are driven by variation in recruitment, survival and dispersal. Survival and dispersal can be measured using ringing recoveries and recruitment is normally measured as productivity (chicks/pair) on the breeding grounds. However, the productivity of well-dispersed breeding waders in remote areas is difficult to measure and information for each year is generally only available from a few breeding sites. As waders are easier to study on the non-breeding grounds, an alternative approach is to measure juvenile recruitment there using the proportion of juveniles in catches. For this work, age ratio data from all cannon net catches of waders in winter (November to March) in Britain between 1992 - 1993 and 2002 - 2003 were examined to determine the best way to calculate an index.

Two alternative methods of calculating an index of recruitment were investigated. For the 'Catch' index the proportion of juveniles in each catch is calculated and a mean of the proportions is worked out. However, the 'Catch' index is strongly affected by small catches, which tend to contain a high proportion of juveniles (Boyd & Piersma 2001). This problem can be overcome to some extent by weighting the importance of catches by catch size. However, this is an arbitrary solution. A catch index for all Dunlin *Calidris alpina* and for those in catches of more than 10 and more than 20 birds was calculated.

To avoid the problem of small catches making a disproportionate contribution to the index, an 'Individual' index was calculated. For the 'Individual' index each bird was treated as an individual sample. A linear model with a logit link, binomial error distribution and an overdispersion factor was used. Using this linear model removes the effect of small catches, accounts for aggregation, produces confidence limits and also allows the inclusion of site and other factors (e.g. region). 'Individual' indexes for all Dunlin and all Oystercatchers *Haematopus ostralegus* were calculated. The Oystercatcher data was also split into eastern Britain (where most wintering Oystercatchers are from the breeding population in Norway) and western Britain (where most wintering Oystercatchers are from the breeding population in Iceland).

The 'Catch' index for Dunlin is shown in Fig. 1 and demonstrates how the proportion of juveniles calculated from the catches reduces when small catches are excluded. Fig. 2 shows the 'Individual' index for Dunlin with 95% confidence limits. Figs. 3-5 show the 'Individual' index for Oystercatcher for the whole of Britain. 'Individual' indexes are also shown for eastern

**Fig. 1.** 'Catch' index for Dunlin *Calidris alpina* from all cannon net catches of waders in winter (November to March) in Britain between 1992/93 and 2002/03. All catches, catches with more than 10 birds, and catches with more than 20 birds are shown.

**Fig. 2.** 'Individual' index for Dunlin *Calidris alpina* from all cannon net catches of waders in winter (November to March) in Britain between 1992/93 and 2002/03 with 95% confidence limits.

(largely Norwegian breeders) and western Britain (largely Icelandic breeders). The different patterns of recruitment between regions may reflect differing conditions on the breeding grounds.

This investigation of the calculation of wader recruitment has suggested that an 'Individual' index using linear modelling should be used. This approach allows statistical testing to take place and factors which might affect a catch to be taken into account. It also avoids the over-representation of small catches that tend to contain a higher proportion of juveniles than larger catches.

**Fig. 3.** 'Individual' index for Oystercatcher *Haematopus ostralegus* from all cannon net catches of waders in winter (November to March) in Britain between 1992/93 and 2002/03 with 95% confidence limits.

**Fig. 4.** 'Individual' index for Oystercatcher *Haematopus ostralegus* from cannon net catches of waders in winter (November to March) in western Britain between 1992/93 and 2002/03 with 95% confidence limits.

It is relatively easy to obtain data on the proportion juvenile of waders present on the non-breeding grounds in order to monitor recruitment, but these data may not be a straightforward representation of productivity. Further work comparing results from the breeding and non-breeding areas needs to be carried out to validate this technique. In addition, aspects of the birds' biology need to be considered in interpreting the data. For example, birds wintering in one area may be from more than one breeding population. Also adults and juveniles may not be randomly distributed geographically (on a variety of scales).

#### ACKNOWLEDGEMENTS

Thanks to all the ringers who worked hard to collect the data on which this paper is based. The British Trust for Ornithology (BTO) Ringing Scheme is funded by a partnership of the BTO, the Joint Nature Conservation Committee (on behalf of English Nature, Scottish Natural Heritage and the Countryside Council for Wales, and also on behalf of the Environment and Heritage Service in Northern Ireland), National Parks and Wildlife (Ireland) and the ringers themselves. This work was funded

## Dynamics of breeding duck populations over the last two decades in key wetlands of the Moscow region

Olga V. Sukhanova & Alexander L. Mischenko

Russian Bird Conservation Union, Shosse Entuziastov, 60, bld.1, Moscow 111123, Russia. (email: almos@redro.msk.ru)

Sukhanova, O.V. & Mischenko, A.L. 2006. Dynamics of breeding duck populations over the last two decades in key wetlands of the Moscow region. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 490.

The Moscow region is one of the most populated and economically developed regions in Russia. The Vinogradovo floodplain and the small number of lakes in the region have remained important for breeding ducks, and different types of artificial wetlands (fishponds, storage reservoirs etc.) have also been created. In the 1980s large numbers of breeding diving ducks used the artificial wetlands and the Vinogradovo floodplain. In the first half of the 1980s, Tufted Duck *Aythya fuligula* broods accounted for more than 50% of all recorded broods of ducks in fishponds with Pochard *Aythya ferina* accounting for approximately 30%. On the Vinogradovo floodplain Tufted Duck broods accounted for 10-13%, Pochard 15-17%; and Pintail *Anas acuta* 8-10%. Broods of Gadwall *Anas strepera* were sporadic.

By the beginning of the 1990s, numbers of breeding ducks in the region had sharply declined and colonies of Black-headed Gull *Larus ridibundus* had almost disappeared from most wetlands. This was primarily due to an increase in recreational activities and the intensity of spring hunting everywhere in the region. On some ponds, paid sport fishing has been introduced. On some systems of fish ponds, employees undertake unregulated hunting in the autumn season. Property development has also increased and many ponds are now surrounded by large groups of dachas and cottages. In the Vinogradovo floodplain cover by emergent water plants has spread widely. All of these factors have negatively affected the regional populations of waterbirds.

From the mid-1980s to the end of the 1990s, the total number of ducks on two pilot fishponds were reduced 1.6 and 2.1-fold and the number for the same period on the Vinogradovo floodplain decreased four-fold. By the end of the 1990s there was a catastrophic decrease in the number of Tufted Duck and Pochard. In 2001-2002 broods of these species were observed in only one fishpond and there were none in the Vinogradovo floodplain. Pintail has completely ceased to breed in the floodplain or in any artificial wetland in the region. However, there was an appreciable growth of the Gadwall population in the Vinogradovo floodplain; forming approximately 15% of all broods in 2001.

Taking into account the very restricted funds of fishpond owners, associations of hunters and local authorities for nature protection, the best way forward for the wise management of fish ponds is an implementation of simple changes or additions to the usual management procedures. These should focus on the creation of islets, the maintenance of the meadow stage of succession and maintenance of emergent vegetation fringing islands. This type of habitat management is cheap; does not require the involvement of many additional people nor any substantial increase in costs for fishpond management.

A management plan for the maintenance of breeding ducks' populations in the Vinogradovo floodplain is under development. It will include guidelines on the expansion of the reserve area, more efficient management of recreation, "waterbird-friendly" agricultural management and cleaning spreading emergent water plants from lakes.

Floodplain wetlands in western Siberia hold important populations of breeding waterbirds as well as providing people with a wide range of ecosystem services, especially fisheries. Photo: Gerard Boere.

## Spotted Crakes *Porzana porzana* breeding in the UK - a history and evaluation of current status

Ian Francis<sup>1</sup> & David A. Stroud<sup>2</sup>

<sup>2</sup>Joint Nature Conservation Committee, Monkstone House, City Road, Peterborough, PE1 1JY, UK. (email: David.Stroud@jncc.gov.uk)

Francis, I. & Stroud, D.A. 2006. Spotted Crakes *Porzana porzana* breeding in the UK - a history and evaluation of current status. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 491-492.

The Spotted Crane *Porzana porzana* is a rare breeding bird in the UK, with around 30-70 pairs nesting annually. It may have increased in recent decades. However, recording standards are poor and an intensive search of new information showed that in most years more than twice as many pairs were breeding than the official record suggested. Totals also reflected observer effort. A failure of observers to submit records is hampering the protection of sites of importance for Spotted Crakes, and the process of rectifying this is time-consuming. Better information flows are urgently needed.

Spotted Crakes are rare breeding birds favouring a small number of sites where suitable wetlands exist. Most records are

of singing birds. Some of these records are passed to local bird recorders and then to the UK Rare Breeding Birds Panel, which includes both of the current authors. The panel's reports estimated a UK population of around 30 pairs. A more intensive national survey in 1999 recorded 73 singing males. This study shows that previous annual figures are also underestimates in most years.

Unpublished and published data sources were searched, mainly local bird reports, and many extra records of Spotted

Male Spotted Crane (right) caught in 2000 at Insh Marshes, Scotland and fitted with radio tag, leading to discovery of a nest and chicks (above). Photos: C. Donald, I. Mackenzie.

Fig. 1. Graph shows comparison of UK totals (Sharrock 1976, Gibbons *et al.* 1993, Gilbert 2002)

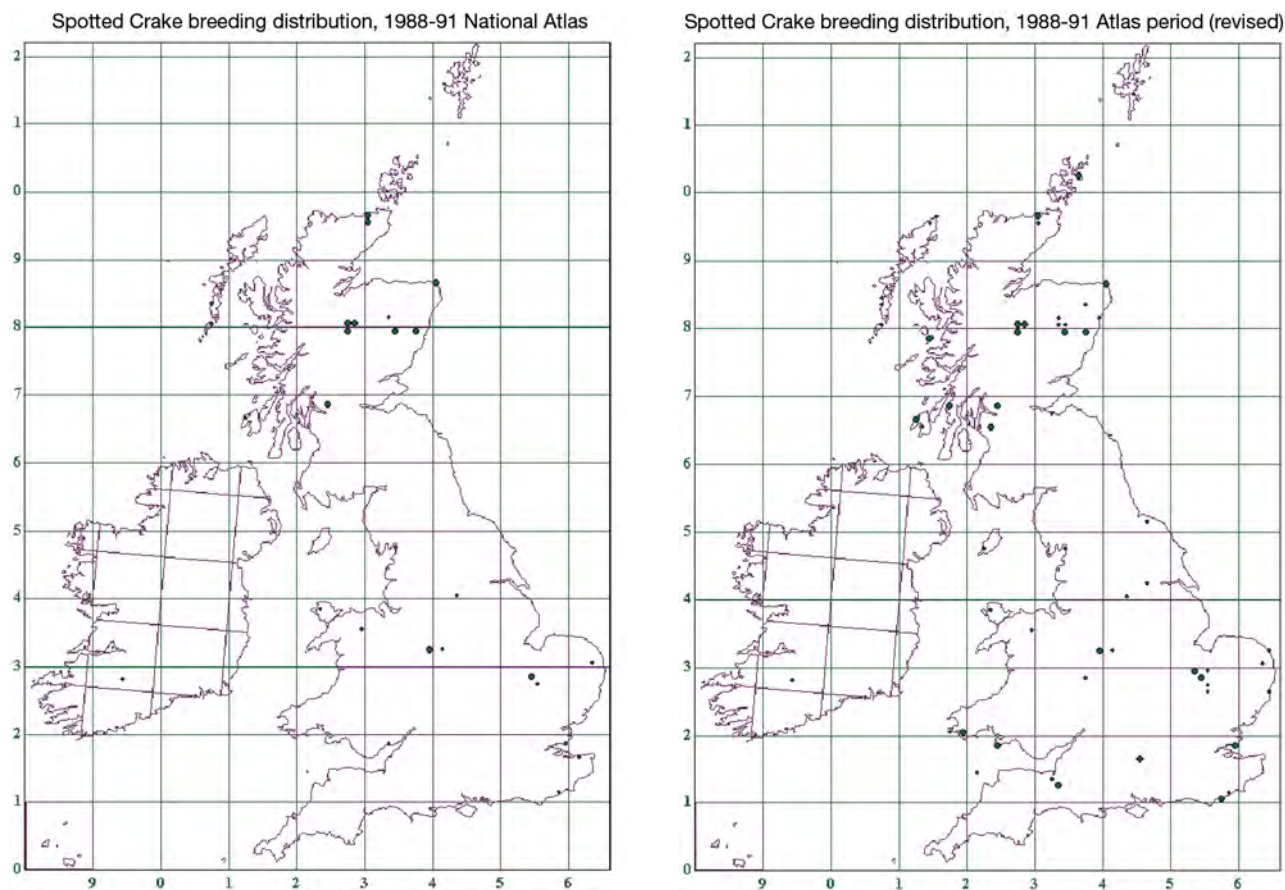

Fig. 2. Comparison of published UK Atlas map (1988-91) (left) with revised map for same period (right).

Crakes each year were found. Many of these had been poorly recorded and normal reporting processes had not been effective. UK totals were adjusted to take account of the new information and the population trend since the early 1800s was reassessed together with current status and distribution.

Evidence from the 19th Century indicates that Spotted Crakes were once significantly more abundant. During the early 20th Century records were few, but this probably implies very little recording. Since the 1960s, numbers have apparently increased, but periods of more intensive survey, such as national breeding bird atlases and the 1999 survey, produced more records (Fig. 1). However, in all years except 1999, the known totals were significant underestimates and even published atlas maps provide an incomplete picture (Fig. 2).

To protect important sites for rare breeding birds such as Spotted Crakes, good information flows are required, at both local and national levels. This study has highlighted deficiencies in UK data collation processes, and shown that they can be rectified. But this is time-consuming, and an improved system for capture of site-based conservation data is urgently needed.

#### ACKNOWLEDGEMENTS

We are grateful to all local observers and county recorders for submitting records to RBBP and to JNCC, the Statutory Country Agencies, RSPB and BTO for provision of information.

## The sixth International White Stork Census: 2004-2005

Kai-Michael Thomsen & Hermann Hötter

Michael-Otto-Institut im NABU, Goosstroot 1, 24861 Bergenhusen, Germany (email: NABU-Inst.Thomsen@t-online.de)

Thomsen, K. & Hötter, H. 2006. The sixth International White Stork Census: 2004-2005. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 493-495.

The decline of the White Stork *Ciconia ciconia* population early in the 20th century has often been used to highlight problems in the environment, notably the loss of wetlands and the changes in agriculture. This paper presents population trends since 1994/95 and first results of the sixth International White Stork Census.

White Storks have been intensively studied in the past: since 1934 there have been five international censuses (1934, 1958, 1974, 1984, 1994/95). The next international census in 2004-05 is to be co-ordinated again by the German Society for Nature Conservation (NABU, the BirdLife Partner in Germany) and the

Michael-Otto-Institute. The Sixth International White Stork Census is a project of BirdLife International, and it is supported by the Royal Society for the Protection of Birds (RSPB) (BirdLife Partner in Great Britain). Altogether, 40 countries in Europe, Northern Africa, the Middle East and Central Asia will take part in the project. The White Stork will be used as a flagship species for public awareness campaigns by several national BirdLife partner organisations.

The International White Stork Census is taking place in 2004 and 2005. In each country a national coordinator or organ-

isation (national BirdLife partners) is responsible for the collection and analysis of data. Where possible the census will cover the total area of the country.

Twenty-four countries participated in the fourth International White Stork Census. This census documented the all time low of the population and revealed a world population size of no more than 135 000 breeding pairs (Rheinwald 1989,

Schulz 1999). Over ten years since the previous census the decline in the western population (20%) was much greater than in the eastern population (10%) (Rheinwald 1989).

Ten years later the fifth International Census documented a population increase of 23%, and the new population estimate was 166 000 pairs (Schulz 1999). White Stork populations had increased in nearly all countries and regions, except Denmark,

Serbia, Bulgaria, Albania and perhaps Turkey (Fig. 1). The western population has increased by about 75% since 1984 whereas the eastern population has increased by only 15%.

There are different reasons for the population increase between 1984 and 1994/95. The strong increase of the western population is attributed to better climatic conditions in the wintering areas in the western Sahel and the development of a wintering population in southern Spain (Tortosa *et al.* 1995). On the Iberian peninsula the increase in the number of irrigated fields and the attractiveness of large garbage dumps for storks may have improved feeding conditions for breeding storks (Schulz 1999).

The reasons for the smaller increase in the eastern population are not clear. The economic difficulties in central and eastern Europe after 1990 and their influence on the intensity of farming possibly had a positive effect on the reproductive success of White Storks.

Since the last (fifth) international census White Stork populations have changed in different ways. In south-western Europe and in the Maghreb region numbers of Storks have increased rapidly. In western central Europe there has been an increase until 2000 and a slight decrease thereafter (Table 1). In most countries the numbers of White Stork are nowadays higher than in 1994/95.

We have received preliminary results of the Sixth International Census from eleven countries (Table 2). In most of them populations of White Storks have increased since the previous census. The largest increases in population size were recorded in those regions inhabited by storks migrating on the western flyway. Here the numbers went up by more than 100%. Populations also increased, however, in the regions hosting storks that migrate on the eastern flyway.

## Monitoring of waterbirds at Bourgas wetlands, Bulgaria

Lyubomir Profirov<sup>1</sup>, Milko Dimitrov<sup>1</sup>, Tanyo Michev<sup>2</sup> & Konstantin Nyagolov<sup>1</sup>

<sup>1</sup> Bourgas Wetlands Project, 8000 Bourgas, PO Box 189, Bulgaria. (email: lovebird@techno-link.com)

<sup>2</sup> Laboratory for General Ecology, 2 Gagarin Str., Central, 1113 Sofia, Bulgaria.

Profirov, L., Dimitrov, M., Michev, T. & Nyagolov, K. 2006. Monitoring of waterbirds at Bourgas wetlands, Bulgaria. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 496-497.

The Bourgas wetlands are the most important ornithological complex in Bulgaria and play a significant role in the conservation of biodiversity in the country. In 1984 Atanasovsko Lake was declared a Ramsar site. Since February 2003, three further sites have gained Ramsar status: Pomoriysko Lake – 814 ha, Vaya Lake – 2 900 ha and Poda Lagoon, including Foros Bay – 307 ha. These sites have been important for many international and Bulgarian ornithologists since the second half of the 19th century (Reiser 1894, Jordans 1940, Patev 1950, Mountfort & Fergusson-Lees 1961, Prostov 1964, Nankinov & Darakchiev 1977, Michev & Profirov 2003, Michev *et al.* 2004).

This paper presents the results of the monthly ornithological monitoring of the Bourgas wetlands from 1996 to 2002. The monitoring covered all natural and some selected artificial wetlands in the Bourgas wetland region, with a total area of c. 9 500 ha. All data were collated to form a single “average” year. This hypothetical year starts with spring migration (March, April and May), followed by the breeding season (June and July), autumn migration (August, September, October and November) and winter (December, January and February). Aerial surveys were conducted by plane and helicopter to count birds breeding in colonies in the reed beds of lakes and to obtain the exact positions of all breeding localities.

Of the 153 species of waterbirds found in the region six are residents, 48 are breeding summer visitors, 34 non-breeding summer visitors, 105 migrants, 92 winter visitors and 17 vagrants. These results indicate that the Bourgas wetlands have the highest diversity of waterbird species during migration time. Highest numbers are observed in the winter period, with large concentrations of geese, ducks, diving ducks, waders etc. During the breeding season, species diversity is relatively poor. The highest number of waterbird species in a single monitoring scheme was in September 1999, with 71 species recorded and

**Fig. 1.** Average total numbers and average species number of waterbirds in all Bourgas lakes.

the highest total number of waterbirds recorded was in December 2000, with 186 236 individuals. The seasonal dynamic of average total numbers of waterbirds and average species numbers are presented in Fig. 1, with the average monthly numbers of all waterbirds at the different lakes of the Bourgas wetlands presented in Fig. 2.

The biggest concentrations of waterbirds were recorded during the winter months from December to February in the freshwater basins of Vaya and Mandra lakes. The ten most numerous waterbird species in the Bourgas wetlands are presented in Table 1.

The results obtained indicate that the Bourgas wetlands are of international importance for many waterbird species. Among them are several globally threatened species with the maximum numbers recorded as follows: Pygmy Cormorant *Phalacrocorax pygmeus* 10 600 in December 1999; Dalmatian Pelican *Pelecanus crispus* 647 wintering in January 1999, Red-breasted

## Monitoring overlapping populations: the Greylag Goose *Anser anser* in the Iceland-Britain flyway

Richard Hearn<sup>1</sup> & Morten Frederiksen<sup>2,3</sup>

<sup>1</sup> The Wildfowl & Wetlands Trust, Slimbridge, Gloucestershire, GL2 7BT, UK. (email: Richard.Hearn@wwt.org.uk)

Hearn, R. & Frederiksen, M. 2006. Monitoring overlapping populations: the Greylag Goose *Anser anser* in the Iceland-Britain flyway. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Edinburgh, Office, UK. pp. 498-499.

Greylag Geese *Anser anser* in Britain are comprised of three populations. This paper discusses the difficulties of monitoring these populations and reports on changes in survey procedures designed to overcome these difficulties.

Three populations of Greylag Goose are currently recognised in the UK: the Iceland Greylag Goose – a migratory population present between October and April, and two sedentary populations – the NW Scotland Greylag Goose and the re-established Greylag Goose. NW Scotland Greylag Geese are the remnant of a population that was once more widespread in Britain, and predominantly occur in western Scotland with others in mainland northern Scotland. The re-established Greylag Goose was reintroduced into this former range, predominantly by hunters, between the 1930s and 1960s, and in most cases stock derived directly from the NW Scotland population. Whilst the two sedentary populations have increased in abundance and distribution in recent years, best available data indicate that the Iceland Greylag Geese declined by approximately 20% during the 1990s.

Monitoring population parameters for most UK goose populations is achieved through The Wildfowl & Wetlands Trust's (WWT) Goose Monitoring Programme (GMP): a suite of integrated surveys that provide estimates of abundance and distribution, reproductive success, movements and survival. Estimates of abundance of Iceland Greylag Geese have been made annually since 1960 through the Icelandic-breeding Goose Census (IGC): counts of the two sedentary populations are conducted at least annually in most key areas, and are supported by more comprehensive surveys on a nine-yearly basis. All are currently site-based look-see surveys, with no attempt to locate birds away from sites known to support them.

In recent decades, changes in abundance and distribution mean that these populations now overlap in many areas where they were formerly discrete. This has provided complications for monitoring protocols, and thus the assessment of conservation status. Recent modelling (see Frederiksen *et al.* 2004) found that the IGC and estimates of harvest rate in Iceland were incompatible for Iceland Greylag Goose; using each of these data sources

The Loch of Strathbeg in Aberdeenshire is of international importance as a roost for the Icelandic population of Greylag Geese *Anser anser*, holding over 3% of the total population, with peak use in the mid-winter period. Photo: David Stroud.

in population models provided widely differing estimates of abundance. In other words, either the Icelandic hunting bag was over-estimated or the IGC missed a proportion of the population (or both to a lesser degree).

Examination of the way in which hunting bag data in Iceland are reported found no evidence of widespread identification problems, or that double-reporting was an important bias. This suggested that underestimation of the autumn population size was a problem, either through undercounting in the UK or due to a large part of the population wintering outside the UK. A workshop that reviewed the results of Frederiksen *et al.* (2004) led to the production of a series of recommendations for future monitoring effort (Frederiksen 2001) that are now providing the basis for initiatives under development as part of the GMP.

Progress has already begun with a number of these. Closer collaboration with other countries supporting wintering Iceland Greylag Geese has been developed, so that counts from there are now included as part of the IGC. This includes Norway, where recent re-encounters of marked birds have highlighted the presence of a regular flock, previously believed to be overwintering birds from the Northwest Europe population. Surveys have yet to establish whether other flocks of Iceland Greylag Geese occur regularly. Recommendations on methodological changes to the current IGC that would establish whether large numbers of Iceland Greylag Geese in the UK are currently undetected have been made, and moves to implement these are underway. This includes the development of a September count and a stratified sample survey. Finally, material is being collected for stable isotope analysis to test whether this is an effective way of estimating the proportion of migratory and sedentary Greylag Geese in different parts of the UK, and thus address the identification problems posed by the presence of other populations.

The current difficulties with monitoring Greylag Geese in the UK pose a number of problems for conservationists wishing

to secure a favourable conservation status for these populations and achieve effective allocation of conservation resources. They also highlight issues for all surveys dealing with overlapping populations: changes in biological patterns may require methodological changes to be made to surveillance tools, and it is vital that methods are reviewed as part of any monitoring programme in order to ensure continued effectiveness. Questions are also raised about the future likelihood of continuing to monitor three separate Greylag Goose populations in the Iceland-Britain flyway and the consequences of this for biodiversity conservation.

## ACKNOWLEDGEMENTS

The contribution to this work by a number of colleagues, notably Carl Mitchell, Arnór Sigfússon and Bob Swann is gratefully acknowledged. A partnership between the Wildfowl & Wetlands Trust and the Joint Nature Conservation Committee has provided funding for much of the count surveys to date. The Peter Scott Trust for Education and Research in Conservation also provided invaluable support for the continuation of other fieldwork, notably ringing. Finally, the GMP would not exist without the support of a network of dedicated volunteer fieldworkers that collect data and ring birds – their continued support is very much appreciated.

## Monitoring and mapping of waders breeding in northernmost Sweden

Åke Lindström

Department of Animal Ecology, Lund University, Ecology Building, S - 223 62 Lund, Sweden. (email: ake@lindstrom@zooekol.lu.se)

Lindström, Å. 2006. Monitoring and mapping of waders breeding in northernmost Sweden. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 500.

Wader species of the northern taiga and tundra regions are difficult to map and monitor on their breeding grounds. Many of them, for example the *Tringa* sandpipers and snipes, are difficult to follow also during winter due to their wide wintering areas and lack of large concentrations. Good monitoring data are scarce for most of these species.

The northern half of Sweden, approximately 61–69° N, consists mainly of taiga, rich in small water bodies suitable for waders, with areas of mountainous tundra farthest to the west and north. Systematic data on distribution and population trends have so far been lacking for the 25 waders species breeding in the area. The Swedish Breeding Bird Atlas (Svensson *et al.* 1999) recorded the presence or absence of birds in 5 km x 5 km squares in the 1970s and 1980s, but only 18% of the area was well covered and data were only available for one year for each square.

A scheme with 724 fixed routes systematically distributed over the whole of Sweden was launched in 1996 as a part of the Swedish Bird Survey (Fig. 1). The aim is to complement the system of point count routes running since 1975 that mainly covers southern Sweden. Routes are positioned on fixed coordinates on the Swedish Grid, and there are 25 km between the routes in W-E and N-S direction. The systematic distribution of routes should result in a representative coverage of the most widespread habitats.

A fixed route consists of an 8 km line transect, formed as a 2 x 2 km square with a 5 minute point count every full km. The route is walked clockwise, starting 04:00. All birds seen or heard are recorded. The person counting may deviate 200 m from the transect, but outside this distance counting stops. It is resumed when the line  $\pm$  200 m can be reached again. Census date varies between late May and early July depending on latitude. Although the scheme best covers passerines, many waders are also recorded.

About 400 of the fixed routes are situated in the northern taiga and tundra regions. Some of them are located in inaccessible areas involving one or two days of walking to reach the route, but a network of roads (due to forestry activities) make most routes readily accessible by car. The aim is to count each route annually, but in practice, many routes will only be visited every 2–5 years. About 200 routes were counted in northern Sweden in 2003, the best year so far. About half of these were carried out by volunteers and the other half by paid people. The scheme has been adopted by several Regional Administrative Boards as their regional monitoring tool, and the economic and logistic support from this cooperation greatly helps covering the routes.

As an example, relative densities of the Wood Sandpiper *Tringa glareola* increase from about 1.2 birds per 8 km line transect in the southern part of its range to 5.6 birds per 8 km line transect in the far north (Fig. 1). There is no significant population trend in 1996–2003 (Fig. 2).

For the first time there is the potential to monitor population trends and relative densities of species like Golden Plover *Pluvialis apricaria* (369 birds recorded on 50 different northern

Fig. 1. The average number of Wood Sandpipers *Tringa glareola* recorded per year on the 8 km line transects (1–8 years per route). Each dot represents a fixed route. Empty spaces indicate routes not yet censused.

## The development of a database for the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*

Gillian Bunting & Christoph Zöckler

World Conservation Monitoring Center, 219 Huntington Road, Cambridge, CB3 0DL, UK. (email: Christoph.Zockler@wcmc.org.uk)

Bunting, G. & Zöckler, C. 2006. The development of a database for the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 501-502.

Recent research on the breeding areas of the Spoon-billed Sandpiper *Eurynorhynchus pygmeus* indicated a sharp decline in the population (Tomkovich *et al.* 2002, Zöckler *et al.* 2006, Syroechkovski *et al.* in press). The species has been upgraded in the Red List and is now considered as Endangered (BirdLife 2004). At the seventh Conference of the Parties to the Convention on the Conservation of Migratory Species of Wild Animals (CMS) in Bonn, 2002, it was agreed to promote and support the development of a species Action Plan. Furthermore, the globally threatened status and lack of knowledge about the Spoon-billed Sandpiper led to the formation of a Recovery Team, which had its first meeting at the conference giving rise to these proceedings.

The Action Plan requires accurate, comprehensive and up to date data on species distribution and abundance, in the form of a species database. Although this information is largely available for breeding areas (Lappo *et al.* in press), data on migration or wintering grounds are missing and have not been captured in a central database.

The ultimate aim of the database is to allow easy analysis of the data both over time, to formulate population trends, and

spatially, to assess distribution and migration patterns. However, for cost effectiveness and flexibility, the database structure has been kept as simple as possible. A relational database in MS Access has been constructed, with two linked tables. One contains the information specific to a particular location, while the other details individual sightings.

The Locations table is based on information published by Birdlife (2001). Information on the location of sites is available for each species from the Birdlife web site at [www.birdlife.org](http://www.birdlife.org). As well as a site name and coordinates, to link to GIS, this table contains all available information on habitats. However, information is currently limited and there is scope for further development.

The Observations table is also based on information by Birdlife (2001), textual information from the species account has been converted to tabular form. Key fields include the date of observation, number of birds, observers name or published reference and the site name. Where available, data on age, sex and ring recoveries are also added. Many historical records, which did not contain full date or site information, could not be

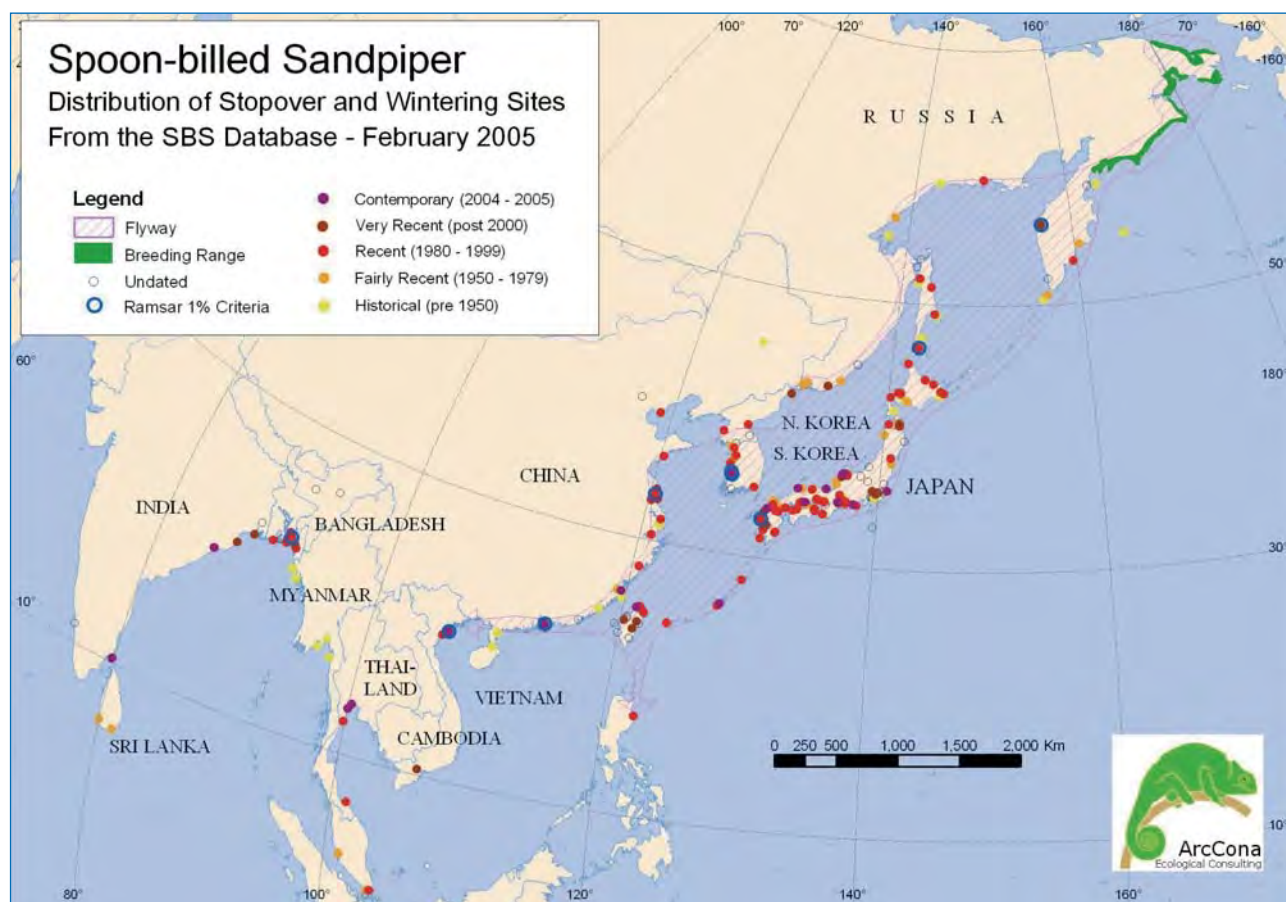

Fig. 1. Distribution of stopover and wintering sites for the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*.

included in this structure. Work is currently progressing to bring the information content of the database up to date, and records published on the internet from 2001 to the present are captured as well as many unpublished observations. At present, the database contains 250 site location records and 300 discrete observations. The authors are aware of many more observations, which are not yet included, and anyone with observations is kindly requested to send it to the authors.

Four new locations have been added to the 'Locations' table. These include the Indian Sunderbans, the Mekong Delta, a new area of the Inner Gulf of Thailand and Yuboo Island in South Korea, all of which are highly significant.

In the Indian Sundarbans delta, Sharma (2003) describes observations from eight different locations made in November and December 2001, with up to 14 sightings recorded. Although these observations were not substantiated in 2005 (Zöckler *et al.* in press) large flocks in neighbouring Bangladesh point to potentially crucial wintering sites in this region. The largest flock ever recorded outside a breeding area was in the outer sandbanks of the Ganges Delta in Bangladesh (Howes & Parish 1989). This evidence, combined with early results from stable isotope analysis (Zöckler *et al.*, this volume) suggest that the Ganges delta may be a core area of the wintering range.

In the Mekong Delta, an observation made in southern Vietnam is significant, as it was the first from that region. Its location, at the southern tip of Indochina, supports the suggestion that at least some birds migrate along the coastline instead of taking an overland route.

The Inner Gulf of Thailand is one of the most closely watched areas within the wintering range, due to its proximity to the city of Bangkok. It is not unexpected, therefore, that Spoon-billed Sandpiper were observed for the first time at Pak Thale in Thailand. However, it is of some concern that this site, and other parts of the Gulf, are apparently under threat from a major infrastructure development project.

Finally, Yuboo Island is the location of one of the very few recoveries of a leg-flagged Spoon-billed Sandpiper. A juvenile bird was seen there in late September 2004, which was ringed in July 2004 in Meinopylgino, Chukotka, Russia.

Continuation of data collection and recording is essential for both species conservation and the development of the Action Plan. The development of the database and the Action Plan are

closely linked and should be developed jointly, in close collaboration with BirdLife International and Wetlands International. The analysis of data feed directly into the Action Plan, which will prioritise future research and conservation efforts.

## ACKNOWLEDGEMENTS

Without the vision and experience of E.E. Syroechkovski the present fragile status of the species would not have been recognised. We thank the organiser of the Russian Arctic expeditions and the many co-workers. We also thank Mike Crosby from BirdLife International for his continuing support.

## Population size and trend of the Red-crested Pochard *Netta rufina* in southwest/central Europe: an update

Verena Keller

Schweizerische Vogelwarte/Swiss Ornithological Institute, CH-6204 Sempach, Switzerland. (email: verena.keller@vogelwarte.ch)

Keller, V. 2006. Population size and trend of the Red-crested Pochard *Netta rufina* in southwest/central Europe: an update. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 503-504.

The southwest/central European flyway population of the Red-crested Pochard *Netta rufina* is assumed to be a distinct population separate from the eastern European and Asian ones (Scott & Rose 1996, Defos du Rau 2002). An analysis of the results of the International Waterbird Census (IWC) up to 1994 indicated that the overall population size of the southwest/central European flyway population had not increased but that birds had shifted their winter distribution (Keller 2000a, 2000b). This was most likely the consequence of a drought period in Spain and improved wintering conditions in central Europe. This paper updates the situation to 2001, based on the data from the mid-winter counts of the IWC.

Since 1994, wintering numbers of the Red-crested Pochard in central Europe have continued to increase, but numbers in the western Mediterranean have been fluctuating (Fig. 1). Trends and Indicators for Monitoring Data (TRIM) analyses (Pannekoek & van Strien 1998) indicate a significant increase of the total flyway population for the period 1990 to 2001 (overall index trend:  $1.0698 \pm 0.0115$ ). However, high overdispersion and strong fluctuations of numbers at individual sites result in a poor statistical fit of the model. Thus the long-term trend is difficult to interpret, also because coverage by the IWC of sites

used by Red-crested Pochard prior to 1990 was limited (Keller 2000a).

Since the 1990s, Red-crested Pochards have overwintered mainly in Spain and Switzerland/Germany (Fig. 2). They are concentrated on a small number of sites. The six most important sites - Albufera de Valencia and Delta del Ebro in Spain, Bodensee (Switzerland, Germany and Austria), Lac de Neuchâtel and Vierwaldstättersee in Switzerland and Camargue in France hold, on average, about 75% of the total flyway population.

Red-crested Pochards can shift between sites in large numbers within short periods. If censuses are not well co-ordinated the risk of double-counting, or of missing large flocks, is high. Shifts and the high concentrations on a few sites may result in high proportions of the population being missed or double-counted. In 1999, the year with a peak count of 40 000 individuals, the waterbird census on the three main lakes in Switzerland/Germany took place on the same date (17 January). Censuses in Spain were also carried out in mid-January, but exact counting dates are not available.

In the second edition of Waterbird Population Estimates (Rose & Scott 1997) the size of the southwest/central European flyway population was estimated at 25 000 individuals. In the

Fig. 1. Mid-winter numbers of Red-crested Pochards *Netta rufina* in the western Mediterranean (mainly Spain, Portugal and France; dark) and in central Europe (mainly Switzerland and Germany; light) 1972–2001. Data from the International Waterbird Census (IWC).

**Fig. 2.** Main wintering sites of Red-crested Pochards *Netta rufina* in south-west and central Europe in the 1990s.

third edition (Wetlands International 2002) the estimate was increased to 50 000, a revision based largely on the 40 000 individuals counted in January 1999. Although this 1999 census result appears to be realistic, even though double counts cannot be excluded, the total population estimate of 50 000 seems to be rather high. The main sites used by Red-crested Pochards have been well covered from 1996 onwards, making it unlikely that 10 000 individuals were missed in these years.

## ACKNOWLEDGEMENTS

Thanks go to all the waterbird counters collaborating in the IWC and to the national coordinators for permission to use their data. Special thanks go to B. Deceuninck and J. Wahl who provided additional data for France and Germany and to R. Martí, B. Molina and J.C. del Moral who answered many questions on the Spanish data.

Piersma, T. & Warnock, N. 2006. Migration ecology. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 505.

Greenland White-fronted Geese *Anser albifrons flavirostris* flying to staging areas in western Iceland. Recent research, including the use of satellite telemetry, has given a clearer understanding of the energetic implications of the lengthy two-stage migration undertaken by these geese. Photo: Chris Wilson.

Over the last decade many research projects have been undertaken to investigate the ways by which migratory birds handle their energetic needs in relation to flight ranges (including individual decisions of birds regarding these routes), the selection of stopover or staging areas, and the use of available food resources.

The aim of the workshop was to identify the conservation consequences of the many different ecological and life-history strategies that waterbird species use during their annual cycle; to identify and discuss the value of modern research techniques (stable isotopes, geo-locators, satellite tracking); and to formulate priorities for further research.

The advent of satellite tracking has revolutionised understanding of the migration systems of waterbirds, providing near real-time information to be gathered on the location of individual birds. Recent studies of the movements of East Canadian High Arctic Light-bellied Brent Geese *Branta bernicla hrota* are summarised by Robinson *et al.* This technology will probably always be relatively expensive and thus applicable only to small

numbers of individuals. In contrast, new techniques such as genetic analysis (as presented by Svazas for Common Snipe *Gallinago gallinago*) and the use of stable isotopes (as summarised by Atkinson *et al.* for determining population structures of Nearctic Red Knot *Calidris canutus rufa*) have significant potential to help elucidate flyways, and thus assist conservation managers. Although not a waterbird, using the example of the Redwing *Turdus iliacus*, Coiffait *et al.* show how that combined use of stable isotope and DNS analysis can be an effective tool in clarifying population identity – with potential implications for population studies of waterbirds.

The extent of migration can be very considerable. Gill *et al.* present evidence of one of the most extreme: an 11 000 km non-stop flight by Bar-tailed Godwits *Limosa lapponica* from Alaska to New Zealand and eastern Australia. Understanding the eco-physiological constraints of such flights, focuses attention on the critical importance of adequate feeding (re-fuelling) possibilities at the termini of such flights (and on intermediate staging areas where these are used.

## Elucidating the movements of migratory birds through the combined use of stable isotope 'signatures' and DNA markers

Coiffait, L., Bevan, R., Redfern, C., Newton, J. & Wolff, K. 2006. Elucidating the movements of migratory birds through the combined use of stable isotope 'signatures' and DNA markers. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 506-507.

This paper presents the preliminary results of a study using a combination of stable isotope 'signatures' and DNA markers to establish the migratory patterns of Redwing *Turdus iliacus* passing through Wales and England. The approach is of application to waterbirds and is of significance in the light of the increasing use of these techniques to elucidate the breeding or wintering areas of waterbird species, especially those which are highly threatened.

For many birds, migration is a fundamental aspect of their life history, and knowledge of the links between breeding, wintering and intermediate stopover sites is crucial for determining at which points in the annual cycle avian populations are most vulnerable. Whilst there is a considerable amount of information available concerning migration at the species level, far less is known at the population and intra-population level (Bairlein 2001). Groups of birds may be spatially distinct at some stages of the annual cycle, but the extent to which individuals from the same breeding area migrate to the same wintering area and vice versa is largely unresolved.

The conventional technique of ringing birds has limited potential for population level studies because it relies on recapturing individuals, and the probability of this is extremely low. A novel approach combining the use of stable isotope ratios of carbon, nitrogen and hydrogen with multiple DNA markers has therefore been used to examine the migratory movements of the Redwing *Turdus iliacus* and the European Blackbird *T. merula*. The Redwing has a breeding range that covers a vast area from Iceland to eastern Siberia, while a second race *T. i. coburni* nests in Iceland and the Faeroes and differs markedly from nominate *T. i. iliacus* in several aspects of its migration (Milwright 2002). Blackbirds are partial migrants, with a highly complex pattern of movements; their breeding range spans most of Europe (Chamberlain & Main 2002). In this preliminary study, body feathers were sampled from populations of *T. i. iliacus* and *T. i. coburni* (Table 1).

Feathers were washed in 0.25M NaOH followed by deionised water, and dried at 50° C. Carbon, nitrogen and

hydrogen isotope ratios were analysed via continuous-flow stable isotope mass spectrometry (CF-IRMS) capable of measuring  $\delta^{15}\text{N}$ ,  $\delta^{13}\text{C}$  and  $\delta\text{D}$  to  $\pm 0.2$  ‰,  $0.1$  ‰ and  $\pm 2$  ‰ respectively. A Multivariate Analysis of Variance (MANOVA) was used to investigate whether mean stable isotope ratios of  $\delta^{15}\text{N}$ ,  $\delta^{13}\text{C}$  and  $\delta\text{D}$  differed between birds of different origins. Posthoc testing (Tukey's) was carried out to determine where statistical differences occurred.

**Fig. 1.** Mean feather,  $\delta^{15}\text{N}$  and  $\delta\text{D}$  values of adult and first-year Redwings *T. iliacus* collected from three different populations overwintering in the UK, and a single Icelandic breeding population. Values are reported in parts per thousand (‰). Each point represents the mean ( $\pm$  SE) of all birds sampled at that location. Bardsey birds are represented by a diamond (◆ autumn; ◇ spring), Farne Island birds by a circle (●) and Icelandic birds by a square (■).

The two Bardsey populations did not differ significantly for any of the three isotope ratios ( $\delta^{13}\text{C}$ ,  $\delta^{15}\text{N}$ ; Fig. 1) ( $F_{1,130} = 1.041$ ;  $P = 0.377$ ), and are therefore discussed as a single population hereafter. There was a highly significant difference in both  $\delta\text{D}$  and  $\delta^{15}\text{N}$  between birds of Icelandic origin and the Bardsey birds

**Table 1.** Sampling location and size of four populations of Redwing used to investigate the relationship between feather  $\delta^{13}\text{C}$ ,  $\delta^{15}\text{N}$  and  $\delta\text{D}$  values and breeding origin.

Species	Sample site	Breeding origin	n	Collection date
<i>T. i. iliacus</i>	Bardsey, North Wales, UK	Unknown; presumed Continental	111	Oct 1995
<i>T. i. iliacus</i>	Bardsey, North Wales, UK	Unknown; presumed Continental	21	Mar 1998
<i>T. i. iliacus</i>	Farne Islands, Northumberland, UK	Unknown; presumed Continental	10	Nov 2004
<i>T. i. coburni</i>	Iceland	Iceland	20	Sep 2004

( $F_{1,150} > 9.09$ ;  $P \leq 0.003$ ).  $^{13}\text{C}$  did not differ significantly between these two populations. Isotope ratios ( $\delta^{13}\text{C}$ ,  $\delta^{15}\text{N}$  and  $\delta\text{D}$ ) from the Farne Island birds were not significantly different from either the Icelandic or the Bardsey populations, perhaps due to a lack of statistical power.

The highly significant differences in  $\delta\text{D}$  and  $\delta^{15}\text{N}$  between the Bardsey Redwings and the Icelandic birds indicate that this method offers real potential for discriminating between redwings of different breeding origin. The lack of significant difference between the autumn- and spring-sampled Bardsey birds may be expected since, in both cases, the feather isotopic ratios reflect those of the breeding origins. The breeding range of Redwing is known to extend from Iceland to eastern Siberia (Milwright 2002) and the wide range of  $\delta\text{D}$  values birds indicates that they have originated from numerous sites within its range. However, during the course of migration, these birds have subsequently converged into a relatively small area, and whilst the destination of the autumn birds and origin of the spring birds cannot be established, one can speculate that the former were heading for southwest Britain/Ireland, while the latter had overwintered there (Milwright 2002).

A recent study by Hobson *et al.* (2004) indicates that hydrogen isotope ratios in Europe vary with latitude, generally decreasing (i.e. becoming more negative) on a south to north geographical gradient, but that there is little discrimination between the east and west. The next stage of the project is to sample Redwings at representative breeding sites (of different latitudes), to determine whether isotopic ratios of feathers from known breeding sites can be correlated with those collected at overwintering sites. Combining several genetic markers with the stable isotope 'signatures' and biometric data (e.g. Clegg *et al.* 2003, Wennerberg 2001) may reveal population- or regionally-specific groupings and migratory movements as has recently been done with Wilson's Warbler *Wilsonia pusilla* (Clegg *et al.* 2003).

## ACKNOWLEDGEMENTS

We thank Tómas Gunnarsson, The Natural History Society of Northumbria and the National Trust Farne Islands' wardens for their assistance with collecting samples for this project. We thank NERC for providing funding for the project.

Kuijken, E., Verscheure, C., Courtens, W. & Meire, P. 2006. Long-term trends in numbers and distribution of wintering geese in the Oostkustpolders, Flanders (Belgium). *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 508-511.

Long-term goose counts in Flanders, especially in the Oostkustpolders, started in 1959 and still continue on a fortnightly basis. The two main wintering species are White-fronted Geese *Anser albifrons* and Pink-footed Geese *A. brachyrhynchus*. This paper summarises changes in their numbers, distribution, phenology and habitat selection.

Five wintering areas are important: (1) Oostkustpolders, (2) NO-Vlaanderen (Kreken area), (3) Beneden Schelde (lower Scheldt river), (4) IJzervallei and (5) Maasvallei (Border Meuse) (Fig. 1). Pinkfeet occur almost exclusively in (1); Whitefronts also started mainly in (1), but have developed increasing winter populations in the other areas, notably (2) and (4); (5) has been frequented more recently. Other goose species are less important except for Greylag Geese *Anser anser*, which have increased up to 6 000, especially in (1), (3) and (4), partly as a result of increased breeding. Bean Geese *Anser fabalis* mostly appear in small numbers in (2) and (3). Barnacle Geese *Branta leucopsis* rarely reach above 1 000 and prefer the coastal areas in (1), but this species is developing fast-growing feral breeding populations. Dark-bellied Brent Geese *Branta b. bernicla* pass through on migration and only some flocks stop along the coast, mainly in (1).

Pinkfeet in Flanders are increasing faster than the Svalbard population, while Oostkustpolders has become the regular southernmost mid-winter haunt during the last decade, with up to 90% of this population. The actual average maximum is about 35-38 000. White-fronted Geese have not increased as fast as the Baltic-North Sea population, with an average maximum of 25-35 000, representing 2-4% of the estimated total population.

The increase in wintering geese numbers has been affected by the harsh winter of 1978/79, when almost entire populations of Pinkfeet and Whitefronts moved from the north to Belgium and France. Many birds 'discovered' new sites, especially the coastal polders, and with another three hard winters in the 1980s, the birds returned in increasing numbers. A national goose shooting ban was instituted in 1981 and this is still in force, resulting in a further build up of wintering numbers (Fig. 2).

The steady increase of geese in the Oostkustpolders since 1959 has had several consequences on their regional distribution patterns. In the first decade, most birds stayed at Damme (near Bruges), where goose hunting was stopped locally on a voluntary basis. During and after 1978/79 a shift to the west occurred in the coastal areas up to the Oostende region. Whitefronts later

Fig. 2. Winter maxima of White-fronted *Anser albifrons* and Pink-footed Geese *A. brachyrhynchus* in the Oostkustpolders, (Flanders, Belgium) 1959-2003.

Fig. 3. Phenology of wintering geese in the Oostkustpolders based on fortnightly counts; example of 2002/03.

‘discovered’ the IJzervallei (site 2 in Fig. 1): this species is much more mobile than Pinkfeet, which show a high fidelity to the Oostkustpolders site.

The distribution dynamics of the geese changed when the carrying capacity of traditional wintering grounds was reached and an overflow to secondary haunts started in the mid seventies (Kuijken 1969, 1975). This then led to shifting processes with cyclic use of feeding grounds (Meire *et al.* 1988, Meire & Kuijken 1991). In recent times most of the suitable wintering areas in the Oostkustpolders (ca 30 000 ha) are visited from the beginning of the season, and the intensive exchanges between sites no longer have a clear cyclic character.

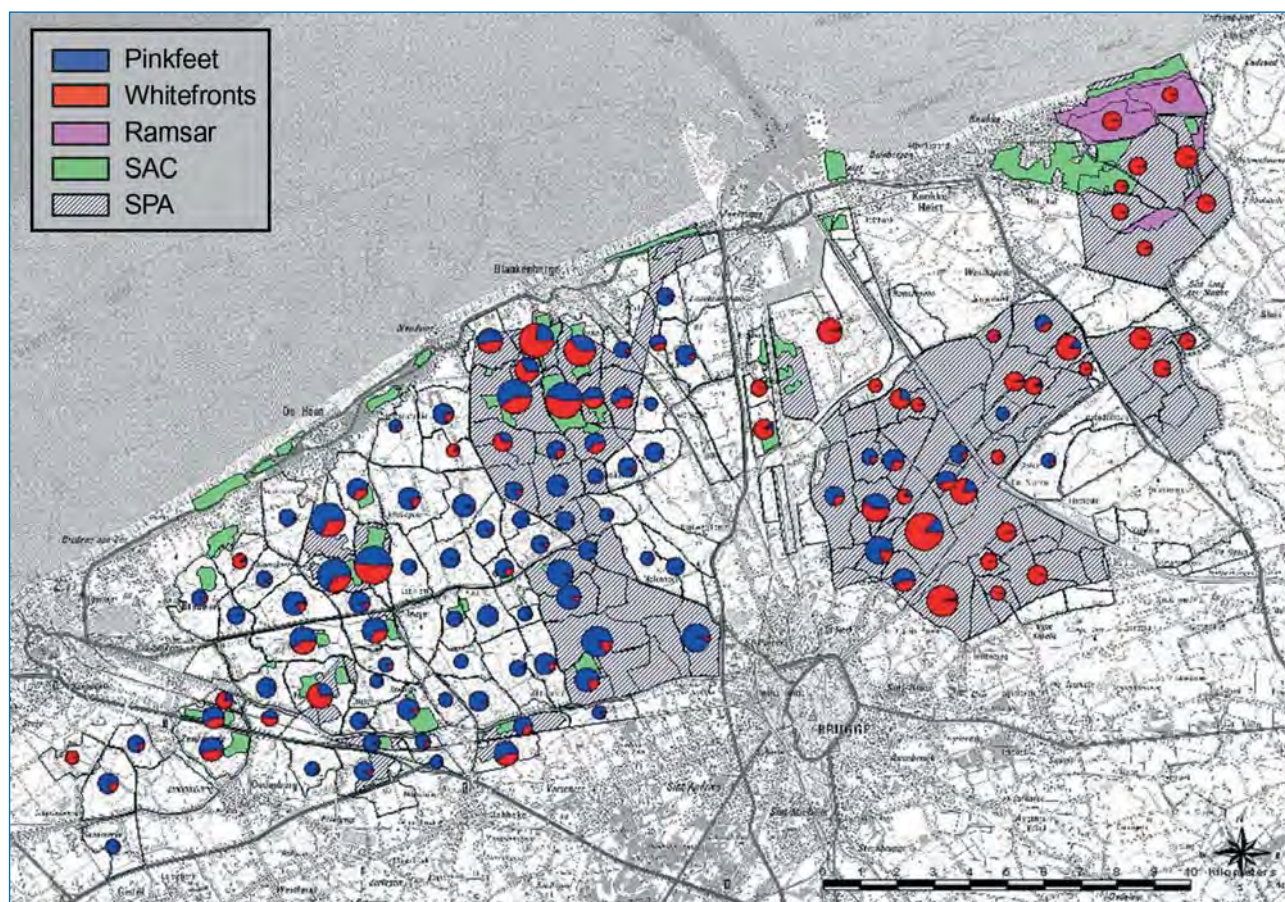

In Fig. 3, the counts for winter 2002/03 show an average phenology for both species, with the peak number dates differing by almost one month. Also the distribution tends to show inter-specific avoidance the more numbers increase (Fig. 4).

Research is continued on feeding ecology, influence of disturbance and changes of agriculture, especially in the coastal polders (Kuijken *et al.* 2001). There has been an important loss of the preferred habitat, “permanent semi-natural wet grasslands with micro-relief”. Both goose species started using arable land more frequently. Integrated protection of traditional polder grasslands is a real need for wintering geese, breeding meadow birds and botanical diversity as important conservation values are threatened by the intensification of agriculture.

The goose shooting ban resulted in less disturbance and enabled a spontaneous goose distribution to the most suitable

**Fig. 4.** Distribution of geese in Oostkustpolders and protection status of wintering grounds; most core areas (large circles) are classified under European Union’s nature Directives as either Special Protection Areas and/or as Special Areas of Conservation (Natura 2000); note some segregation of Pink-footed and White-fronted Geese.

sites without overall agricultural damage, as the total wintering area increased more than the goose numbers themselves. On average the grazing pressure is c. 200 goosedays/ha, with a maximum duration of stay of 4.5 months, and with peak numbers above 10 000 during only 10 weeks. As most geese stay on permanent grasslands (on average 85-95%), the amount of damage to agricultural crops is very limited.

In most winters 90% of the geese have left the Oostkustpolders when spring regrowth of vegetation starts - Pinkfeet especially can leave as early as mid-January, although normally mid- February. Only exceptionally do birds return (pers. obs. 1996).

The effects of the shooting ban caused a change in distribution of wintering geese preferring grassland complexes, the core areas of which have been protected as shown in Fig. 4. A proposal to designate parts of the Oostkustpolders as a new Ramsar site was not finalised. The IJzervalley floodplain is designated as both a Ramsar site and as a Natura 2000 site. For both sites the presence of geese was one of the main criteria.

The Flemish Ecological Network also includes goose areas, and specific projects aim to restore old permanent grasslands, hopefully helping to unify former extensive complexes as optimal habitats for wintering waterbirds and thus avoid conflicts

with agriculture. Finally, some core polders are partly managed as nature reserves (Damme, Uitkerke, Blankaart & IJzervalley etc.) and contribute to the public interest for wild geese.

Krasnov, Yu., Gavrilov, M., Nikolaeva, N., Goryaev, Yu. & Strøm, H. 2006. East-Atlantic flyway populations of seaducks in the Barents Sea region. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 512-513.

This study provides information on the distribution of nine species of seaducks in Kandalaksha and Onega Bays, in the southern part of the Barents Sea, and the northern part of the White Sea and identifies the principal marine areas important for seaducks (Table 1). The most extensive observations were carried out in varying seasons from 1993-2003. Data were collected using various methods including static observations, land-based line and spot counts, aerial surveys by helicopter and fix-winged aeroplane in both coastal and open waters. The major wintering grounds of seaducks were in open coastal areas of the ice-covered north-west portion of the White Sea and the unfrozen Murman coast of the Barents Sea.

In early April 2003, a 500 km transect of the coastline was surveyed, identifying c. 19 500 Barents Sea Common Eider *Somateria mollissima*, 7 000 Atlantic Steller's Eider *Polysticta stelleri* and 4 500 King Eider *Somateria spectabilis* (Krasnov *et al.* 2004). Long-tailed Ducks *Clangula hyemalis* winter mostly along the western Murman coast (Nygård *et al.*, 1995). The distribution of wintering seaducks appeared to be determined by climatic conditions, particularly the extent of ice (Krasnov *et al.* 2004).

During spring migration most seaducks pass through the area, but during autumn migration the southern Barents Sea and northern White Sea provide important staging opportunities, with principal stopover sites in the eastern Pechora Sea shallows. The Black Scoter *Melanitta nigra* is the most abundant species, with flocks of up to 15 000 birds recorded. Steller's Eider and King Eider were observed during migration from Novaya Zemlya and the Kara Sea to the eastern Pechora Sea. Major

Male Common Eider *Somateria mollissima*. Photo: Colin Galbraith.

moulting concentrations of King Eider (c. 40 000 birds) and Black Scoter were found in shallow areas of the south-eastern Barents Sea, while moulting Common and Steller's Eider were found mostly in the north-western White Sea along the shores of the Kola Peninsula (Isaksen *et al.* 2000, Krasnov *et al.* 2002, Strøm *et al.* 2004). The Terskiy and Murman coasts of the Kola Peninsula support high numbers of three species of eiders and Long-tailed Ducks during their moulting and wintering seasons while the south-east Barents Sea supports migrating scoters and moulting King Eiders. Both areas meet the conditions for recognition as marine Important Bird Areas (IBAs).

The rapidly increasing off-shore oil industry in the Russian part of the southern Barents Sea and the White Sea is considered

a major hazard to seaduck populations. The current system of wildlife conservation in the region is based mainly on a network of special protection areas (SPAs) which cannot guarantee sufficient protection for seaducks and their marine habitats against oil-related hazards in shelf areas. It is essential to identify population connections and the demographic structure of Common Eider sub-populations in different areas of the study region, and to obtain numeric data on eiders wintering in Onega Bay and moulting along southern Novaya Zemlya to support enhancing the conservation of seaduck populations in the region.

# Changes in migration patterns and wintering areas of south Swedish Greylag Geese *Anser anser*

Leif Nilsson

Department of Animal Ecology, University of Lund, Ecology Building, S-223 62 Lund, Sweden.  
(email: leif.nilsson@zoekol.lu.se)

Nilsson, L. 2006. Changes in migration patterns and wintering areas of south Swedish Greylag Geese *Anser anser*. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 514-516.

## ABSTRACT

Neck-banding of Greylag Geese *Anser anser* started in south-western Scania, southern Sweden, in 1984, as a part of a Nordic programme to carry out a detailed study of the migration routes of Greylag Geese from different regions of the Nordic countries. By 2002, 2 347 Greylag Geese had been neck-banded in Scania, and these had resulted in about 14 000 readings of neck-bands from abroad. During the course of the study, there was a northward shift in the main winter quarters from a majority of the geese wintering in south-western Spain to a majority wintering in The Netherlands. During the same period, the timing of the autumn and spring migrations also changed. In 2002, the median arrival date of geese staging in The Netherlands in autumn was about 40 days later than in 1986, while in spring, the geese returned to their breeding areas in Scania about 20 days earlier. The implications of these changes for the population dynamics of the species are discussed.

## INTRODUCTION

The population of Greylag Geese *Anser anser* in Sweden, as in most other countries in north-west Europe, has increased markedly during recent decades (Nilsson *et al.* 1999). Thus the September totals in Sweden are now close to ten times higher than they were when the counts started in 1984 (L. Nilsson unpubl. data). The increasing Greylag Goose populations during the late 1970s and early 1980s led to the establishment of many new concentrations of geese in a number of agricultural areas in the Nordic countries, and this gave rise to conflicts with agricultural interests. In response to this, the Nordic Council for Wildlife Research (NKV) started a neck-banding programme in the Nordic countries in 1984. The main aim of this programme was to study the migration patterns and local movements of Greylag Geese in the four Nordic countries (Andersson *et al.* 2001). The presence of a large number of neck-banded Greylag Geese in the population was used to study various aspects of the ecology of the geese, especially in south-western Scania, in southern Sweden (see, for example, Nilsson *et al.* 2001, Nilsson & Persson 1993, 1994, 1996, Nilsson *et al.* 1997).

When the neck-banding programme started in 1984, the majority of the marked geese migrated from the Nordic countries to staging areas in The Netherlands and then continued on to the traditional wintering areas in the Marismas of Guadalquivir in southern Spain (Andersson *et al.* 2001, Paludan 1973, Lund 1971). Some geese remained throughout the winter in The Netherlands in the first year of the study, but this proportion increased during the period of the study. There were also differences in the migration patterns and wintering areas between the various Nordic study populations. The Nordic project was terminated in the early 1990s (Andersson *et al.* 2001), but neck-banding programmes continued in Norway and south-western Scania, southern Sweden.

This paper provides an updated review of the migration patterns of Greylag Geese from south-west Scania since the joint Nordic analysis (Andersson *et al.* 2001) and, more specifically, attempts to elucidate the changes that have occurred in the migration patterns and wintering areas of the Greylag Geese from Scania, and to analyse these changes in relation to different aspects of the population ecology of the species.

## METHODS

Families of flightless Greylag Geese were captured by driving them into nets at four different breeding lakes in a study area in southern Scania in southernmost Sweden. The study area and methods of capture have been described in other reports from the study (Andersson *et al.* 2001, Nilsson & Persson 1994). During the period 1984-2002, a total of 2 321 Greylag Geese were neck-banded in the study area, comprising 588 adults and 1 733 yearlings.

Intensive observations were undertaken in the study area to establish the presence and return rate of the marked geese on an annual basis and to establish their breeding success. In some years, intensive checks were also undertaken as a part of other local studies. Observations were made in the staging and wintering areas by a network of more than a thousand voluntary observers who regularly checked their local areas. National marking programmes in the various countries along the migration route also co-operated in the study. Furthermore, during several years of the present study, Hakon Persson was undertaking a special study of the geese in Spain.

## RESULTS

Of the 2 321 geese which were marked, 98% of the adults and 86% of those marked as young birds were seen after marking. A total of 467 adults (81% of all those marked and seen after marking) and 1 086 birds marked as yearlings (73%) were encountered abroad, providing information on migration patterns and wintering areas. The largest numbers of observations of marked birds were in The Netherlands, followed by Spain (Fig. 1).

Small numbers of Greylag Geese from Scania were recorded in The Netherlands during the summer, especially during the first years of the study, when Oostvaardersplassen in Flevoland was still the major moulting site for Greylag Geese from Scania (Nilsson *et al.* 2001). During the first two periods of the study (1984-1990 and 1990-1996), the main migration into The Netherlands occurred in October, but in the period 1996-2002, the main arrival occurred in November (Fig. 2). Peak numbers were recorded in October in the first study period, and in November and December in the second and third periods, respectively. Throughout the study, there has been a significant trend in the later arrival of Scanian Greylag Geese in The

**Fig. 1.** Percentages of neck-banded Greylag Geese *Anser anser* from south-west Scania, southern Sweden, that were seen abroad (as a percentage of those seen after marking).

**Fig. 2.** Monthly distribution of observations of neck-banded Greylag Geese *Anser anser* from south-west Scania, southern Sweden, seen in The Netherlands during three time periods. Each individual is included only once per month and year.

**Fig. 3.** Median arrival time (in ten-day periods from 1 August) in The Netherlands of neck-banded Greylag Geese *Anser anser* from south-west Scania, southern Sweden ( $R = 0.92$ ,  $P < 0.001$ ).

Netherlands, the median arrival date now being about 40 days later than it was at the start of the study (Fig. 3).

During the first part of the study, Scanian Greylag Geese had already arrived in their wintering areas in southern Spain in October, after a short stay in The Netherlands (Andersson *et al.* 2001), but the main arrival occurred later in later years (Fig. 4).

**Fig. 4.** Monthly distribution of observations of neck-banded Greylag Geese *Anser anser* from south-west Scania, southern Sweden, seen in Spain during three time periods. Each individual is included only once per month and year.

**Fig. 5.** Percentage distribution of Greylag Geese *Anser anser* from south-west Scania, southern Sweden, in their wintering areas in 1986-2001.

**Fig. 6.** Median arrival time (in ten-day periods from 1 January) of neck-banded Greylag Geese *Anser anser* in the breeding/marking areas in south-west Scania, southern Sweden ( $R = 0.67$ ,  $P < 0.001$ ).

However, it is more difficult to establish the true peak in the occurrence of marked geese in south-west Spain, as the birds often move into areas in the Marismas where the reading of neck-bands is very difficult.

Over the years, there has been a gradual shift in the winter distribution of Scanian Greylag Geese. A higher proportion of

the geese remain throughout the winter in the Dutch Delta area, and fewer birds migrate to Spain (Fig. 5). Some geese now spend the winter on the German North Sea coast, and a wintering tradition has even been established in Sweden, where there has been a wintering population of about 5 000 birds in January in the last few years (L. Nilsson unpubl. data).

The spring migration has also changed. The median date of arrival at the breeding areas is now about one month earlier than it was in the earliest period of the study (Fig. 6).

## DISCUSSION

The changes in the migration pattern of the Scanian Greylag Goose population are not unique. Within the Nordic Greylag Goose Project, a similar change has been noted in the Norwegian population, with the geese now arriving at the staging areas in The Netherlands later than was formerly the case (A. Follestad & L. Nilsson unpubl. data). Similarly, in Sweden, there has been a marked northward shift in the distribution of autumn staging Taiga Bean Geese *Anser fabalis fabalis* in recent years (Nilsson 2000).

The changes seen in the migration pattern of the Greylag Goose, as in other species, can most probably be related to the recent trend in milder winters and earlier springs. In Sweden, the last really cold winter was in 1987; winters since then have been mild or with only short cold periods, at least in southernmost Sweden (Swedish Meteorological Institute Monthly reports). In the province of Scania, mean February and March temperatures show an increasing trend since the goose project started in 1986, but the situation is better described as a marked change in winter temperatures after the cold winter of 1987, with much milder temperatures since then.

Even if milder winters and earlier springs are important factors behind the change in migration patterns, changes in agriculture may also be of importance (Nilsson & Persson 2000). In Sweden, there has been an increase in the acreage of autumn-sown cereals in recent years, offering the geese good feeding conditions after the ploughing of stubble fields and root crops.

It is interesting to speculate what effects these changes in winter distribution and migration pattern can have on the Greylag Goose populations. Nilsson & Persson (1996) found a significantly higher survival rate for Greylag Geese wintering in The Netherlands than for those wintering in Spain. This difference was most probably related to differences in hunting pressure, but it was also found that drought conditions in the Marismas led to higher mortality rates in some years. The difference in the length of the migration is probably of minor importance.

The geese wintering in The Netherlands showed a higher breeding success than the geese wintering in Spain (Nilsson & Persson 1996). The recruitment rate of young geese into the breeding population was, among other factors, also found to be related to the choice of winter quarters by the parents (Nilsson *et al.* 1997). Nilsson & Persson (1994) found a significant relationship between early arrival and high breeding success, and this could be related to the location of the winter quarters, as geese wintering in The Netherlands are in a better position to return early to the breeding areas in Scania than geese wintering in Spain.

To conclude, the results demonstrate the importance of continuing the neck-banding programmes in Europe, in order to monitor and analyse ongoing and future changes in the migration patterns and wintering distributions of European geese in relation to a variety of underlying factors.

## ACKNOWLEDGEMENTS

The Nordic marking programme was started by the Nordic Council for Wildlife Research (NKV), which also funded the programme during the early years. Further support was obtained from the Swedish Environmental Protection Agency, the Carl Trygger Foundation for Scientific Research and the Öresunds Bro Consortium. The catching and marking of the geese was undertaken by Hakon Persson. The study would not have been possible without the participation of over a thousand voluntary observers in many countries who reported their neck-band readings.

## Identifying and characterising the feeding areas of Dark-bellied Brent Geese *Branta bernicla bernicla* in and around Special Protection Areas in the UK

Helen E. Rowell & James A. Robinson<sup>1</sup>

The Wildfowl & Wetlands Trust, Slimbridge, Gloucestershire, GL2 7BT, UK. (email: helen.rowell@wwt.org.uk)

<sup>1</sup>Present address: RSPB Northern Ireland, Belvoir Park Forest, Belfast, BT8 4QT, UK.

Rowell, H.E. & Robinson, J.A. 2005. Identifying and characterising the feeding areas of Dark-bellied Brent Geese *Branta bernicla bernicla* in and around Special Protection Areas in the UK. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 517-518.

In 2003, The Wildfowl & Wetlands Trust (WWT) undertook a survey to identify and characterise the inland feeding areas of Dark-bellied Brent Geese *Branta bernicla bernicla* around the 19 Special Protection Areas (SPAs) in the UK for which it is a qualifying species. The Dark-bellied Brent Goose is a winter visitor to the UK from its breeding grounds in Siberia. Most winter on estuaries with extensive intertidal areas in southern and eastern England. A flyway population increase from 22 000 in 1960/61 to around 300 000 in the late 1990s resulted in a rapid seasonal depletion of natural foods such as eel-grass *Zostera* spp., green algae *Enteromorpha* spp. and saltmarsh plants. This has led to an increase in the use of cropped habitats such as coastal grasslands and cultivated cereal crops.

Nineteen SPAs were selected for the study of Dark-bellied Brent Geese in the UK. These generally included only intertidal areas and those immediately adjacent to them. However, Dark-

bellied Brent Geese are known to rely on inland agricultural habitats for feeding. In general, sites having a low degree of 'naturalness', such as a large proportion of improved agricultural land, have not been selected for SPA classification in the UK, but these areas could be considered the 'most suitable areas' for species such as the Dark-bellied Brent Goose. The regularity of use, and the types of cropped habitats used, by this species around existing SPA boundaries were investigated to inform any subsequent process for site identification and the inclusion of cropped land within existing SPAs.

A questionnaire was sent out to local experts for each SPA requesting information on whether or not Dark-bellied Brent Geese had used coastal/estuarine feeding areas within/around the SPA during the previous five winters (1998/99-2002/03), and which estuaries were visited by birds recorded within the SPA. It also asked for inland feeding areas within/around the SPA to be marked on 1:25 000 maps of the sites. Experts were also asked to estimate the percentage of the total numbers on the site using different inland habitats in autumn, winter and spring, to mark on the map the land use type of each field used by birds, and to indicate the average number of birds within individual fields over the previous five winters.

There were marked differences in the amount and types of information provided for the survey, and general patterns in habitat use across the SPA suite shown by the results should therefore be treated with caution. However, inland feeding was recorded at all sites for which information was provided. The results showed a general pattern of birds feeding on their traditional estuarine habitats after they arrived in autumn, moving inland to feed as the winter progressed and back to estuarine areas in the spring. The site maps showed that, for each SPA, inland feeding areas were generally located just outside the SPA boundary see Fig. 1 for one example. Overall, feeding on permanent pasture was recorded at 38% of sites, on fertilised pasture (63%), on winter cereals (88%), on oilseed rape (38%), on golf courses (19%), on amenity/recreational land (25%), and on other grassed habitats (19%). There were no records of birds feeding on spring cereals.

The proportion of time spent feeding on improved permanent pasture, winter cereals and oilseed rape peaked in winter (Fig. 2). The use of permanent pasture increased through to spring. Birds only used golf courses and amenity/recreational land after November.

A large number of Dark-bellied Brent Geese associated with many SPAs feed on cropped habitats outside the SPA boundary. Consideration should thus be given to the inclusion of these areas within the SPA as part of a functional site for the birds, in

**Fig. 1.** Feeding areas for Dark-bellied Brent Geese in and around Langstone Harbour SPA (boundary indicated by black line) (key to habitats: Yellow-arable, Green-pasture, Red-amenity, Purple-unknown). **Fig. 2.** Mean percentage use of different inland feeding habitats by Dark-bellied Brent Geese in and around SPAs in the UK (bars represent 1 standard error)

keeping with the principle of the 'most suitable territories'. The study also demonstrated that although there is a large amount of information gathered on habitat use by this species, detail varies markedly between sites and information is generally not collected using any standard methodology. To improve monitoring of habitat use for this and other large herbivorous waterbirds, there is a need to develop standardised methods to inform the future conservation and management of site networks.

## Flyways of the East Canadian High Arctic Light-bellied Brent Goose *Branta bernicla hrota*: results of a satellite telemetry study

James A. Robinson<sup>1</sup>, G.A. Gudmundsson & P. Clausen

<sup>1</sup>Present address: RSPB Northern Ireland, Belvoir Park Forest, Belfast, BT8 4QT, UK.

Robinson, J.A., Gudmundsson, G.A. & Clausen, P. 2006. Flyways of the East Canadian High Arctic Light-bellied Brent Goose *Branta bernicla hrota*: results of a satellite telemetry study. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 519.

In 2002, six East Canadian High Arctic Light-bellied Brent Geese *Branta bernicla hrota* were tracked by satellite telemetry from staging grounds in Iceland, via Greenland, to breeding grounds in Canada, and back to wintering grounds in Ireland. This was the first time that this migration route had been tracked. The study confirmed the importance of the west coast of Iceland as a staging area in the spring and autumn and identified areas used briefly by birds on the east and west coasts of Greenland and northeast Canada. The distribution of these geese during the summer was also assessed, identifying the probable locations of breeding and moulting sites. The study also identified some of the threats faced by these geese during migration. One of the geese died from natural causes in Iceland, probably raptor predation, whilst at least one other goose was shot in Canada. The results of the study made media headlines across the world and a web site 'Brent Goose 2002', hosted by the Wildfowl & Wetlands Trust, was designed to enable others to follow the journeys made by these geese. Additional satellite telemetry work is planned for 2004 and 2005 to improve our understanding of the migratory routes of this population of geese.

## A review of the effects of intensive fish production on waterbird breeding populations

Petr Musil<sup>1</sup>

<sup>1</sup> Dept. Zoology, Faculty of Science, Charles University, Vinicna 7, CZ-128 44 Praha 2, Czech Republic. (email: p.musil@post.cz)

Musil, P. 2006. A review of the effects of intensive fish production on waterbird breeding populations. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 520-521.

The breeding populations of most water bird species in the Czech Republic increased until the 1970s and then dropped. Fishpond management has been shown to be an important factor, and this paper summarizes current knowledge about effect of fishpond management on waterbird breeding populations.

In the Czech Republic, breeding populations of many resident water bird species (e.g. Black-necked Grebe *Podiceps nigricollis*, Gadwall *Anas strepera*, Pochard *Netta rufina*, Marsh Harrier *Circus aeruginosus*, Black-headed Gull *Larus ichthyaetus* have increased during the past 100 years, whilst species such as Mute Swan *Cygnus olor*, Tufted Duck *Aythya fuligula*, Red-crested Pochard *Netta rufina* and Goldeneye *Bucephala clangula* have started to breed, frequently in new areas (Hudec & Černý 1977, Hudec 1994). However, since the early 1980s numbers of grebes, ducks, coots and Black-headed Gulls started to decline. By the mid 1980s, the population of several duck species had declined by 30%. Moreover, the gradual decline in the size of the breeding population of other species (e.g. Teal *Anas crecca*, Garganey *Anas querquedula*, Shoveler *Anas clypeata*, Common Snipe *Gallinago gallinago*) continued as the result of changes in landscape use, especially the draining of wetlands (Šťastný *et al.* 1987, Musil & Fuchs 1994, Šťastný *et al.* 1997, Musil *et al.* 2001).

One cause of this decrease may have been the direct effect of fishpond management, especially the negative effect of increasing fish stocks (Musil & Šálek 1994, Musil *et al.* 2001). Fishponds represent the most common wetland type in the Czech Republic, with about 20 000 fishponds covering 50 000 ha. These fishponds are the result of landscape modifications by several generations that have led to the development of shallow, eutrophic water bodies, often over-grown with littoral macrophytes, and thus suitable for breeding, resting or migrating waterfowl. Fish production (mostly Carp *Cyprinus carpio*) was about 50 kg/ha until the end of the 19th century, increasing to more than 1 000 kg/ha from 1950 to 1980.

More recently, the important grazing effect of fish (especially Carp) has been recognised as a factor affecting benthic and plankton communities, the extent of littoral vegetation, and consequently water transparency and chemistry. As a result, there is an overgrowth of phytoplankton, water turbidity increases, and the light cannot penetrate to the deeper water layers where anaerobiosis may occur.

Negative effects of fish stock density on the July density of diving ducks were found by Pykal & Janda (1994) in fishponds in South Bohemia. A similar relationship was also found in Mallard, Gadwall, Pochard, Tufted Duck and Coot in fishponds near Ismaning – an important moulting site for waterfowl in the whole Central European Region (Krosick & Köhler 2000). The numbers and reproductive output of waterfowl in non-fishpond wetlands have also been negatively affected by fish stock density

(Eriksson 1978, Giles 1994). The response of individual waterbird species to competition for food with fish depends on many factors, but the most vulnerable are specialised species requiring certain groups or a certain size of benthic animals (Draulans 1982, Giles 1994; Winfield & Winfield 1994). The survival rate of the flightless young may be affected by the availability of food close to nesting sites (Cox *et al.* 1998, Sjöberg *et al.* 2000).

A preference for fishponds with younger fish stock and higher water transparency was found in diving duck broods (Musil *et al.* 1997, 2002) and in Little Grebe (Cepák *et al.* 1999) in fishponds of the Třeboň Biosphere Reserve, and in several duck and grebe species (Pavelka & Košťál 2000) in fishponds of the Poodří Landscape Protected Area in North Moravia. Comparisons of habitat selection in adults and broods of Pochard and Tufted Duck (Musil *et al.* 2002, Musil *et al.* in litt.) show that fishponds with younger fish stock and higher water transparency were preferred especially by broods and adults in July (i.e. in the moulting period). On the other hand, larger, isolated fishponds with well developed littoral stands are more preferred in March and April (Musil *et al.* in litt.).

Fishponds currently represent the most important habitat for waterfowl breeding in the Czech Republic (Musil *et al.* 2001). Although any management recommendations have to respect the original purpose of fishponds, fish stock density could be lowered in some selected fishponds, such as those in SPAs or Nature Reserves. The development of natural food supplies (large zooplankton, benthos, littoral fauna) should be supported and the physical characteristics of fishponds improved, especially water transparency.

Fishponds with conditions suitable for breeding waterbird species are those having a fish stock density less than 400 kg/ha and water transparency more than 50 cm. Generally, a typical fish stock composed of Carp should be replaced by a mixed fish stock of Tench and Pike or Perch. The biomass of fish in mixed stock has to be lower in the first year of a two-year cycle (c. 100-150 kg/ha). Fishpond systems should include ponds with fry (i.e. fish hatched in the current year) which may be very important for waterfowl broods moving to habitats with low fish-competition and high invertebrate food availability (Pykal 1995, Musil *et al.* 2001).

## Identification of Common Snipe *Gallinago gallinago* flyways in the Western Palearctic by analysis of ringing recoveries and genetic studies

Saulius Svazas<sup>1</sup> & Algimantas Paulauskas<sup>2</sup>

<sup>1</sup>Institute of Ecology of Vilnius University, Akademijos 2, LT-2600 Vilnius, Lithuania. (email: svazas@ekoi.lt)

<sup>2</sup>Vytautas Magnus University, Vileikos 8, LT-3035 Kaunas, Lithuania.

Svazas, S. & Paulauskas, A. 2006. Identification of Common Snipe *Gallinago gallinago* flyways in the Western Palearctic by analysis of ringing recoveries and genetic studies. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 522-523.

The Common Snipe *Gallinago gallinago* is a common and widely distributed species in the Western Palearctic. It is mostly migratory in Europe, although those breeding in Ireland, UK and maritime countries of Western Europe are only partially migratory or sedentary (Cramp & Simmons 1983). There are major gaps in our knowledge about the flyways of the Common Snipe in the Western Palearctic, notably how breeding and wintering grounds are linked.

As a secretive and widely dispersed bird, the Common Snipe is one of the most difficult species to count within the framework of the International Waterbird Census (IWC). The maximum regional IWC count total of about 20 000 birds is much smaller than 1% of the total European population of the Common Snipe (Gillissen *et al.* 2002). The great majority of ring recoveries are from Western Europe and these are of mainly passage migrants of unknown origin. The main flyways outside Western Europe are poorly known.

A new ringing scheme for the Common Snipe was recently developed by the international association "Migratory Birds of the Western Palearctic" ("OMPO") in Lithuania, NW Russia, Belarus and Poland. In 1998-2003 about 3 500 Common Snipe were ringed and measured, including 486 birds from breeding populations of Lithuania, NW Russia and Belarus (juveniles or adults mist-netted in the nesting territory). A total of 38 ringing recoveries have been reported.

Analysis of recoveries of Common Snipe of Lithuanian origin indicates a tendency of these birds to concentrate in the autumn-winter period along the North Sea coast of France. More than 80% of all recoveries were from northern France (Svazas *et al.* 2002). A similar pattern of recoveries has been reported for Common Snipe ringed in NW Russia (Kharitonov 1998). The great majority of migrating Common Snipe ringed at the Baltic coast of Poland were also recovered in northern France, with some recoveries also from Ireland and Britain (Meissner 2000).

There is a different pattern of recoveries of Common Snipe ringed in Belarus (Mongin 2002): only a few from northern Belarus were from northern France, and southern Belarus breeding birds migrate towards the West Mediterranean region. Ringing data indicate that Belarus is located on a dividing line between two different flyways.

Analysis of the genetic structure of the Common Snipe population was performed to determine possible genetic divergence within different sub-populations of this species. A total of 164 samples were collected for genetic analysis from breeding populations in Lithuania, Belarus and NW Russia, and from migratory/wintering populations in France, Britain and Morocco. The random amplified polymorphic DNA (RAPD) method was applied. Ten primers were used for amplification. Three primers, each consisting of ten base pairs, were effectively used for amplification by means of the RAPD method. All three

primers formed a certain number of fragments of the genomic DNA. The fragments of a different size corresponded to various analyzed sampling units. The value of genetic similarity between different populations was defined calculating the number of common fragments and total number of fragments.

The results of this analysis have revealed that the breeding population in the Eastern Baltic region is very similar, with a high coefficient of genetic similarity (0.888) to the genetic structure of wintering birds collected in northern France (Paulauskas & Svazas 2002). Genetically similar birds were collected in southern France and in breeding sites located in southern Belarus (coefficient of genetic similarity 0.727). Common Snipe sampled in central and eastern France represented a genetically transitional population structure, intermediate between the NW Europe and Central Europe/West Mediterranean populations. The genotype of sub-species *Gallinago gallinago faroeensis*, collected in the Hebridean islands, was significantly different from all other investigated populations.

Combined ring recoveries data and the results of these genetic studies suggest that there are four flyways of the Common Snipe in the Western Palearctic (Fig. 1). The Northeast Atlantic flyway includes breeders from Iceland, the Faeroe Islands and northern Scottish islands, wintering mostly in Ireland and Britain. The NW

**Fig. 1.** Designated flyways of the Common Snipe in the Western Palearctic: Northeast Atlantic flyway (1), North-West Europe flyway (2), Continental Europe flyway (3), and South-East Europe flyway (4).

Europe flyway includes breeders from northern Russia, Fennoscandia, Baltic States, northern Belarus, northern Poland and maritime countries of Western Europe, wintering in northern France, Britain, Ireland and in NW Africa. Results of this study indicate the existence of a distinct Continental Europe flyway, including breeders of central Russia, southern Belarus, western Ukraine and Central Europe, migrating largely towards the West Mediterranean region. According to available direct recoveries, Common Snipe wintering in Central and Western Africa can be ascribed to the Continental Europe flyway (Kharitonov 1998, Rouxel 2000). Kharitonov (1998) has defined the SE Europe flyway, linking breeding grounds of Common Snipe in southern Russia and eastern Ukraine with their wintering sites located in the Black Sea/East Mediterranean region, Eastern Africa and the Middle East.

The designated population limits are very similar to those suggested by Hemery & Nicolau-Guillaumet (1979), from analysis of more than 1 500 recoveries of the Common Snipe in France. The suggested NW Europe flyway of the Common Snipe is identical to population limits defined by means of analysis of ring recoveries of Fennoscandian birds (Kålås 1980). Kharitonov (1998) has suggested the existence of two major migratory routes of the Common Snipe in the Western Palearctic: European-West African and Southern Russia and Central/East African/Middle East. These were defined from analysis of nearly 200 ring recoveries available in the former USSR. The data from our study indicate that the European-West African migratory route, suggested by Kharitonov (1998), includes two different NW Europe and Continental Europe flyways.

The defined limits of different flyways of Common Snipe in the Western Palearctic are essential for conservation and wise management of this species. A continuous chain of available key habitats stretching throughout the whole flyway is an obligatory condition for the survival of the Common Snipe population (Devort *et al.* 1997, Rouxel 2000).

#### ACKNOWLEDGEMENTS

This study would not have been possible without the support of OMPO who funded field surveys and the genetic study of the Common Snipe in Eastern Europe, and provided samples of Common Snipe for genetic analysis from Western Europe and Africa.

## ABSTRACT

Populations of the Bar-tailed Godwit *Limosa lapponica* embark on some of the longest migrations known among birds. The *baueri* race breeds in western Alaska and spends the non-breeding season a hemisphere away in New Zealand and eastern Australia; the *menzbieri* race breeds in Siberia and migrates to western and northern Australia. Although the Siberian birds are known to follow the coast of Asia during both migrations, the southern pathway followed by the Alaska breeders has remained unknown. Two questions have particular ecological importance: (1) do Alaska godwits migrate directly across the Pacific, a distance of 11 000 km; and (2) are they capable of doing this in a single flight without stopping to rest or refuel? We explored six lines of evidence to answer these questions. The distribution of resightings of marked birds of the *baueri* and *menzbieri* races was significantly different between northward and southward flights, with virtually no marked *baueri* resighted along the Asian mainland during southward migration. The timing of southward migration of the two races further indicates the absence of a coastal Asia route by *baueri*, with peak passage of godwits in general occurring there a month prior to the departure of most birds from Alaska. The use of a direct route across the Pacific is also supported by significantly more records of godwits reported from within a direct migration corridor than elsewhere in Oceania, and during the September to November period than at other times of the year. The annual but rare occurrence of Hudsonian Godwits *Limosa haemastica* in New Zealand and the absence of records of this species along the Asian mainland also support a direct flight, and are best explained by Hudsonian Godwits accompanying Bar-tailed Godwits from known communal staging areas in Alaska. Flight simulation models, extreme fat loads, and the apparent evolution of a wind-selected migration from Alaska further support a direct, non-stop flight.

Note: This paper is an abbreviated version of the original that appeared in the February 2005 issue of *The Condor*.

## INTRODUCTION

The timing of human settlement of the Earth's biomes appears to be related not only to the physical extent of ecological barriers encountered but also to their inhospitable nature. In this sense, the

Pacific Ocean arguably represents the most formidable ecological barrier, with human expansion into the far reaches of Oceania occurring only within the past 3 000-4 000 years (Hurles *et al.* 2003). But does the Pacific Ocean present a similar ecological barrier to birds? Obviously not to those forms adapted for existence on and from the sea. And surprisingly it appears not to for many land-birds, as more of these species have migrations crossing portions of the Pacific than across any other ocean (Williams & Williams 1999). For example, several species of shorebirds migrating from Alaska must cross a minimum of 3 500 km of open ocean before reaching Hawaii, and even large portions of these populations overfly the Hawaiian Archipelago en route to the next available land 3 000 km farther south (Thompson 1973, Williams & Williams 1988, 1990, 1999, Marks & Redmond 1994, Johnson 2003). The limits of such non-stop flights are pushed even further by Red Knots *Calidris canutus* and Bar-tailed Godwits *Limosa lapponica* that migrate northward from south-eastern Australia and New Zealand to staging sites along the coast of the Yellow Sea, a distance of over 8 000 km (Battley 1997, Battley & Piersma 2005, J. Wilson and C. Minton unpubl. data).

Two subspecies of the Bar-tailed Godwit occur in the central Pacific basin (Higgins & Davies 1996, Engelmoer & Roselaar 1998, McCaffery & Gill 2001). The *L. l. menzbieri* population breeds in central northern Siberia and spends the non-breeding season in western and northern Australia. Members of the *L. l. baueri* population nest in Alaska and spend the non-breeding season in New Zealand and eastern Australia. In the Anadyr Basin area of Chukotka, there is a third, much smaller breeding population of unresolved taxonomic affinity (Engelmoer & Roselaar 1998, see Discussion). The *menzbieri* population, numbering about 170 000 birds, appears to migrate both north and south in a two-stage flight with the leg from western Australia to the Yellow Sea and Korean Peninsula entailing a 6 000 km-long non-stop effort (Barter & Wang 1990, Wilson & Barter 1998, J. Wilson and C. Minton unpubl. data), and the southward leg an 8 000 km-long flight from the Sea of Okhotsk (M. Barter pers. comm.). The *baueri* population is slightly smaller (Gill & McCaffery 1999, McCaffery & Gill 2001, Minton in press), and during northward migration birds are thought to undertake a single flight of between 5 000 and 8 000 km (Riegen 1999, J. Wilson and C. Minton unpubl. data). The advent of intensive marking programs initiated

in New Zealand and Australia in the late 1970s (Riegen 1999, J. Wilson and C. Minton unpubl. data) has shown that birds marked within the non-breeding range of *baueri* do not occur along the Asian coast during southward migration. This led Barter (1989) and others (Barter & Wang 1990, Riegen 1999, J. Wilson and C. Minton unpubl. data) to speculate that the southward flight is instead direct across the Pacific, a minimum distance of about 9 700 km to north-eastern Australia and 10 800 km to New Zealand.

Māori folklore lends support to godwits crossing this large ecological barrier. When living on a small Pacific island north of New Zealand, they noticed that the kōaka (Bar-tailed Godwit) migrated every year in a southerly direction. From this evidence, they deduced that land was to be found to the south, and canoes were outfitted for a voyage that eventually led to the discovery of Aotearoa (New Zealand), their new home (Gudgeon 1903, Te Paa 1912, Phillips 1966, Riley 2001).

Building upon these millennia-old observations, our objective here is to answer two fundamental and oft-pondered questions concerning the southward migration of the *baueri* race of the Bar-tailed Godwit: (1) do birds migrate across the Pacific Ocean between Alaska and New Zealand, a distance of 11 000 km, and (2) are they capable of doing this in a single flight without stopping to rest or refuel? We address these questions by exploring six lines of evidence: (1) distributional records and chronology of occurrence of godwits during migration periods; (2) differential resighting rates of leg-flagged birds seen during northward and southward migrations; (3) comparisons between departure and arrival events recorded at migration termini; (4) annual occurrence of a congener, the Hudsonian Godwit *L. haemastica*, in Oceania; (5) analyses of maximum flight ranges; and (6) synoptic weather and wind-field analyses across the Pacific and atmospheric trajectory models at the time of known departures from Alaska.

## METHODS

### Distributional records and chronology throughout Oceania

If godwits undertake a direct trans-Pacific flight from Alaska to New Zealand and eastern Australia, they would be expected to occur in central Oceania either as occasional fall-outs from migrating flocks or at regularly used stopover sites. To assess this, we turned to three principal sources (see Gill *et al.* 2005 for details). Combined, they represent over 300 field assessments (with 568 monthly records) collected since the early 1920s (see Gill *et al.* 2005 for assumptions).

We also assessed seasonal occurrence from census data obtained at sites where counts have been conducted throughout the annual cycle (Gill *et al.* 2005).

### Band recoveries and sightings of leg-flagged birds

We used band recovery and resighting data to assess seasonal migration routes of godwits. The banding databases for godwits contain a combined total of about 14 000 records, including about 10 000 since the early 1980s representing birds on which various colors of leg flags, specific to individual countries or regions, were applied. Much of the information for godwits has previously been summarized by Riegen (1999), Minton *et al.* (2002), and J. Wilson and C. Minton (unpubl. data). Almost annually since the mid-1990s, there have been efforts dedicated to observing marked godwits, both on the migration staging

grounds in Alaska (Gill & McCaffery 1999) and at migration stopover sites in Japan, Korea, and China (J. Wilson and C. Minton unpubl. data).

### Timing of arrival and departure

To assess levels of concordance between periods of departure and arrival, we relied on available seasonal census data from breeding, non-breeding, and migratory stopover sites of both the *baueri* and *menzbieri* subspecies. Most of these studies were conducted independently of each other and focused on site-specific issues and not broad geographic regions or range-wide assessments. Nevertheless, they are of sufficient number and scope that comparisons can be made, especially within the past decade, when we made concerted efforts to document departures from Alaska and arrivals in New Zealand.

### Maximum flight range predictions

For an energy-based evaluation of the proposed 11 000 km-long trans-Pacific flight by godwits, we computed maximum flight ranges (i.e. the distance flown in still-air conditions until the fuel store is depleted) and changes in other variables using an advanced program that encompasses the family of flight-mechanic models presented in Pennycuik (1989). These were later modified to account for use of protein stores during long-distance flights (Pennycuik 1998). The variables used in program FLIGHT and assumptions we make for several of these variables are presented in Table 1 of Gill *et al.* (2005).

### Environmental data

In the previous predictions, we assumed that flight speed was unaffected by winds, but a number of waterbird species staging in south-western Alaska have been shown to have wind-aided southward migrations (see Discussion). To learn if departures of godwits from Alaska were correlated with weather, we looked at synoptic weather and wind-field data from the September–November migration period. From this, we wanted to learn not only what weather characteristics were associated with known departure events, but also the frequency, intensity, and track of storms that occurred throughout the North Pacific during the staging period. This investigation also lead us to look at en route winds, both those associated with departures and those across the central and southern Pacific Ocean. To learn the extent of favorable winds provided by storms during departure, we used a Lagrangian atmospheric trajectory model (CMC 2001).

To assess winds over the Pacific Ocean once birds had departed on migration, we used two sources. For the observed departure in 1987, we obtained data (2.5° latitude x 2.5° longitude grid) from the NOAA-CRIES Climate Diagnostic Center (CDC 2004); for all other departures, we used data (presented by 0.9° x 0.9° grid) from the CMC Global Data Assimilation and Forecast System (CMC 2004). (For this effort, both have been converted to a 10° x 10° grid). Even though it is unlikely that birds migrate at a constant altitude, we simplified our analysis by selecting winds at the 850 mb (c. 1 500 m) level, a general height at which shorebirds in other studies have been shown to migrate (citations in Green 2003). See Gill *et al.* (2005) for additional details.

### Statistical analyses

Reported values are means  $\pm$  SD. For assumptions associated with various statistical tests, see Gill *et al.* (2005).

Airframe mass at start (g) <sup>j</sup>	188, 213, 239

<sup>a</sup> The great circle distance between the most northerly Alaska staging site (Yukon Delta) and the northern tip of New Zealand is 10 700 km; that between the most southerly staging site (Nelson Lagoon) and northern Queensland, Australia, is 9 700 km. We assume godwits follow a great circle route (orthodrome), although a constant compass course (loxodrome route) would likely add little additional distance since the departure and arrival sites occur along a north-south axis.

<sup>b</sup> Based on standard settings in the program Flight and as verified by Pennycuik & Battley (2003).

<sup>c</sup> Changing it to the passerine equation in view of high BMR in many shorebirds (Kersten & Piersma 1987) has remarkably little effect on the model outcomes (see program FLIGHT).

<sup>d</sup> This is the ratio of water released and lost through respiration as dry protein is combusted, assuming that water makes up 69% of wet protein.

<sup>e</sup> Specific to southward migrating *baueri* godwits, with the body drag coefficient and altitude being varied.

<sup>f</sup> Flight speed (i.e. true air speed; see program FLIGHT) is a function of the starting body mass.

<sup>g</sup> Based on a sample of 26 male *baueri* godwits from non-breeding grounds in New Zealand (Battley & Piersma 2005).

<sup>h</sup> Based on a sample of wing tracings of three *baueri* godwits from Alaska (C. J. Pennycuik pers. comm.).

<sup>i</sup> Computed from wing span and aspect ratio.

<sup>j</sup> Based on a variety of body mass and body composition values.

## RESULTS

### Seasonal occurrence, distribution, and numbers of birds in Oceania

We found records of godwits in Oceania during every month of the year (Fig. 1A), but most frequently during the southward migration period (September–November) when 49% of all monthly records ( $n = 254$ ) are attributed. No other month accounted for more than 8% of the total. We found a similar temporal pattern at Suva Point, Fiji, the only site in Oceania at which systematic counts of godwits have been conducted for extended periods (Fig. 1B).

**Fig. 1.** (A) Percentage of total records of occurrence ( $n = 254$ ) of Bar-tailed Godwits *Limosa lapponica* throughout Oceania each month. Numbers above bars show number of records. (B) Number of godwit records during monthly censuses at Suva Point, Fiji; solid bars from Skinner (1983) and open bars from D. Watling (unpubl. data).

The geographic occurrence of godwits in Oceania was widespread, with birds noted from most (77%) of the 30 major archipelagoes and from over 350 different atolls and islands within. Only from central and eastern Polynesia (e.g. Southern Cook, Marques, Austral, Gambier, Line, most of the Tuamotu, and Pitcairn islands) have birds not been recorded.

We also found a significant difference between the southward migration period and the rest of the year ( $21 = 32.4$ ,  $P < 0.001$ ) when we looked at geographic distribution of records in Oceania by season. Most sites where godwits were recorded during the September–November period occurred throughout a corridor linking Alaska and the non-breeding grounds in eastern Australia and New Zealand (Fig. 2). The same pattern was found when total maximum counts per site were compared inside and outside the migration corridor. When adjusted for sites with multi-year records, 93% ( $n = 868$ ) of all godwits noted during the southward migration period came from sites within the likely migration corridor. The proportion increased to 97% when records just outside but east of the corridor (Hawaiian and Cook

**Fig. 2.** Distribution of records of Bar-tailed Godwits *Limosa lapponica* throughout Oceania during the southward migration period (September–November). Filled circles = sites reporting godwits; unfilled circles = sites at which no godwits were noted during the period. Map projection = Orthographic (central meridian = 180; reference latitude = -10). Lateral bounds of stippled region = plotted great circle routes.

islands) were also considered (Fig. 2). Most (87%) of the 868 birds were recorded from four sites in the southern half of the migration corridor: Mankin Atoll (120 birds) in the Tuarua Islands, Rewa River (200 birds) and Suva Point (121 birds) in Fiji, and Chatham Island (314 birds) east of New Zealand (Fig. 2). When these four sites are not considered, the average maximum number of godwits recorded at sites elsewhere in Oceania during southward migration was similar both outside ( $4.6 \pm 7.1$ , range 1–21) and inside ( $2.8 \pm 3.9$ , range 1–20) the corridor (Mann-Whitney *U*-test:  $z = 0.9$ ,  $n = 13, 37$ ,  $P = 0.19$ ).

### Resightings of marked birds

The proportions of color-flagged godwits of the two subspecies that were resighted along the coast of Asia during northward

**Fig. 3.** Timing of southern passage of Bar-tailed Godwit *Limosa lapponica* races *baueri* (unfilled bars) and *menzbieri* (cross-hatched bars) at different locations along their migration route. Filled portions of bars indicate periods of peak passage; dashed lines indicate periods of movement. See Gill *et al.* (2005) for sources.

and southward migrations differed markedly (Table 2;  $\chi^2 = 36.8$ ,  $P < 0.001$ ). On northward migration, both *baueri* and *menzbieri* regularly used intermediate stopover sites; during southward migration, however, *menzbieri* were still commonly sighted along the coast of Asia whereas *baueri*, with but three exceptions, have gone unreported. Sightings of marked *baueri* ( $n = 136$ ; R. Gill and B. McCaffery unpubl. data), but not of marked *menzbieri*, on the Alaska staging grounds from late August through September (1999–2004) further indicate the extent of separation of the two subspecies during southward migration.

### Timing of departure and arrival

The average peak departure of godwits from Alaska and peak arrival in Fiji, New Zealand, and south-eastern Australia occur within a two- to three-week period from late September to mid-October (Fig. 3). Both departure from Alaska and arrival in New Zealand can be earlier, however, as recorded in 2003, when birds were seen leaving during the first week of September (Table 3) and the first arrivals were noted in New Zealand 6–10 days later (A. Riegen and P. Battley unpubl. data). In contrast, the southward passage of *menzbieri* godwits along the coast of Asia and arrival in Western Australia is a month earlier and essentially over before *baueri* godwits depart Alaska (Fig. 3).

**Table 2.** Seasonal distribution of resightings and recoveries of the *baueri* and *menzbieri* subspecies of the Bar-tailed Godwit *Limosa lapponica* along the coast of East Asia during the northward and southward migration. All putative *baueri* were marked on the non-breeding grounds in New Zealand and eastern Australia; *menzbieri* were marked in western Australia (but see footnotes for the few exceptions). See Gill *et al.* (2005) for sources of data.

### Maximum flight range predictions

With a starting body mass of 485 g, a fat mass of 200 g (= 41% body fat), and pectoral muscles adjusted to body mass, male Bar-tailed Godwits would be able to cover 11 000 km under still air conditions only if their body drag coefficient would be as low as 0.05 (Table 4, Fig. 4). Under either assumption for body drag, arrival body mass (213–214 g, or 75% of the lean mass at start) would be reasonable. (Note that Battley *et al.* 2000 found lean mass of Great Knots *Calidris tenuirostris* that arrived after a 5 400 km long flight to be c. 80% of lean mass at departure). Pectoral muscle masses of godwits at arrival (21–33 g) were small, but not unrealistically so (Landys-Ciannelli *et al.* 2003). A body drag coefficient of 0.05 appears to be realistic for godwits, since it produces a more consistent prediction of air speed (18.6 m sec<sup>-1</sup>, or 67 km hr<sup>-1</sup>), i.e. a value that is much closer to empirical values obtained by radar for godwits of the *L. l. taymyrensis* subspecies

during northward migration (18.4 m sec<sup>-1</sup>; M. Green and T. Piersma unpubl. data), than for air speeds (15.6 m sec<sup>-1</sup>) obtained with a body drag coefficient of 0.1 (Table 1).

Reducing body mass by 30 g and leaving fat mass at 200 g (44% fat) enhanced the predicted maximum flight range (Fig. 4), but led to inappropriately low arrival masses and very small pectoral muscle masses (Table 4). Increasing body mass by 30 g lean tissue (39% fat) led to lower maximum flight ranges but also to reasonable values for remaining body and pectoral muscle masses at the point of fat depletion (Table 4). When we decreased pectoral muscle mass at departure to 54 g based on the fraction of body mass measured in the sample of *baueri* from New Zealand (0.111; Battley & Piersma 2005), final body mass was of the right order but pectoral muscle mass (24 g) remaining after the flight was certainly too low (Table 4). When we gave birds with a lean mass of 285 g an extra 30 g of fat (thus

**Fig. 4.** Predicted maximum flight range (the distance to fuel depletion) in male Bar-tailed Godwits *Limosa lapponica*. Plot is a function of body mass (515, 485, or 455 g), variation in the percent fat of body mass at the start of the flight from Alaska (39–44%; with correlated variation in body mass, fat-free mass, and pectoral muscle mass, but with a constant fat load of 200 g), and two values for body drag coefficient (BDC). Solid circles indicate simulations using a BDC value of 0.1; unfilled circles indicate simulations using a value of 0.05. The solid horizontal lines represent great circle distances transited by godwits: the upper line at 10 800 km is the distance between the northernmost staging site in Alaska (Yukon Delta) and the northern tip of North Island, New Zealand; the lower line at 9 700 km is the distance between the southernmost staging site in Alaska (Nelson Lagoon) and Townsville, Queensland, Australia, the suspected northern portion of the non-breeding range of *baueri* in Australia. For a bird with a starting body mass of 485 g, a BDC of 0.1, an average constant flight speed of 15.4 m sec<sup>-1</sup>, but with an average tail wind of 4.5 m sec<sup>-1</sup> for the entire distance, the flight range would be increased by 2 000 km, as indicated by the arrow and broken horizontal line. A similar proportional increase in flight range would occur in birds having a BDC of 0.05 (unfilled circles).

increasing pectoral muscle mass from 72 g to 76 g), they increased their maximum flight range, but reduced final body mass and pectoral muscle mass to quite low values.

#### Departures in relation to weather

Actual departures of birds on southward migration from Alaska were observed on four occasions between 1987 and 2003 (Table 3; Gill *et al.* 2005). Observed departures spanned almost a seven-week period between early September and mid-October (Table 3). All four events occurred in association with moderate troughs with imbedded storms having central pressures between 976 and 998 mb (average 984 mb) and centered between 650 and 1 400 km south of the departure sites (Table 3, Fig. 5). Such storms are propagated in the Aleutian low pressure system along a track that, beginning in September, passes south along the Aleutian Islands and then northward into the Gulf of Alaska. During the period 1976–2000, storms with central pressure of between 975 and 1 000 mb occurred annually along this track on average twice in September, between two and three times in October, and just over three times in November. Local winds during the departure events varied in both direction and intensity, ranging between 0 and 10 m sec<sup>-1</sup> from north to north-east. The positions of the storm centers at the time of departure (Fig. 5) suggest that birds would have to have flown on a slight

west-south-west heading (200–240°) before obtaining maximum benefit from tail winds, but once positioned within the “upstream” side of the systems, birds flying in a southerly direction would have encountered strong direct to quartering tail winds averaging 15 m sec<sup>-1</sup> (mid-point of ranges, Table 3). Winds of this approximate speed and direction would have been maintained on average over a distance of about 1 000 km, with conditions associated with the 1996 departure, for example, extending almost 1 500 km south (Table 3, Fig. 6).

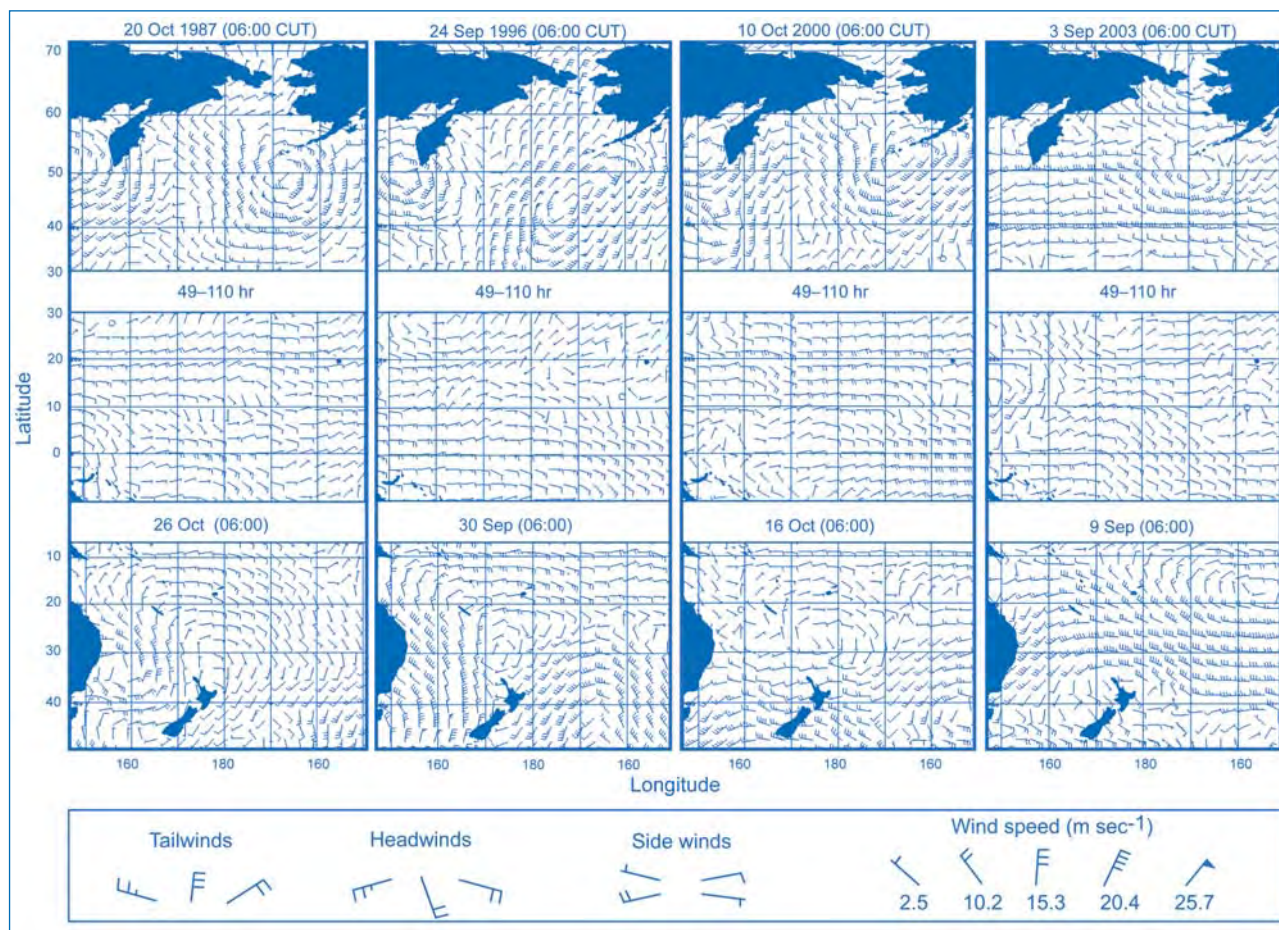

Winds during the mid-portion (latitudes 20° N to 20° S) of each of the four suspected flights (Fig. 5) were very similar and characterized by light (2–8 m sec<sup>-1</sup>) crosswinds or quartering tail to head winds. Once into the southern realm of the south-east trades and austral westerlies at about days five and six of the flight, godwits again experienced strong direct tail or quartering tail winds over the last 1 000 km of the flight, especially if New Zealand was the destination. Any birds attempting to go to eastern Australia during the 2003 event would have experienced moderate to strong head winds from central Queensland south to Victoria, but mostly calm winds if landfall were in northern Queensland (Fig. 5).

#### DISCUSSION

The evidence we present supporting a direct non-stop flight by *baueri* godwits between Alaska and New Zealand is straightforward and compelling: (1) *baueri* godwits are extremely rare along the central East Asian mainland on southward migration; (2) peak southward departure from Alaska and peak arrival in New Zealand occur within the same relatively short period, and both are a month later than for godwits (*L. l. menzbieri*) that do follow a continental Asia route; (3) too few godwits have been noted in Oceania to suggest any regularly used intermediate stopover site(s), but the birds that are recorded there peak in occurrence and number in October and within a direct corridor linking Alaska and New Zealand/eastern Australia when fallout of transients would be expected; (4) the annual occurrence of Hudsonian Godwits in New Zealand and eastern Australia (but their absence from mainland Asia) can best be explained by their accompanying Bar-tailed Godwits on a trans-Pacific flight; (5) birds appear energetically and mechanically capable of such a flight based on current knowledge of aerodynamics and measured fuel sources; and (6) known departures from Alaska coincide with favorable winds for a southward flight but are in opposition to a more south-westerly continental route. Aspects of several of these lines of evidence warrant additional discussion.

#### Factors constraining flight range

The simulations with program Flight suggest that even under still air conditions Bar-tailed Godwits leaving staging sites in Alaska with realistic body and fat mass values should be able to reach New Zealand in a non-stop flight of between 9 800 and 10 700 km. If the godwits are able to use tail winds routinely en route (see below), we can relax the assumption of a body drag coefficient of 0.05 (but see Elliott *et al.* 2004) and accept a value closer to the more often used 0.1 (Kvist *et al.* 2001, Pennycuik & Battley 2003). In addition to fat as fuel, protein availability and water (dehydration) can limit flight range (Klaassen 1995, Jenni & Jenni-Eiermann 1999). For the *L. l. taymyrensis* subspecies during a 4 300 km-long northward flight from western Africa to Europe, Landys *et al.* (2000) concluded that

**Fig. 5.** En route winds (850 mb altitude) associated with the four recorded departures of Bar-tailed Godwits *Limosa lapponica* from Alaska. See Table 3 for location of departure sites. The upper panels represent winds at time of departure ( $\pm 3$  hr, CUT = Coordinated Universal Time), middle panels show typical conditions between the 49th and 110th hr of the flight, and lower panels the conditions at the end (but are also representative of the preceding 24–36 hr). The long, unflagged portion of the axis of each wind bar points towards the direction the wind is blowing; the number and type of short flags perpendicular to the long axis of each wind bar indicate wind speed. The original wind vectors are depicted in knots and converted here to  $\text{m sec}^{-1}$ . The legend indicates the range of directions that would be tail winds, head winds, or side winds along the proposed trans-Pacific migratory corridor between Alaska and eastern Australia and New Zealand.

flights ranging in altitude from sea level to 3 000 m would avoid dehydration, and in fact found no evidence for dehydration in arriving godwits. Interestingly, Landys *et al.* (2000) also had to assume a body drag coefficient as low as 0.05 for the virtual godwits to complete their flight.

Our simulations have made clear that the necessary minimum protein use during non-stop flights does limit maximum flight range. Birds leaving Alaska with a lean mass lower than 275 g are predicted to have exhausted their fat when their lean mass is as low as 200 g and their pectoral muscles have become tiny (Table 4). The small-sized juvenile Bar-tailed Godwits with a lean mass of only 166 g and a fat store of 200 g that died during a collision probably just after take-off on a southward flight (Piersma & Gill 1998) are predicted (using the assumptions listed in Table 1) to be able to cover more than 11 000 km non-stop. Not surprisingly, they are also predicted to arrive with perhaps unrealistically low lean and pectoral muscle masses (for a body drag coefficient of 0.05, lean mass after 11 000 km of flight under still air conditions would be 170 g and pectoral muscle mass 25 g; with a coefficient of 0.1, the predicted final mass values are 130 g and 20 g, respectively). Given such values upon arrival in New Zealand, it seems unwar-

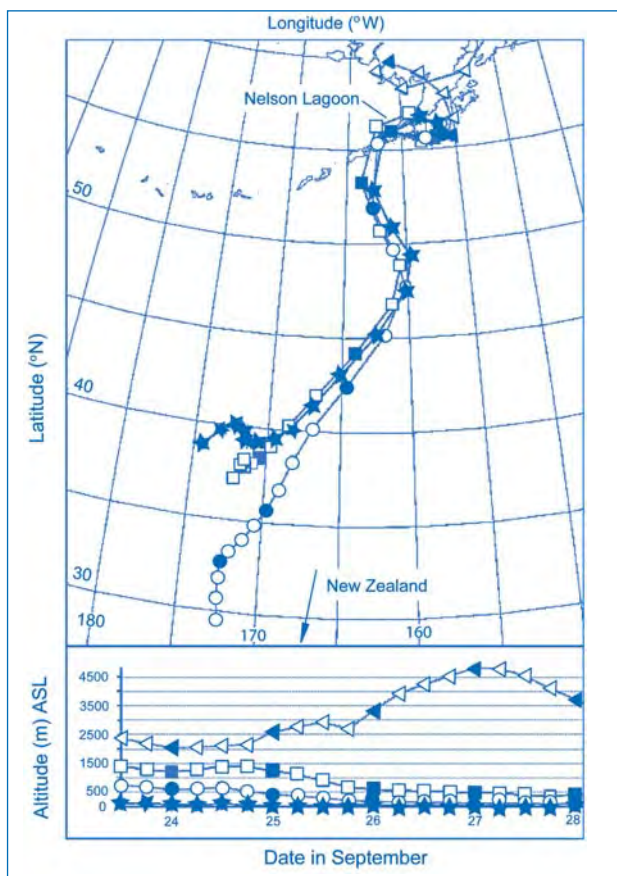

ranted to expect these birds to have been capable of reaching the South Pole, an additional distance of 6 000 km, as predicted by Pennycuik & Battley (2003) who accommodated unrealistic lean mass values. Lowering the minimum energy obtained from protein to 2% does not resolve the problem. In view of the absence of hard data on body composition for adult godwits, and the problematic departure condition of the juveniles from 1987, detailed studies on body condition at departure in relation to performance during the ensuing flight and pin-pointing the exact arrival time in New Zealand are clearly needed.

#### A direct route or one with stopovers?

##### A direct flight by a congener

Hudsonian Godwits breed in subarctic and temperate North America and migrate to southern South America (Elphick & Klima 2002), yet are rare annual visitors to New Zealand (Higgins & Davies 1996, Elphick & Klima 2002) and occasionally elsewhere in Oceania (Watling 2001), with up to nine different individuals seen in a single year. What might explain the regular appearance of this species a hemisphere removed from its normal non-breeding range? It is highly unlikely that the Hudsonian Godwit, although also a long-distance migrant

**Fig. 6.** Air flow over a five-day period for objects entering the air column at Nelson Lagoon, Alaska, at the time of the observed departure of Bar-tailed Godwits *Limosa lapponica* on 23 September 1996. The objects, entered into the air column at various altitudes, are then tracked at successive six-hour intervals; filled star = surface, unfilled circle = 750 m, unfilled square = 1 500 m, and unfilled triangle = 2 500 m elevation above sea level (ASL). Their respective filled symbols denote 24-hour periods. During the initial 60 hours of the model run between Nelson Lagoon and about 40° N latitude, winds at 750 m and 500 m altitude varied between 10 and 15 m sec<sup>-1</sup>. The arrow to New Zealand approximates the direction but not necessarily the route taken.

(McCaffery & Harwood 2000), reaches southern Oceania by following a continental route via the east Asian mainland, a distance of over 16 000 km. Indeed, we could find only a single record of the species from Asia, and that from Chukotka, almost 150 years ago (in Kessel & Gibson 1978). It is also highly unlikely that birds reach New Zealand via a 9 000 km-long flight across the Southern Ocean after an initial flight of 8 000 to 11 000 km from eastern Canada to southern South America. The most logical explanation for their occurrence in New Zealand is that they accompany Bar-tailed Godwits on the godwits' southward flight across the Pacific (see also Kessel & Gibson 1978). Recent observations of small numbers of Hudsonian Godwits (all juveniles to date) support this idea.

### Stopovers

As it is energetically more favorable to cover a certain migration distance in many small steps than in one long hop (Piersma 1987), the assembled evidence that some 150 000 Bar-tailed Godwits annually make an 11 000 km-long non-stop flight from Alaska to New Zealand/eastern Australia begs the question of

why do they not make stopovers, either along the east Asian mainland, if such a route is followed, or during a trans-Pacific crossing. First, the evidence we have assembled fails to support use of a continental route, with or without use of stopover sites. Given the paucity of records of *baueri* along the east Asian mainland during southward migration, if they were migrating along the Asian coast, this would entail a non-stop flight of almost 16 000 km, i.e. 40% longer than a flight directly across the Pacific. Such a long flight is improbable, given the fuel loads of departing godwits and predicted arrival mass upon fuel depletion (contra Pennycuik & Battley 2003). In addition, during the recorded departures, birds would have initially encountered moderate to strong head winds and then a long fetch of strong southerly winds if they had followed a more south-westerly route along the Asian mainland. Such a flight would have forced birds either to fly into opposing winds or to detour around the systems, both of which would have added substantially to energetic costs.

We likewise found no evidence suggesting use of intermediate stopover sites if birds followed a direct route across the Pacific. Arguably, the Pacific Ocean is vast and it could harbor yet undiscovered stopover site(s), but the region has received considerable attention from ornithologists, and its indigenous peoples are intimately in tune with their natural resources. We find it beyond reason to expect the annual use by 150 000 godwits at stopover site(s) in Oceania to have gone undetected by either group of people. Indeed, the 80-year span of records that we searched accounted for a total of only about 4 000 godwits having been recorded throughout all of Oceania – this from a projected total of some 12 million godwits that could have stopped somewhere en route during this period. Although we cannot rule out that birds alight on open ocean waters during transit, it is likely that this would be for relatively short periods and then related to adverse conditions (Piersma *et al.* 2002) and not for rest.

Thus, a single flight over the Pacific is not only likely but in several ways advantageous as it may be safer (there are rarely aerial predators in central Oceania; cf. Ydenberg *et al.* 2002), healthier (as encounters with pathogens will be avoided; Piersma 1997), and faster and more direct (as the time required to settle at new stopover areas is avoided; Alerstam & Lindström 1990). It could also indicate the high quality of the western Alaskan staging sites relative to potential staging/stopover areas along the east Asian coastline or throughout Oceania (Gill & Handel 1990, Gudmundsson *et al.* 1991). Indeed, soft substrate intertidal habitat, the preferred feeding substrate for non-breeding godwits, is extremely limited throughout Oceania, occurring mostly on Fiji, the one site in Oceania that regularly hosts godwits (Watling 2001). See Gill *et al.* (2005) for a more detailed discussion of this topic.

### The role of wind systems over the Pacific

The *baueri* subspecies of the Bar-tailed Godwit can be added to a growing list of birds that have evolved wind-sensitive migration strategies, especially southward migrations, within the subpolar marine low pressure belt that circles the Northern Hemisphere (Richardson 1979, Åkesson & Hedenström 2000, Green 2003, M. Green and T. Piersma unpubl. data). This phenomenon is especially evident in the North Pacific, where the Aleutian low pressure system shapes and dominates weather and wind patterns

throughout the year (Christoforou & Hameed 1997, Overland *et al.* 1997). In particular, two taxa of large-bodied, medium-distance migrant geese, the Brent Goose *Branta bernicla* and Cackling Canada Goose *B. canadensis minima*, annually initiate trans-oceanic flights from the Alaska Peninsula to the Pacific coast of North America in conjunction with the passage of moderate to strong low pressure systems (Dau 1992, Gill *et al.* 1997). Not surprisingly, even small-bodied birds, such as the Dunlin *Calidris alpina*, with similar non-breeding ranges often depart on the same weather systems as those used by geese (Warnock & Gill 1996, R. Gill unpubl. data). The emerging pattern is that godwits, geese, and Dunlin can use the same storms, only varying their departures in accordance with the position of the storm center and the birds' final destination.

Evolving a migration system in conjunction with winds at the departure site is one thing, but in the case of godwits which are crossing the entire Pacific, they must pass through at least five other latitudinal zones of defined winds and pressure. It is beyond the scope of this paper to present a thorough analysis of wind conditions along the entire projected flight path (cf. Piersma & Jukema 1990, Piersma & van de Sant 1992, Åkesson & Hedenström 2000). However, what emerges from the four cases we studied suggests that winds were generally favorable throughout the migration corridor during the calculated six-day transit time, and certainly in no instance was there strong opposing wind for any appreciable distance. The most obvious question relating to this is to what extent local departure cues are related to favorable "downstream" winds. Is weather across the Pacific structured (teleconnected) such that certain departure cues at northern latitudes translate to assure relatively favorable conditions along most of the route (McCaffery & Gill 2001)? The Aleutian low pressure center is a large-scale dominating feature of the North Pacific (Christoforou & Hameed 1997, Overland *et al.* 1997) that has obviously shaped the evolution of equally large-scale geographical migration patterns similar to systems described elsewhere in the Northern Hemisphere (citations in Green 2003). However, the godwits' migration strategy, involving flights that span hemispheres, is unlikely to have been selected for solely on the basis of factors occurring over just a portion of the range and independently of those elsewhere along the migration corridor.

This raises obvious questions about global climate change and its affects on wind regimes and thus on wind-selected avian migrants. The ecological effects of climate fluctuations are many, and are projected to be most profound in regions with large-scale patterns of climate variability such as the North Atlantic and North Pacific (Stenseth *et al.* 2002). Models of global climate change suggest an intensification of propagating weather systems moving across the North Pacific. Such would result in a shift of the Aleutian Low center eastward that would in turn increase the number and intensity of storms and bring stronger northerly winds over a longer fetch on the backside of individual low pressure centers. Godwits may, however, be able to adapt to this as the Aleutian Low and adjacent Hawaiian High have been found to shift position and intensity (seesaw pattern) on a decadal scale during most of the twentieth century (Christoforou & Hameed 1997, Overland 1999). The phenomenon, however, also needs to be assessed in the Southern Hemisphere as well in terms of the teleconnection patterns between the two hemispheres.

Development of suitable remote-sensing satellite technology would greatly enhance our understanding of the complexity of the godwits' migration system and flight behaviour of long-distance trans-oceanic migrants in general. With such technology, answers would be forthcoming to questions about (1) mechanisms of orientation, (2) how birds select winds (vertical and lateral) at all stages of the flight, (3) whether they adjust air speed for wind drift, (4) whether they adjust air speed during the course of the flight, and (5) the extent to which they can assess and react to changes in downstream flight conditions.

## ACKNOWLEDGMENTS

This work benefited from numerous discussions with colleagues throughout the Pacific basin, including M. Barter, D. Rogers, and C. Minton in Australia; P. Battley in New Zealand; G. McCormack in the Cook Islands; P. Tomkovich and Y. Gerasimov in Russia; and C. Dau, C. Handel, B. McCaffery, and D. Ruthrauff in Alaska. Unpublished information on the occurrence of godwits throughout Oceania was provided by P. Bruner, P. Donaldson, W. Johnson, J. Marks, G. McCormack, R. Pyle, F. Ward, and D. Watling. A cadre of New Zealanders helped assess the arrival of godwits following observed departures in Alaska, especially P. Battley, H. and Z. Clifford, T. Habraken, D. Lawrie, D. Melville, R. Schuckard, and B. and B. Woolley. M. Whalen helped prepare our graphics. Earlier versions of the manuscript benefited by comments and suggestions from P. Battley, M. Barter, D. Dobkin, R. Drent, C. Handel, M. Klaassen, C. Minton, L. Tibbitts, and two anonymous reviewers.

### ABSTRACT

Identifying demographic mechanisms is fundamental to understanding the causes of population change in waterbirds. This may be relatively easy for static breeding and wintering populations, but populations of mixed breeding or wintering origin often occur in stopover sites in spring and autumn, and thus estimates of survival and recruitment from these areas are inevitably representative of all the birds marked, rather than individual populations. We used stable isotope analysis of flight feathers to identify the different wintering populations of Red Knot *Calidris canutus rufa* that passed through Delaware Bay, north-eastern USA, in the springs of 2004 and 2005. Here, they feed and fatten on an abundance of Horseshoe Crab *Limulus polyphemus* eggs before flying to their Arctic breeding areas.  $\delta^{13}\text{N}$  values separated birds from wintering areas in southern South America ("southern" birds) and Brazil/south-eastern USA ("northern" birds). Northern birds were further separated using  $\delta^{13}\text{C}$  values. Approximately 55% of the birds caught within Delaware Bay were from the southern population, 22.5% from Brazil, and 12.5% from the south-eastern USA, while 10% were of unknown (although most likely "northern") origin. At a site on the Atlantic coast of Delaware Bay, where only Mussel *Mytilus* spp. spat were available, the proportion of short-distance migrants from the south-eastern USA was much higher, and is most likely related to their shorter-hop migration strategy that allows them to take advantage of this hard-shelled prey resource.

### INTRODUCTION

The migration of shorebirds is one of the most inspiring and impressive spectacles in the natural world. The Red Knot *Calidris canutus* is a flagship species among long-distance shorebird migrants. In the Americas, populations winter in the

south-eastern USA, in northern Brazil and the Caribbean, and at sites in Tierra del Fuego and Patagonia. In order to reach breeding grounds in the Canadian Arctic, some individuals make an annual round-trip of 30 000 km. For these birds, Delaware Bay is the last major northward staging site where they join hundreds of thousands of other shorebirds to feed on the eggs of Horseshoe Crabs *Limulus polyphemus*. During a 10-14 day stopover, Red Knots increase their body mass by over 70%, gaining the fuel for their final non-stop flight to the breeding grounds.

Over the past five to ten years there has been a dramatic reduction in the numbers of Red Knot passing through Delaware Bay (Baker *et al.* 2004), with similar declines noted in the South American wintering areas (Morrison *et al.* 2004) but apparently not in the relatively poorly known population wintering in the south-eastern USA (Niles *et al.* in prep.). For a species that makes such long distance migrations to tight deadlines (Piersma *et al.* 2005), there are many potential pressure points in the annual cycle.

One of the major aims of a study, initiated in 1997, is to determine the causes of the change in the Red Knot populations of the West Atlantic Flyway by marking individuals and using survival and recruitment models (White & Burnham 1999) to estimate demographic rates. However, one of the problems of studying birds on passage sites is that individuals from several different populations may mix. Ideally, demographic rates would be estimated for each population separately, thereby enabling better understanding of the issues under study. This requires a means of assigning individuals to different populations, which in the case of shorebirds is often difficult owing to no single clear distinguishing feature. Morphometrics and genetic markers can sometimes partly or wholly distinguish different subspecies of shorebirds (Wenink

*et al.* 1994, Baker 2002) but not individual birds. One technique, used successfully in other species, is measurement of light element stable isotope ratios in feathers (Chamberlain *et al.* 1997, Hobson 1999, Webster *et al.* 2002, Bearhop *et al.* 2005).

Using carbon and nitrogen stable isotopes in flight feathers from a pilot sample of 100 individual Red Knots sampled in Delaware Bay in spring 2003, Atkinson *et al.* (2005) showed that birds from at least four different wintering populations passed through Delaware Bay in spring 2003. The basic technique involves measuring isotope ratios in feathers moulted in known wintering areas, then deriving comparable figures from individuals caught in Delaware Bay so that they can be assigned with confidence to one of the wintering areas. This paper develops and applies this method to 1 220 and 947 individual Red Knots caught during spring staging in Delaware Bay in 2004 and 2005, respectively. We determine the proportion of birds originating from the major wintering areas, and seek to give guidance on the use of stable isotopes in migration studies.

## METHODS

### FEATHER SAMPLING AND ISOTOPE ANALYSIS

To determine the wintering area of birds caught in Delaware Bay, we took a sample of the sixth primary covert, measured ascendantly, from each bird caught. This feather was used because it is moulted at the time of the birds main primary moult and is likely to be indicative of the main wintering area (for full details see Atkinson *et al.* 2005). Each feather was washed in a solution of 0.25M sodium hydroxide to remove dirt and grease, rinsed thoroughly in distilled water, then dried overnight in an oven at 75°C. Each sample was finely chopped using surgical scissors into pieces no longer than 2 mm in length, and between 0.5 and 1 mg of each feather was accurately weighed into tin capsules and loaded into an automatic sampler. Stable isotope ratio measurements of carbon and nitrogen were made using CF-IRMS (Continuous Flow Isotope Ratio Mass Spectrometry). All stable isotope values are reported in permil (‰) using the delta (δ) notation:

$$\delta \text{ isotope} = \left[ \left( \frac{R_{\text{sample}}}{R_{\text{standard}}} \right) - 1 \right] \times 1000$$

where δ isotope is the sample isotope ratio (<sup>13</sup>C or <sup>15</sup>N) relative to a standard (traceable to a primary international standard), and R is the ratio of heavy to light isotopes (<sup>13</sup>C/<sup>12</sup>C or <sup>15</sup>N/<sup>14</sup>N) in the sample or standard. δ<sup>13</sup>C and δ<sup>15</sup>N are reported relative to their primary international standards, namely Pee Dee Belemnite (V-PDB) and atmospheric nitrogen (V-AIR), respectively. Routine measurements were precise to within 0.1‰ for δ<sup>13</sup>C and 0.3‰ for δ<sup>15</sup>N.

### STATISTICAL ANALYSIS

First, a small number of sub-adult birds were identified by having a carbon isotope signature (δ<sup>13</sup>C < -19.5‰) typical of the freshwater systems where their feathers were grown. These birds were therefore hatched in the previous summer and were approximately 10–11 months old. A two-stage process was then used to estimate the origins of adult birds caught in Delaware Bay in 2004 and 2005: first, birds were divided into northern or southern winterers; second, northern winterers were divided into those of USA or Brazilian/Caribbean origin.

Atkinson *et al.* (2005) showed that there was a clear division in the values of δ<sup>15</sup>N between birds wintering in Patagonia and

**Table 1.** δ<sup>13</sup>C values of primary coverts of adult Red Knot *Calidris canutus* known to belong to the two northern wintering populations based either on birds caught or individually-marked birds observed in the wintering areas. Winter refers to the boreal winter in which the coverts were grown.

Winter	Brazil	n	Florida/Georgia	n
2003/2004	-16.06 ± 1.06	8	-17.31 ± 0.8	18
2004/2005	-15.3 ± 1.03	33	-16.58 ± 0.41	19

Tierra del Fuego (δ<sup>15</sup>N > 13.5‰, termed “southern” birds) and elsewhere (δ<sup>15</sup>N < 13.5‰, termed “northern” birds). Northern birds comprise two geographically distinct populations, in the southern-eastern USA and Brazil, but the isotope signatures of birds from each overlap. We therefore calculated the mean and SD of the δ<sup>13</sup>C values of birds known to winter in each area from birds either caught there (33 birds caught in Maranhão State, Brazil, in November 2004 and February 2005) or observations of known individuals which had been sampled the previous spring in Delaware Bay (Table 1). To estimate the proportion of individuals originating from each wintering area, we assumed that the distribution of δ<sup>13</sup>C values of northern birds caught in Delaware Bay was a composite of two overlapping normal distributions, one of δ<sup>13</sup>C values from Brazilian birds and the other of δ<sup>13</sup>C values from birds from the south-eastern USA. We used a least squares method to fit two normal curves (based on the means and SDs of δ<sup>13</sup>C values of birds from known wintering areas) to the observed frequency distribution of the δ<sup>13</sup>C values from birds in Delaware Bay. δ<sup>15</sup>N values were not used, as there was little difference between the two means. We excluded any outlying “northern” type birds that had δ<sup>13</sup>C or δ<sup>15</sup>N values more than 2 SD from either of the two known reference sample means, and classed these birds as unknown. The proportion of birds from each wintering area was adjusted until the overall sum of squares of the observed minus estimated numbers for each δ<sup>13</sup>C category was minimized. As isotope values may differ annually, year-specific values of δ<sup>13</sup>C were used. This method gave a means of estimating the relative proportion of birds from Brazil versus the south-eastern USA, but did not permit individual northern birds to be allocated to one of these populations, although it was, of course, possible to assign the probability of belonging to each population based on the δ<sup>13</sup>C values.

## RESULTS AND DISCUSSION

### Origin of the birds passing through Delaware Bay in 2004 and 2005

In both 2004 and 2005, stable isotope ratios of individual Red Knots separated well (Fig. 1) according to the divisions used by Atkinson *et al.* (2005). Sub-adult birds (i.e. birds < 1 year old) made up a small proportion of the total birds caught in Delaware Bay, with 28 individuals in 2004 and 31 in 2005. Averaged across the two years, 51.8% of the adult birds were from the southern population (Tierra del Fuego/Patagonia) and 48.2% were from the northern population (south-eastern USA/Brazil and other as yet unknown areas). Approximately 20% of northern adults deviated by > 2 SD from the δ<sup>13</sup>C and δ<sup>15</sup>N means of birds from known wintering areas (Fig 1, box) and

**Fig 1.** Plots of  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  values of Red Knot *Calidris canutus* caught in Delaware Bay in (a) spring 2004 and (b) spring 2005. Southern birds refer to the population wintering in Patagonia and Tierra del Fuego; northern, to those wintering in north-western Brazil, the Caribbean and the south-eastern USA.

**Table 2.** Wintering origin (numbers and percentage) of adult and sub-adult Red Knot *Calidris canutus* caught on passage in Delaware Bay in spring 2004 and 2005. Unknown refers to northern wintering birds whose  $\delta^{13}\text{C}$  values were outside the range of the Brazilian and south-eastern USA wintering population. (Sub-adults are birds less than one year old and still with juvenile primary coverts grown soon after hatching).

Year	Number of individuals		Southern adults	Northern adults		
	Adults	Sub-adults		SE USA	Brazil	Unknown
2004	1 192	28	669 (56.1%)	150 (12.6%)	262 (22.0%)	111 (9.3%)
2005	916	31	434 (47.4%)	206 (22.5%)	185 (20.2%)	91 (9.9%)

were labelled as of unknown origin. Decomposition of the frequency distribution of  $\delta^{13}\text{C}$  values of the remaining northern birds then divided into approximately 45:55 south-eastern USA to Brazil (Fig. 2). These translate into proportions of the Delaware passage population as 21.1% from Brazil, 17.6% from the south-eastern USA and 9.6% unknown, with mostly small differences between years (Fig. 1, Table 2). There was one major difference in the composition of the catches between years. More birds with a south-eastern USA origin were caught in 2005 than in 2004, due to a change in catching locations. In 2004, all individuals were caught within the confines of the bay

itself, whereas in 2005, catches were also made on the beaches and marshes on the Atlantic coast of Delaware Bay. These latter catches contained a much higher proportion of the shorter-distance migrants from the south-eastern USA.

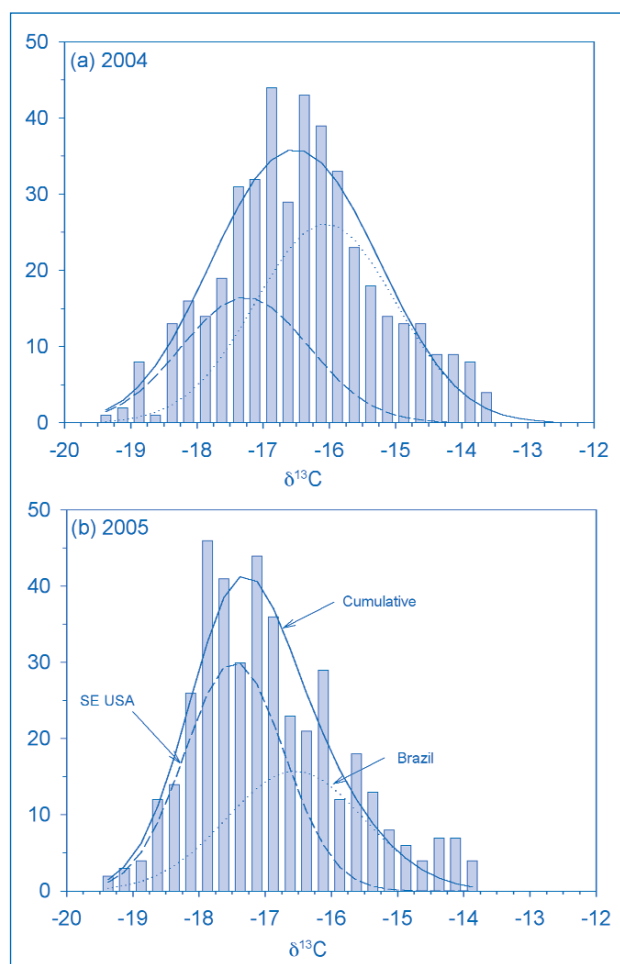

Prior to this study, it was originally thought that the majority of the birds passing through Delaware Bay were from the populations wintering in Tierra del Fuego and Patagonia. However, the stable isotope data indicate that in 2004 and 2005 only approximately half of the individuals were from there.

#### Use of stable isotopes in studies of birds on passage sites

These results show that the use of stable isotopes can be an extremely useful tool for assigning individual birds to distinct populations in cases where these populations have distinct stable isotope signatures. In this case, birds from very different geographical areas (northern and southern groups) were distinguishable. As a tool for population biologists, this is extremely useful because it may help to explain the basis of heterogeneity in survival and re-sighting rates, and opens the door to calculating population-level demographic parameters from mixes of populations. For instance, in coming years it will be possible to evaluate survival, recruitment, passage times and staging behaviour for specific Red Knot wintering populations, thus helping to elucidate the causes of declines and best management for recovery.

To use stable isotopes successfully in this way, it is necessary to collect reference material from known wintering areas, and this is labour-intensive if the species in question migrates to many different areas. Fortunately in this case, Red Knot are only known to winter in a small number of well-known and well-studied sites, although even for this species, around 10% of the passage birds in Delaware Bay were classed as unknown. This is not to say that they are necessarily from different wintering locations, but these unknowns could be birds adopting a different diet or moulting at a different time of year. Indeed they might be two year old birds. Isotope ratios vary temporally in response to, for example, changing seasons, and Red Knot in their first year of life do not return to the breeding grounds the following summer. Instead, they remain on or near the wintering areas and tend to undergo a full primary moult several months earlier than the adults returning from the breeding areas. Although poorly understood at present, this is likely to be the explanation for the “unknown” northern signatures and will be the subject of further study.

As well as discriminating between locations separated by large geographical distances, isotope ratios may change over a relatively small scale. Isotope signatures from Red Knot known to winter in Bahia Lomas in Chile and Rio Grande in Argentina,

**Fig. 2.** Frequency distribution of  $\delta^{13}\text{C}$  values from adult Red Knot *Calidris canutus* of the “northern” wintering population captured in Delaware Bay during spring passage in a) 2004 and b) 2005. Bars show the actual frequency distribution; lines show the individual fitted normal curves from reference samples, and cumulative fitted curve for south-eastern USA and Brazilian birds.

Red Knot *Calidris canutus rufa* at Delaware Bay, May 2006. Photo: Rob Robinson.

approximately 160 km apart, are found to be very different (Atkinson *et al.* 2005). This is most likely due to the fact that the city of Rio Grande is at the head of the estuary and discharges from the city are likely to alter  $\delta C^{13}$  and  $\delta N^{15}$  values in the sediments surrounding the estuary. In this case, such differences are useful. This also prompts caution in applying broad-scale isotopic gradients to large areas without knowledge of the processes operating on the ground.

This method relies on birds growing feathers or other tissues in areas with predictably different isotope ratios. For species that are more widespread in winter, or use similar habitats in different locations, such clear-cut results may not be achieved. For example, in a study of the American Golden Plover *Pluvialis dominica* and Pacific Golden Plover *P. fulva*, feathers grown in the wintering grounds showed no differences in  $\delta D$ ,  $\delta^{13}C$  and  $\delta^{15}N$  values between species, despite wintering on different continents (Rocque 2003).

These results also show that some isotope ratios are prone to annual fluctuations, probably related to climate. Thus, although the threshold  $\delta^{15}N$  and  $\delta^{13}C$  values used to distinguish northern and southern birds, and adults and sub-adults (still with juvenile primaries), appear to be robust from year to year, there were more marked annual differences in the south-eastern USA/Brazil distinction. This suggests that samples should be collected over several years to help evaluate natural variation in isotope signatures and limit its impact on misclassification of individuals. Analysis of additional isotopes may also help classification, but may be prohibitively expensive.

#### Linking breeding and wintering locations

In certain circumstances, stable isotopes allow researchers to draw links throughout the flyway of individual species. Provided the necessary reference samples have already been discriminated, samples from adults on the breeding grounds may enable direct linkages to be drawn between breeding and wintering

locations. However, for high Arctic breeders such as the Red Knot, sampling feathers from juveniles on the wintering grounds to identify breeding grounds is less productive. This is because there appear to be few consistent and predictable geographic patterns in isotope ratios in the largely terrestrial/freshwater tundra habitats. For lower latitude breeders, differences may be more apparent where large-scale differences in geology or primary production exist. For instance, the strontium signature found in bones of the Common Redshank *Tringa totanus* can be used to distinguish birds from Iceland, with a relatively young geology, from those breeding in Scotland, where rocks are much older (Evans 2004).

In conclusion, stable isotopes coupled with colour-marking birds as individuals can offer a useful way of distinguishing mixed populations of shorebirds on passage sites. In situations similar to Delaware Bay, their usage offers the opportunity of calculating parameters such as survival, recruitment, mass gain, stopover time etc. for populations that winter many thousands of kilometres apart.

#### ACKNOWLEDGEMENTS

We would like to thank all the volunteers who helped out with the shorebird banding programmes in Argentina, Chile and Delaware Bay. We are grateful to the U.S. Fish and Wildlife Service and National Environment Research Council (NERC) for funding the isotope analyses, and would like to acknowledge Greg Breese for his help and support of the project. The fieldwork was funded, in part, through a grant from the Delaware Division of Fish and Wildlife with funding from the Division of Federal Aid, U.S. Fish and Wildlife Service, under State Wildlife Grants appropriation 05020201-2330. Stable isotope analyses were carried out at the NERC Life Sciences Mass Spectrometry Facility under a grant from NERC, by Dr Alina Marca at the Stable Isotope Laboratory at the University of East Anglia and by Dr Tom Maddox at the University of Georgia.

### ABSTRACT

The Dunlin *Calidris alpina* is the most abundant species of shore-bird using the East Atlantic Flyway. This flyway links breeding areas in Greenland, Iceland, northern Europe and northern Russia with wintering areas in western Europe and Africa. Differences in migration pattern and segregation between Dunlin populations on their wintering grounds have already been indicated by analyses of morphometric data and ringing recoveries. Here, we use genetic markers (mitochondrial DNA) to analyse the extent of such segregation along the flyway, comparing birds from different stopover sites and wintering areas. We sampled birds from different wintering areas (Sweden, Portugal, Morocco, Guinea-Bissau) and compared their mtDNA haplotype frequencies. All birds from wintering areas in north-west Africa had the western (European) haplotype, while the eastern (Siberian) haplotype was present in all samples from wintering areas in Europe, with the highest frequencies occurring furthest north (in Sweden). Comparison with the haplotype frequencies in breeding populations revealed that birds from Greenland, Iceland and northern Europe were predominant in wintering areas in West Africa, while populations wintering in western Europe (the Iberian Peninsula and Sweden) originated from more eastern breeding grounds in Russia.

### INTRODUCTION

A comparison of the migration ecology of waders reveals a large variation in migration patterns between species (Pienkowski & Evans 1984, del Hoyo *et al.* 1996, Wernham *et al.* 2002). In some species, this variability also occurs between populations, sex or age classes that may be segregated, fully or partially, on their wintering grounds (Nebel *et al.* 2002). This seems to be the case for populations of the Dunlin *Calidris alpina* that use the East Atlantic Flyway, the main migration flyway connecting breeding areas from Canada to Siberia with wintering areas in western Europe and Africa (Smit & Piersma 1989). At least three subspecies of Dunlin, *C. a. arctica*, *C. a. schinzii* and *C. a. alpina*, migrate along the East Atlantic Flyway to reach wintering areas extending from southern Scandinavia to West Africa (del Hoyo *et al.* 1996).

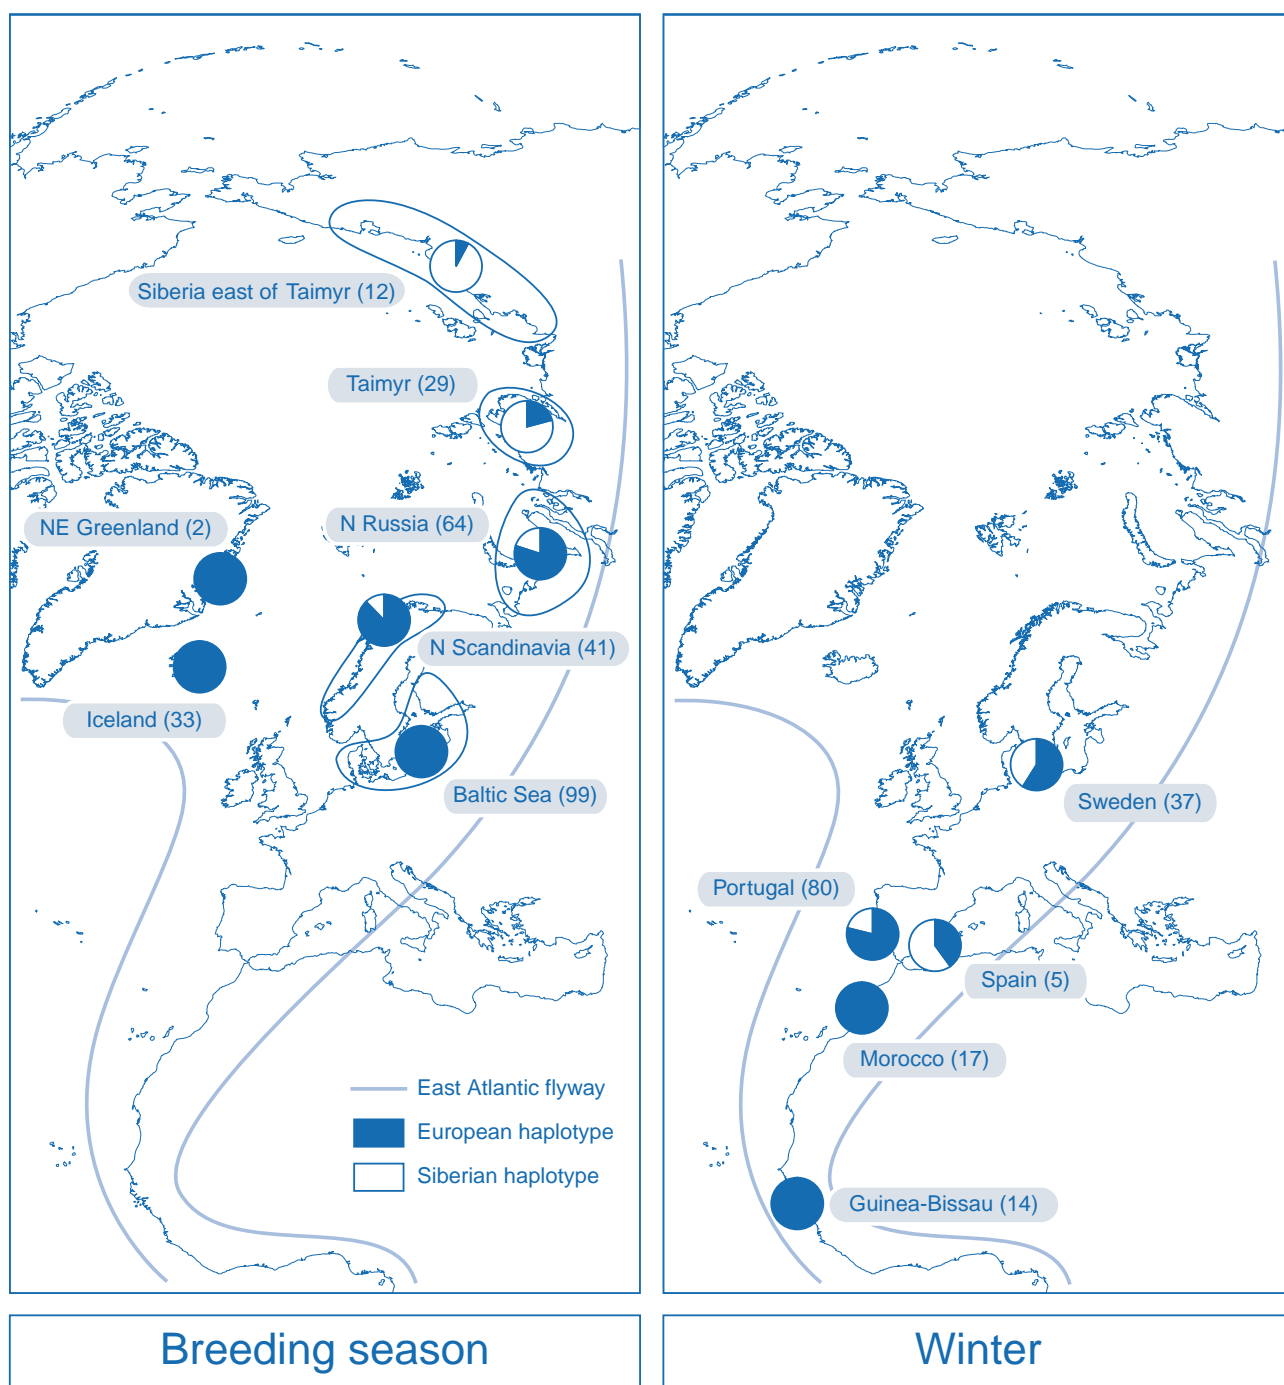

It is known that breeding populations from northern Scandinavia, European Russia and Siberia winter mainly in the northern parts of the wintering range, while populations from Greenland, Iceland and north-west Europe winter mainly in West Africa (Pienkowski & Evans 1984). These conclusions were based mainly on analyses of morphometric data and ringing recoveries (Pienkowski & Dick 1975, Wymenga *et al.* 1990). However, both of these methods have their limitations.

Morphological measurements differ between subspecies, but as there is also some sexual dimorphism, substantial overlap exists between the subspecies (Greenwood 1986) and this complicates determination of breeding origin based on morphometric data from unsexed birds. The potential of ringing recoveries to reveal the breeding origin of wintering birds has been limited by the scarcity of ringing recoveries from Arctic breeding areas as well as from wintering grounds in West Africa (e.g. Greenwood 1984, Wymenga *et al.* 1990, Gromadzka & Ryabitshev 1998).

Genetic methods have been used to identify breeding populations of the Dunlin on a global scale (Wenink & Baker 1996, Wennerberg 2001). Within the breeding areas of Dunlin using the East Atlantic Flyway, sequencing of mitochondrial DNA (mtDNA) has revealed the presence of two mtDNA lineages: a European haplotype and a Siberian haplotype. The frequency of the European haplotype decreases with longitude of the breeding area, while the frequency of the Siberian haplotype increases (Wennerberg 2001). By comparing the haplotype composition in a flock of non-breeding Dunlin with that of various breeding populations, the breeding origin of the flock can be estimated. This methodology has been applied mainly to migrating flocks (Wenink & Baker 1996, Tiedemann 1999, Wennerberg 2001, Wennerberg *et al.* 2001), and there have been few attempts to analyse wintering populations, probably because of the difficulty of obtaining DNA samples from some of the wintering areas. We here update current knowledge of the wintering distribution of Dunlin along the East Atlantic Flyway using these genetic markers to investigate the presence of geographical segregation.

### MATERIAL AND METHODS

Dunlin were sampled at wintering sites along the East Atlantic Flyway (Sweden, Portugal, Morocco and Guinea Bissau) during the winters of 1995 to 2001. Blood samples were taken from all birds and DNA was extracted according to standard procedures. The mtDNA was amplified by Polymerase Chain Reaction (PCR), and PCR products were digested with the restriction enzyme *Alu I* (for details, see Lopes 2004). *Alu I* was chosen because it cuts the mtDNA at positions that separate the two mtDNA lineages: the European and Siberian haplotypes (Wenink *et al.* 1996). Published data on the haplotypes of wintering flocks in Spain and Sweden (from Wennerberg 2001) have also been included in the analysis. Information on breeding populations has been obtained from the published results of mtDNA analyses of 280 breeding birds from 22 breeding populations (Wenink *et al.* 1993, 1996, Wennerberg *et al.* 1999, Wennerberg 2001) and some additional unpublished data (Wennerberg unpubl. data).

**Fig. 1.** The mtDNA haplotype frequencies of Dunlin *Calidris alpina* sampled during winter along the East Atlantic Flyway. For comparison, the European haplotype frequencies of Dunlin sampled in the breeding regions are also shown. Sample sizes are shown in brackets.

## RESULTS AND DISCUSSION

### Population segregation in the wintering areas

Our data confirm the results obtained from analyses of morphometric data and ringing recoveries, and show that there is partial segregation of Dunlin populations during winter. The mtDNA haplotype frequencies of wintering Dunlin populations differed between locations along the East Atlantic Flyway (Fig. 1). A clear distinction was observed between West Africa, where only the European haplotype was present in wintering flocks, and western Europe, where both the European and Siberian haplotypes were present. A major shift occurred between Morocco and the Iberian Peninsula. Within Iberia, Dunlin from the east coast (Tarragona, Spain) tended to include more birds

with the Siberian haplotype than birds from the west coast (Tagus estuary, Portugal), but the sample size from Spain was too small for any firm conclusions to be drawn (Fig. 1). Birds wintering in southern Sweden, which comprise one of the northernmost wintering populations in the flyway, had a higher frequency of the Siberian haplotype than any wintering population further south (Fig. 1).

### Assignment of breeding origin

Wintering flocks could be assigned to their respective breeding areas by comparing their haplotype frequencies with those from breeding populations (Fig. 1). The frequency of haplotypes from the West African winter assemblages corresponded to frequencies

found on breeding areas in the western part of the breeding range (Greenland, Iceland, Baltic Sea). The Portuguese winter assemblage was similar to the northern Scandinavian and northern Russian breeding populations (Fig. 1). Although the sample from Spain was very small, it was possible to identify a northern Scandinavian or Russian breeding origin for these birds as well, based on the occurrence of Siberian haplotypes in the sample. The mtDNA haplotype frequencies from birds wintering in Sweden corresponded to breeding populations in northern Russia and the Taimyr Peninsula (Fig. 1).

These would be the obvious conclusions if there was no mixing of birds from different breeding populations in the wintering areas. However, in some parts of the wintering range, there is evidence of considerable mixing of breeding populations (Pienkowski & Dick 1975, Batty 1993). For example, evidence from ringing has shown that *C. a. schinzii* breeding in the Baltic region (and lacking the Siberian haplotype) may winter in several different areas, including France, Iberia and Morocco (Jönsson 1986). Recoveries of birds from the British breeding population of *C. a. schinzii* suggest that these birds winter mainly in West Africa, although a few may also winter in the Iberian Peninsula (Wernham *et al.* 2002). Thus, it is possible that the haplotype frequencies reported in Iberia might include some birds from breeding populations in which the frequency of the European haplotype is 100%. If this is the case, the other birds that contribute to the Iberian wintering flocks must originate from breeding populations with a high proportion of the Siberian haplotype, as in the eastern part of the breeding range, mainly in Russia.

In addition to confirming the presence of segregation on the wintering grounds, the results of the present study give more information on the composition of the winter assemblages in terms of their breeding origins, especially in Morocco and Iberia (see below). Analyses of morphometric data and ringing recoveries show that it is unlikely that there is a large influence of the nominate subspecies in Guinea-Bissau and Mauritania (Wymenga *et al.* 1990, Wintermans 1998). The results of the present study point to the occurrence of birds from northern Russia and Siberia in northern Europe in winter, as also indicated by the small number of ringing recoveries that link breeding grounds in northern Russia and western Siberia with wintering areas in northern Europe (Hardy & Minton 1980, Petterson *et al.* 1986, Greenwood 1984, Gromadzka 1989, Wernham *et al.* 2002). Our results also provide evidence that birds from these north-eastern breeding populations occur as far south as Iberia.

### Morocco

Morphometric data indicate the presence of a considerable proportion of the nominate subspecies in Morocco during winter; minimum estimates of 20–25% *C. a. alpina* have been suggested (Pienkowski & Dick 1975, Greenwood 1984, Kersten *et al.* 1983). There have also been recoveries in Morocco of birds ringed on passage in Scandinavia and believed to have originated from breeding grounds further to the east (Pienkowski & Dick 1975, Greenwood 1984, Kersten *et al.* 1983). However, our study did not record any birds with the Siberian haplotype in Morocco, as would have been expected if birds from the eastern breeding populations were present. Further work with larger samples and over a number of years is required to clarify this question and determine the importance of Morocco as a wintering area for the nominate subspecies.

### Iberian Peninsula

The Iberian Peninsula has been considered to be one of the wintering areas of the nominate subspecies and also a wintering area for *C. a. schinzii*. Batty (1993) analysed bill lengths of birds wintering at Ria Formosa (southern Portugal), and concluded that most of the Dunlin were *C. a. schinzii*. In contrast to these results, an analysis of all ringing recoveries in Portugal (Lopes 2004) showed that most of the birds found in Portugal during winter (December and January) were recorded in the eastern part of Great Britain, the Wadden Sea, the Baltic region and northern Scandinavia, indicating eastern migration routes. The results of our genetic analysis clearly support the occurrence of wintering assemblages with a high proportion of the nominate subspecies in Iberia.

### Future applications and integration of methods

The analysis of ringing recoveries requires the compilation of data throughout an extended sampling period, in most cases decades, before any clear picture emerges. However, there is an urgent need to develop research tools that can be used to study the relatively quick responses in the population dynamics of migratory birds to environmental factors, such as habitat alteration and climate change, so that actions can be implemented in time. Furthermore, there are still some major gaps in our knowledge of the migration patterns and winter distribution of the Dunlin (e.g. occurrence of segregation between age classes or the sexes). Morphometric studies can play a major role in this regard. By using genetic sexing methods for smaller samples, we will be able to analyse the differences between populations much more accurately, from local to flyway scale (e.g. Lopes 2004).

Genetic population markers, such as the ones used in this study, have also a big potential for monitoring wintering populations. Other genetic techniques (e.g. micro-satellites, nuclear DNA sequencing, and amplified fragment polymorphisms – AFLP) and bio-geochemical approaches (e.g. ratios of stable isotopes) may prove to be useful in discerning between populations (e.g. Clegg *et al.* 2003). Techniques such as AFLP provide an efficient way of screening the nuclear genome for population markers. Genetic markers with higher mutation rates, such as micro-satellites, are potentially useful for distinguishing populations on a smaller geographical scale.

### CONCLUSIONS

Although the genetic markers which have been used to date lack enough resolution to pinpoint the breeding origin of each bird individually, their use has narrowed the range of possible breeding origins and made it possible to reject other regions with a high degree of confidence. This has allowed us to review and confirm our current understanding of the segregation of Dunlin populations, as revealed by morphometric data and ringing recoveries. The use of the methodology based on genetic markers can help to improve the conservation of the Dunlin as well as other long-distance migrants, and can be integrated with other methods for monitoring and management purposes.

### ACKNOWLEDGEMENTS

We would like to thank all those who have helped with the sampling of birds, especially Theunis Piersma (Guinea-Bissau), José L. Arroyo (Morocco) and Christer Persson (Sweden).

This research was funded by Fundação para a Ciência e a Tecnologia (FCT) through the grant PRAXIS XXI/BD/16250/98 and by the National Centre for Biosystematics, National History Museum, University of Oslo.

### ABSTRACT

One hundred and thirty-two Western Sandpipers *Calidris mauri* were radio-marked at two sites on the Pacific coast of North America (San Francisco Bay, California, and Grays Harbor, Washington) and at an interior wetland in the western Great Basin (Honey Lake, California). The northward migration of these birds was monitored at a network of 12 major stopover sites and four breeding areas. Eighty-eight percent of the birds were relocated at 10 stopover sites and two breeding areas between San Francisco Bay and the Yukon-Kuskokwim Delta, Alaska (c. 4 200 km). On average, birds were relocated at fewer than two sites, with the Copper River Delta in Alaska being the single most important stopover site. Migrant birds radio-marked at the interior site shifted to the coast between Oregon and Washington, and then continued their migration along the Pacific coast. Individual birds used a wide variety of migration strategies, from stopping at sites 200-300 km apart to flying as far as 2 100 km in under 48 hours. At the population level, we observed heterogeneity in phenology and site use, a strategy well adapted to the changing landscape that Western Sandpipers must navigate during migration, especially in interior regions.

### INTRODUCTION

Large-scale marking studies have been successful in providing information on bird migration routes and stopover areas (Lincoln 1959, Butler *et al.* 1996). Determining how individual, small (<35 g) birds such as Calidrid sandpipers migrate over large distances has been challenging because of technological, logistical, and financial constraints. Systematic data on sites used or not used by individual shorebirds along major segments of their migration flyways did not exist until Iverson *et al.* (1996) first documented the coastal migration routes of individual Western Sandpipers *Calidris mauri* between San Francisco Bay, California, and Cook Inlet, Alaska, during spring 1992.

The Western Sandpiper, a mid- to long-distance migrant (Johnson & Herter 1990), is the most numerous shorebird along the Pacific Flyway. In some years, its population can number over four million individuals (Bishop *et al.* 2000). This Nearctic shorebird breeds principally in western Alaska, with smaller numbers in north-eastern Russia and northern and central Alaska (Kessel 1989, Wilson 1994, Bishop & Warnock 1998). The wintering areas extend from California to Peru, and from the southern

Atlantic coast of the USA and the Gulf of Mexico to northern South America (Wilson 1994).

Along the Pacific Flyway, five coastal migratory stopover sites have been documented which support over 500 000 migrant Western Sandpipers in spring: San Francisco Bay (Stenzel & Page 1988), Grays Harbor, Washington (Wilson 1993), Fraser River Delta, British Columbia (Butler *et al.* 1987, Butler 1994), Stikine River Delta, Alaska (G. Iverson unpubl. data) and Copper River Delta, Alaska (Isleib 1979, Bishop *et al.* 2000). Areas in the Central Valley of California and the western Great Basin of the United States also host large numbers of migrating Western Sandpipers (Harrington & Perry 1997, Oring & Reed 1997), but the use of these interior areas by Western Sandpipers and other shorebirds remains poorly understood.

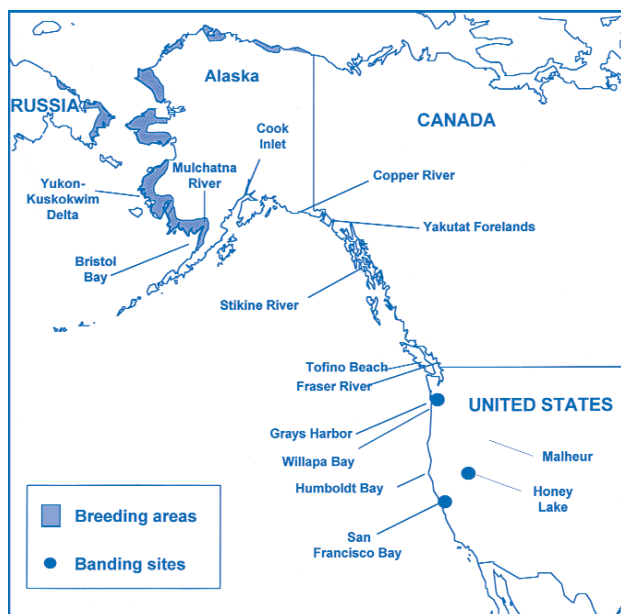

Our previous work has shown that Western Sandpipers migrate northward from San Francisco Bay along the Pacific coast using a rapid, short-flight migration strategy (Iverson *et al.* 1996) which includes short (1-3 days) stays at large estuarine habitats (Warnock & Bishop 1998). Males precede females, and between the sexes there are differences in the likelihood of a stopover being used (Bishop *et al.* 2004). Our research also provided evidence that the Yukon-Kuskokwim Delta in Alaska is the final breeding destination for many of the birds migrating through San Francisco Bay and other areas on the Pacific coast (Bishop & Warnock 1998).

Here, we examine spring migration by individual Western Sandpipers radio-marked in 1995 and 1996 in North America at two sites on the Pacific coast and an interior site in the Great Basin. We describe and analyze the effects of year and banding location on phenology and use of stopovers during the northward migration to the breeding grounds, a distance of more than 4 000 km. We also describe a previously unknown migration route of Western Sandpipers through the western Great Basin.

### METHODS

We captured Western Sandpipers from 17 to 30 April 1995 and 17 April to 3 May 1996 at two sites on the Pacific coast, San Francisco Bay (hereafter referred to as San Francisco; 37°46'N, 122°26'W) and Grays Harbor (46°57'N, 124°03'W), and at an interior wetland in the Great Basin, Honey Lake, California (40°14'N, 120°21'W; Fig. 1). Generally, capture dates corresponded with the peak migration at the trapping sites. Birds were trapped in mist-nets placed in salt ponds, mudflats, and

**Fig. 1.** Banding and monitoring sites for Western Sandpiper *Calidris mauri* telemetry study, spring 1995 and 1996. Combined monitoring sites include: Grays Harbor and Willapa Bay, Washington; Fraser River Delta and Tofino Beach, British Columbia; eastern and western Cook Inlet, and Bristol Bay, Alaska (combines two stopover and two breeding areas).

freshwater ponds during daylight hours. Each bird was weighed to the nearest 0.5 g, and the exposed culmen, flattened wing chord, and tarsus were measured (in mm). Sex was determined by length of exposed culmen (males <24.2 mm; females >24.8 mm; unknown 24.2–24.8 mm; Page & Fearis 1971); birds were not aged.

Radio-transmitters weighing 0.9 g (Model BD-2; Holohil Systems Ltd., Woodlawn, Ontario, Canada) were glued to the lower backs of 132 Western Sandpipers (1995,  $n = 61$ ; 1996,  $n = 71$ ), following methods described in Warnock & Warnock (1993). Retention time was previously found to be more than seven weeks in this species (Warnock & Takekawa 1996). The transmitter averaged about 3% of a bird's body mass, and

the expected battery life was more than four weeks. The battery life of test transmitters averaged  $39.0 \pm 2.5$  days ( $n = 5$ ).

We searched for radio-marked Western Sandpipers from the ground and fixed-wing aircraft at 15 sites in 1995 and 19 sites in 1996 (Fig. 1, Table 1; see Bishop & Warnock 1998 and Warnock & Bishop 1998 for dates and locations). Monitoring began north of the banding sites as soon as radio-marked birds were suspected of departing and continued until either all radio-marked birds had departed, or when minimal migratory activity was observed. The number and timing of flights varied by area and year. In 1996, daily flights occurred at Grays Harbor, in the Fraser River Delta, and in the Stikine River Delta, Yakutat Forelands, Copper River Delta and Kachemak Bay in Alaska (Fig. 1). During peak migration in 1996, two flights were flown per day at the Fraser River Delta ( $n = 2$  days) and Copper River Delta ( $n = 6$  days).

For our analyses, we combined monitoring sites into 11 sites (Fig. 1). Each site beyond the banding location where an individual bird's radio signal was detected was counted as one relocation, with a maximum of one detection per monitoring site, regardless of how many times the bird was detected at that site. We assumed that all radio-marked birds present at a banding or monitoring site were detected regardless of the monitoring method. High winds prevented monitoring at the Copper River Delta on 6 May 1995; we assumed that birds detected on 7 May had arrived on 6 May ( $n = 7$ ). Of the 71 radio-marked birds in 1996, four radio frequencies were identical to transmitters on Caribou *Rangifer rangifer* at Bristol Bay in western Alaska, and were only monitored at more southerly sites. Where appropriate, these four birds and one bird that died or lost its radio at Stikine River Delta were excluded in some analyses.

Statistical analyses were performed using STATA (Computing Resource Center, Santa Monica, California 1992). Data were examined for departures from normality and homogeneity by preliminary graphing and testing of data. For analyses, yearly dates were converted into Julian dates (JD). When reporting results, we adjusted all 1996 dates to 1995 (1996 date + 1 day), since 1996 was a leap year. For all tests, significance was determined if  $P \leq 0.05$ . Means are reported  $\pm$  one standard deviation (SD).

**Table 1.** Distance (km) between banding sites of radio-marked Western Sandpipers *Calidris mauri* and more northerly monitoring sites.

Monitoring site	Banding site		
	San Francisco CA	Honey Lake CA	Grays Harbor WA
Humboldt Bay CA	410		
Grays Harbor WA	1 110	790	
Fraser River Delta BC	1 350	1 030	240
Stikine River Delta AK	2 410	2 090	1 300
Yakutat Forelands AK	2 940	2 620	1 830
Copper River Delta AK	3 250	2 930	2 140
Cook Inlet AK	3 590	3 270	2 480
Mulchatna River AK	3 880	3 560	2 770
Bristol Bay AK	4 000	3 680	2 890
Yukon-Kuskokwim Delta AK	4 200	3 880	3 090

CA = California, USA; WA = Washington, USA; BC = British Columbia, Canada; AK = Alaska, USA.

## RESULTS

### Relocations

In 1995, we relocated 51 of the 61 Western Sandpipers (84%) a total of 85 times at eight of the nine monitoring sites. In 1996, 64 of 69 Western Sandpipers (93%) were relocated a total of 140 times at 10 of the 11 monitoring sites (Table 2, Fig. 2). For all monitoring sites, the number of birds relocated between years was not significantly different ( $\chi^2_1 = 2.65$ ,  $P = 0.10$ ). We failed to relocate 15 birds after departure from their banding site (six males and nine females), both years combined. The number of birds not found was not significantly different among banding sites ( $\chi^2_2 = 0.91$ ,  $P > 0.60$ ).

In 1995, birds banded at San Francisco stopped at an average of  $1.6 \pm 0.6$  sites (max. 3); birds banded at Honey Lake at  $1.6 \pm 0.8$  sites (max. 3); and birds banded at Grays Harbor at  $1.7 \pm 0.5$  sites (max. 2). In 1996, with more extensive aerial monitoring efforts at five sites (Humboldt Bay, Grays Harbor, Yakutat Forelands, Copper River Delta, and Bristol Bay), San Francisco radio-marked birds were relocated at an average of  $2.6 \pm 1.1$  sites (max. 5), Honey Lake birds at  $1.6 \pm 0.7$  sites

**Table 2.** Numbers of Western Sandpipers *Calidris mauri* radio-marked and percent relocated at least once to the north. Spring 1995 and 1996.

Banding location		1995 Banded	% Relocated	1996 Banded	% Relocated

	Female	7	86	6	100
	Unknown	0	0	1	100

<sup>1</sup> One bird not included due to overlap with Caribou frequency at northern site.

**Fig. 2.** Relocations (%) of radio-marked Western Sandpipers *Calidris mauri* at areas north of banding sites in spring 1995 and 1996. Stopover areas, beginning at the southernmost monitoring site: HB = Humboldt Bay, California; GH = Grays Harbor and Willapa Bay, Washington; FR = Fraser River Delta and Tofino Beach, British Columbia; SR = Stikine River Delta, Alaska; YF = Yakutat Forelands, Alaska; CR = Copper River Delta, Alaska; CI = Cook Inlet, Alaska; BB = Bristol Bay, Alaska (a stopover and breeding area). Breeding areas: MR = Mulchatna River, Alaska; YK = Yukon-Kuskokwim Delta, Alaska. There were no relocations at Malheur Lake, Oregon.

(max. 3), and Grays Harbor birds at  $1.6 \pm 0.6$  sites (max. 3). In 1996, we relocated three San Francisco birds (two males, one female) at five stopover sites.

The Copper River Delta was the stopover site with the highest number of relocations, with 61% of marked birds stopping there in 1995 and 80% in 1996. Significantly more radio-marked birds were relocated at the Copper River Delta in 1996 than in 1995 ( $\chi^2_1 = 4.97$ ,  $P = 0.03$ ). San Francisco birds had the fewest relocations (55%, 1995), while Grays Harbor birds had the most relocations (93%, 1996; Fig. 2). In 1996, we conducted twice-daily flights on the Copper River Delta during six days and relocated 40 different radio-marked birds. Four birds (10%) were detected on one flight only, indicating that these birds migrated through the Copper River Delta in less than 12 hours.

We also relocated radio-marked Western Sandpipers at Humboldt Bay, Willapa Bay, Yakutat Forelands, Bristol Bay (a stopover and breeding area), and two other breeding areas in Alaska (Fig. 1). Although Willapa Bay is only 35–90 km (depending on location) south of Grays Harbor, no sandpipers relocated at Willapa Bay were detected within Grays Harbor. However, one Willapa bird was detected at the mouth of Grays Harbor on the outer beach. At the Yakutat Forelands, sandpipers were located along a 100 km stretch from Yakutat Bay south-east to the East Alsek River, with the majority of relocations occurring between Ocean Cape and the Seal Creek-Ahrnklin River estuary. On the breeding grounds, birds were relocated on Alaska's Yukon-Kuskokwim Delta in both years and near the confluence of the Nushagak and Mulchatna Rivers in 1996, the only year that this site was monitored.

Despite extensive coverage in both years, no radio-marked birds were relocated north of Redoubt Bay (north-western Cook Inlet) or along the Alaska Peninsula between Naknek and Unimak Island. Nor were radio-marked birds relocated during our one year of monitoring efforts at Malheur Lake in eastern Oregon (Fig. 1) and at Cape Peirce, Alaska (west of Bristol Bay). In 1995, no birds were detected at Humboldt Bay in northern California, although they were detected in 1996 when we increased our effort.

### Phenology

The mean departure dates of radio-marked Western Sandpipers from the three banding sites ranged from 26 April to 3 May in 1995 and from 27 April to 8 May in 1996 (Table 3). The average arrival dates at sites monitored ranged from 29 April at Humboldt Bay to 20 May at the Yukon-Kuskokwim Delta (Fig. 3). For radio-marked birds departing from San Francisco, this indicates a 25 day migration period over the final c. 4 000 km of their migration route. Depending on the year, for monitoring sites up to and

**Table 3.** Banding and mean departure dates from banding sites of radio-marked Western Sandpipers *Calidris mauri* captured at three locations. Dates adjusted so that the 1996 leap year dates equal 1995 (1996 date + one day).

Banding location	Year	Banding dates	Mean departure date	Range	N
San Francisco CA	1995	17-19, 21-23 Apr	28 Apr	20 Apr - 5 May	29
	1996 <sup>1</sup>	18-23 Apr	28 Apr	22 Apr - 9 May	30
Honey Lake CA	1995	27, 28, 30 Apr	1 May	27 Apr - 8 May	18
	1996 <sup>1</sup>	26 Apr	27 Apr	27 Apr - 30 Apr	13
Grays Harbor WA	1995	24, 25, 28 Apr	3 May	24 Apr - 9 May	14
	1996	28-30 Apr, 1,3,4 May	8 May	3 May - 13 May	28

<sup>1</sup> 1996 includes two birds dropped from other analyses (one from San Francisco and one from Honey Lake).

**Fig. 3.** Mean arrival dates ( $\pm$  SD; dates adjusted for leap year) for radio-marked Western Sandpipers *Calidris mauri* at stopover and breeding sites where four or more relocations were recorded; spring 1995 and 1996. Stopover areas: HB = Humboldt Bay, California; GH = Grays Harbor and Willapa Bay, Washington; FR = Fraser River Delta and Tofino Beach, British Columbia; SR = Stikine River Delta, Alaska; YF = Yakutat Forelands, Alaska; CR = Copper River Delta, Alaska; CI = Cook Inlet, Alaska. Breeding area: YK = Yukon-Kuskokwim Delta, Alaska.

including the Copper River Delta, the migration window for radio-marked birds (number of days between the first arrival of a radio-marked bird and last departure of a radio-marked bird) was shortest (10 days) for Humboldt Bay, Grays Harbor and Stikine River Delta, and longest for the Fraser River Delta and Copper River Delta (20 days each). At the Copper River Delta, the mean arrival dates for Western Sandpipers banded at San Francisco were 7 May 1995  $\pm$  4 days ( $n = 16$ ) and 10 May 1996  $\pm$  4 days ( $n = 20$ ); Honey Lake, 14 May 1995  $\pm$  3 days ( $n = 11$ ) and 13 May 1996  $\pm$  2 days ( $n = 7$ ); and Grays Harbor, 8 May 1995  $\pm$  5 days ( $n = 10$ ) and 14 May 1996  $\pm$  2 days ( $n = 26$ ).

## DISCUSSION

### Stopover use

Overall, individual radio-marked Western Sandpipers showed a wide variety of migration strategies, from stopping at sites 200-300 km apart to flying as far as 2 100 km in less than 48 hours.

On average, individual radio-marked Western Sandpipers were relocated at fewer than two of the 10 monitoring sites (including stopover and breeding sites). We may have missed some birds at our monitoring sites (i.e. birds passing through a site in less than 24 hours), but from our twice-daily flights at the Fraser and Copper River Deltas, the number of birds missed does not appear to be over 10%. It seems likely that birds were stopping at smaller, unmonitored sites, since travel times between known stopover areas were too long for uninterrupted flight (Bishop *et al.* 2004).

Iverson *et al.* (1996) concluded that Western Sandpipers from San Francisco were more likely to be detected at stopover sites with increasing latitude. This study fails to support that contention. At Humboldt Bay, c. 400 km north of San Francisco, we relocated 30% of birds radio-marked at San Francisco in 1996 when we increased ground coverage and added aerial coverage. Relocations at Grays Harbor were slightly higher than the more northerly sites of Stikine River Delta and Yakutat Forelands during both years of this study, even though fewer aerial surveys were conducted at Grays Harbor. We suggest that the low stopover use at Grays Harbor (3.4% of 58 birds) found by Iverson *et al.* (1996) was probably a result of insufficient coverage. Their monitoring at Grays Harbor in 1992 only included Bowerman Basin (approximately 10% of the exposed mudflats within Grays Harbor; Wilson 1993), and monitoring was from the ground, rather than from the air. More perplexing are the differences in stopover use at the Fraser River Delta, where monitoring coverage was comparable between the two studies. Whereas Iverson *et al.* (1996) recorded only 8.6% of San Francisco radio-marked birds stopping at the Fraser River Delta in 1992, we relocated 27-28% in both 1995 and 1996.

At the population level, all of the sites that were regularly monitored north of San Francisco up to and including the Copper River Delta were used by at least 20% of the radio-marked Western Sandpipers during one of the two years of this study. If we assume that the radio-marked birds are representative of the Western Sandpiper's Pacific Flyway population, then each of these stopover sites qualifies, at a minimum, as an "international shorebird site" under the criteria used by the Western Hemisphere Shorebird Reserve Network (WHSRN), i.e. a site used by at least 10% of the flyway population of a species. As of January 2005, Humboldt Bay, Grays Harbor, the Fraser River Delta and the Copper River Delta are official WHSRN sites. However, Controller Bay, an area of high shorebird use (M.A. Bishop unpubl. data) located just east of the Copper River Delta, is not part of the Copper River Delta WHSRN hemispheric site designation. Alaska's Stikine River Delta and Yakutat Forelands also lack WHSRN designation.

Similar to previous studies (Iverson *et al.* 1996, Bishop *et al.* 2000, Bishop *et al.* 2004), our relocations revealed the importance of the Copper River Delta in south-central Alaska for Western Sandpipers. It has been asserted that virtually all of the world's population of Western Sandpipers stops at the Copper River Delta during their northward migration (Wilson 1994). Even accounting for birds that pass through too quickly to be relocated, it appears that in some years, some western Great Basin and San Francisco birds may not be stopping at the Copper River Delta. For birds radio-marked at Grays Harbor however, the high numbers of relocations recorded in both years (>71%) indicate that the Copper River Delta is of great importance for birds migrating through this site. In contrast, the Fraser River Delta (240 km to the north of Grays Harbor) in British Columbia had lower use (<15%) by Grays Harbor birds, and relocations at Stikine River Delta and Yakutat Forelands were only slightly higher.

Our study has also revealed the importance of Yakutat Forelands for the Pacific Flyway population of Western Sandpipers. Radio-marked birds from all three banding sites used Yakutat Forelands in both years, in particular the area between the town of Yakutat and the Ahrnklin River. Subsequent ground surveys at the Seal Creek-Ahrnklin River estuary confirmed that Western Sandpipers are the most abundant shorebird in spring in this area (Andres & Browne 1998).

### Migration routes

The western Great Basin is one of the least studied areas in North America for shorebirds (Neel & Henry 1997). For the first time, we established a northward migration route for Western Sandpipers passing through the western Great Basin. Western Great Basin birds, represented by birds marked at Honey Lake, were relocated at coastal sites from Grays Harbor to the Copper River Delta. However, no Honey Lake birds were detected at Humboldt Bay in either year, nor were Honey Lake birds detected inland at Malheur National Wildlife Refuge, Oregon, in spring 1996 during four monitoring days that included one aerial survey. Many sites used by Western Sandpipers in the western Great Basin are dry in some years (Robinson & Warnock 1997). The springs of 1995 and 1996 were wet (N. Warnock unpubl. data) and habitat was abundant. In wet years, these birds may be moving more slowly through the Great Basin than in dry years, before shifting to the coast.

Western Sandpipers can be abundant in the Willamette Valley of Oregon during spring (Paulson 1993). A possible migration route for these interior migrating birds is to travel up the western side of the Great Basin through the Klamath Basin in northern California, into the Willamette Valley of Oregon to the Columbia River, and then shift westward onto the Washington coast. Greater White-fronted Geese *Anser albifrons* migrating through the Central Valley of California, just west and parallel to the western Great Basin, follow a similar route to their breeding grounds (Ely & Takekawa 1996) which overlap with those of the Western Sandpiper.

### Effects of radio-marking on phenology

Several studies have shown that shorebirds lose body mass during and immediately after capture (Pienkowski *et al.* 1979, Davidson 1984, Lindström 1995, Warnock *et al.* 1997). Our previous work suggests that radio-marked birds may require additional days to

regain weight and adjust to the radio (Warnock & Bishop 1998, Warnock *et al.* 2004). In this study, we radio-marked birds just prior to and during peak migration at San Francisco (about 20-25 April; Storer 1951, Stenzel & Page 1988) and at Grays Harbor (late April to early May, N. Warnock unpubl. data). Nevertheless, the average departure from both sites occurred a few days later than peak migration in both years. This pattern was repeated at other stopover sites. We cannot rule out an effect of capture or the radio-transmitter on the migration timing of the marked birds; however, it appears to be a short-term effect, as evidenced by our very high relocation rate at sites to the north, including the breeding grounds. For some birds, there was no apparent capture effect. For instance, two Grays Harbor birds left the day they were captured and were seen at Fraser River one day later.

### CONCLUSIONS

At the individual level, data on inter-annual differences and flight strategies used by shorebirds during migration are still lacking. This would involve trapping and tracking the same individual in consecutive years, an improbable event in the case of Western Sandpipers, or use of a long-lived transmitter and attachment. At the population level, however, this study suggests that the migration strategies of Western Sandpipers vary, as they do in other shorebirds (Myers *et al.* 1990, Davidson & Wilson 1992, Skagen & Knopf 1994, Warnock *et al.* 2004). There appears to be heterogeneity in phenology and site use during migration, a strategy that is well adapted to the changing landscape that Western Sandpipers must navigate during migration, especially in interior regions.

In future studies, it would be valuable to examine the migration strategies of Western Sandpipers during early and late spring migration and during autumn migration, periods not covered by this study. Our study reveals the importance of maintaining a network of stopover sites along the coast and interior of the Pacific Flyway. At the same time, our study demonstrates the singular importance of the Copper River Delta for migrant Western Sandpipers in spring. The conservation of Western Sandpipers clearly hinges on this network of stopover areas.

## Indicators of body condition, energy demand and breeding success in the Ruddy Turnstone *Arenaria interpres*, a species of concern

Deborah E. Perkins & Rebecca L. Holberton

Department of Biological Sciences, University of Maine, Orono, ME 04469-5751, USA. (email: pourmeariver@gci.net)

Perkins, D.E. & Holberton, R.L. 2006. Indicators of body condition, energy demand and breeding success in the Ruddy Turnstone *Arenaria interpres*, a species of concern. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 551-552.

Although the Ruddy Turnstone *Arenaria interpres* is a species of high concern in Canada (Donaldson *et al.* 2000) and the United States (Brown *et al.* 2001), its breeding ecology is poorly understood (Nettleship 2000). Reproductive physiological and energetics studies are critical to understanding how environmental conditions affect breeding success and population viability. The breeding ecology and behavioral endocrinology of Ruddy Turnstones were studied at East Bay, Southampton Island, Nunavut, Canada in 2003. Hormonal patterns associated with energy regulation and sex-specific parental efforts were investigated to understand better how high latitude breeders meet energy demands. Normally, plasma corticosterone (CORT; the major energy-regulating hormone) is low, but can rise rapidly to help an individual through periods of potential stress (the adrenocortical response; Wingfield 1994, Harvey *et al.* 1984). While acute high CORT levels redirect behavior to life saving activities, chronic levels can compromise reproduction (Wingfield 1994). Previous studies have shown some Arctic-breeding birds reduce this response during critical breeding stages (Wilson & Holberton 2004, Reneerkens *et al.* 2002, Holberton & Wingfield 2003, O'Reilly & Wingfield 2001), possibly increasing the threshold for life-saving responses that may otherwise compromise breeding success, e.g. desertion.

The study used the Mayfield method to estimate nest success (Bart & Robson 1982). Incubation period was assumed to be 23 days (Nettleship 2000). Body condition was assessed by size-corrected body mass, with the body mass divided by the flattened wing length cubed (Winker *et al.* 1992, Summers 1988, Davidson 1983). Relative incubation effort was assessed during twelve 24-hour behavioural watches: six at mid-incubation (eight to fifteen days after onset of incubation) and six at late incubation (sixteen to twenty-three days after onset of incubation). To measure the adrenocortical response at different parental stages, blood samples for CORT were taken within four minutes (baseline) and at 10 and 30 minutes after capture during mid-incubation and early brooding, which includes the stage from when the first chick is hatched to when all chicks were hatched and found in the immediate vicinity of the nest. A direct radioimmunoassay procedure was used to determine CORT concentrations (Wingfield *et al.* 1992).

Nest success was 0.33 (95% CI 0.19-0.55; 321 exposure days); 42% of nests were lost to predators.

Overall, incubating females were significantly leaner than incubating males (stages pooled;  $t = 2.254$ ,  $P = 0.032$ ). There was some indication that body condition varied by stage, and this difference approached significance (main effect of stage:  $F_{2,51} = 3.067$ ,  $P = 0.055$ ). However, there were no differences in body condition between the sexes within each stage (stage \* sex

**Fig. 1.** The adrenocortical response of Ruddy Turnstones *Arenaria interpres* at East Bay, Southampton Island, Nunavut, Canada, during mid-incubation (day 8-15) and early brooding (with 1-2 day old chicks). Sexes pooled. Solid line = mid-incubation ( $n = 21$ ); dashed line = brooding ( $n = 15$ ).

interaction:  $F_{2,51} = 0.070$ ,  $P = 0.932$ ). Females were somewhat leaner than males within the mid-incubation stage, and this difference approached significance ( $t = 2.01$ ,  $P = 0.059$ ).

Regarding parental effort and CORT secretion, breeding pairs shared incubation duties equally (total contribution by either sex did not differ significantly from 50% at either mid- or late-incubation;  $t = 1.1$ ,  $P = 0.321$ ,  $t = 0.79$ ,  $P = 0.467$ , respectively), and this was reflected in their similar patterns of CORT secretion. Specifically, males and females showed extremely similar adrenocortical responses during mid-incubation (main effect of sex:  $F_{1,18} = 0.344$ ,  $P = 0.565$ ; sex \* time interaction:  $F_{2,36} = 0.797$ ,  $P = 0.458$ , two factor repeated-measures ANOVA,  $P > 0.05$  for all Tukey post hoc comparisons of each sampling interval). As during the mid-incubation stage, males and females showed extremely similar CORT profiles during the early brooding stage (main effect of sex:  $F_{1,13} = 0.478$ ,  $P = 0.501$ ; sex \* time interaction:  $F_{2,26} = 0.530$ ,  $P = 0.595$ , two factor repeated-measures ANOVA,  $P > 0.05$  for all Tukey post hoc comparisons of each sampling interval).

In contrast to the mid-incubation period, brooding birds did not express an adrenocortical response: CORT concentrations did not increase significantly in response to capture and handling during early brooding (repeated measures ANOVA, within subjects:  $F_{2,26} = 1.326$ ,  $P = 0.283$ ). CORT concentrations were not significantly different between the sexes at any time during sampling (*post hoc* for repeated measures time 0,  $P = 1.00$ ; time

10,  $P = 0.725$ ; time 30,  $P = 0.447$ ).

However, both males and females (sexes pooled) showed dramatic changes in adrenocortical secretion patterns between mid-incubation and brooding (main effect of stage:  $F_{1,33} = 0.116$ ,  $P = 0.736$ ; stage \* time interaction:  $F_{2,66} = 29.18$ ,  $P < 0.001$ , two factor repeated-measures ANOVA; Fig. 1). Baseline CORT was significantly higher during the brooding stage (Tukey,  $P < 0.001$ ; Fig. 1). While ten minute values did not differ, CORT concentrations at the 30 minute sampling period were significantly lower during the brooding stage as compared to the mid-incubation stage (Tukey:  $P = 0.015$ ; Fig. 1).

Nest success of Ruddy Turnstones at East Bay was relatively low in 2003 compared to other years (1.00 in 2000, 0.83 in 2001; P. Smith, pers. comm.), and the predation rate (42%) was higher than estimates from other areas within their North American breeding range (18-27%; Nettleship 1967, Parmelee & MacDonald 1960).

In this study, incubating females were significantly leaner than incubating males, possibly owing to their greater initial reproductive investment via egg production. Due to the severe environment in which they breed, females breeding at high latitudes may not be able to regain energy reserves until brood desertion is a viable option for them during the early to mid-fledging period. Poor condition upon arrival may subsequently affect parental effort and breeding success in both sexes, as effects may be cumulative throughout the breeding season. If a female begins the season in poor condition, a male's ability to compensate for her early desertion would depend on his own energy reserves. Further research is needed during spring migration and throughout the annual cycle to identify factors limiting arrival condition, and, thus, breeding success of both sexes in high latitude breeders.

Previous studies of Arctic-breeding shorebirds have not compared parental effort, as reflected by the adrenocortical response, during the brood care and incubation phases. Caring for precocial young can be demanding (Hegyi & Sasvari 1998), especially for high latitude breeders facing time and energy constraints (Ashkenazie & Safriel 1979, Byrkjedal 1989). An increase in baseline CORT during brooding may be the proximate mechanism that helps parents meet the demands of parental care at high latitudes by facilitating the additional foraging and feeding required to meet their own energy needs while caring for offspring. The reduced expression of the adrenocortical response during brooding may be a mechanism to increase the threshold for abandonment during this period of greater parental effort, especially when faced with few or no re-nesting opportunities.

Rudenko, A.G. 2006. Migration of Pontic Gulls *Larus cachinnans* form 'ponticus' ringed in the south of Ukraine: a review of recoveries from 1929 to 2003. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 553-559.

### ABSTRACT

The Pontic Gull *Larus cachinnans* form 'ponticus' breeds on islands and lagoons along the coast of the Black Sea and Sea of Azov. Censuses in 1998 revealed a total of population of 28 226 pairs. Pontic Gulls have been ringed at breeding colonies in the south of Ukraine since the late 1920s, and by 2003 there had been 1 169 recoveries of birds ringed in the Black Sea Biosphere Reserve, Swan Islands and Sivash. A total of 817 gull chicks were colour-ringed in the Black Sea Biosphere Reserve between 1999 and 2002, and 20 of these have subsequently been recovered or re-sighted. This paper reviews the recoveries of Pontic Gulls ringed in Ukraine, and compares the movements of young birds with those of adults. The great majority of adults remain within the Azov-Black Sea region throughout the year. Most young birds also remain in the region, but a small number of birds undertake lengthy migrations in their first calendar year, mostly in a south-westerly direction (Romania, Bulgaria, Turkey, Cyprus, Greece and Egypt) or north-westerly direction (Poland, Germany, Denmark and The Netherlands). Some of these birds continue their nomadic movements in their second year.

### INTRODUCTION

Large white-headed gulls of the *Larus argentatus/cachinnans* complex breed in the south of Ukraine (Stepanyan 1990). Some authors assign the birds breeding in the Black Sea, Caspian Sea and eastern Kazakhstan to a distinct species, the Caspian Gull *L. cachinnans* (Olsen & Larsson 2002), while those birds breeding in the northern Black Sea and Sea of Azov have been assigned to the form "ponticus" – Pontic Gull. In Ukraine, the breeding area of the Pontic Gull lies between latitudes 45° and 47°N and longitudes 29° and 39°E, and includes islands and lagoons along the coast of the Black Sea and Sea of Azov. The westernmost colonies are situated in the Danube Delta, and the easternmost,

on Krivaya Spit in the Sea of Azov. The northern limit of the breeding range is probably in the region of the Kiev water storage basin, and the southern limit is on the coast of the Crimean Peninsula (Kistaykovsky 1957, Klestov & Fesenko 1990, Siokhin & Grinchenko 1988; Fig. 1).

### Size of the breeding population in the Azov-Black Sea region

The main breeding colonies of the Pontic Gull are located in Yagorlitsky Bay (Konsky and Krugly Islands) and Tendra Bay (Orlov and New Islands) in the Black Sea Biosphere Reserve, on islands in Jarylgachsky Bay, in the Sivash (e.g. Kitaj, Martinaychy and Chongarsky Islands), on the Swan Islands (Lebayzhie) in Karkinitzky Bay (Kistaykovsky 1957, Klimenko 1951, Sabineevsky 1958, Kostin 1983), and on Molochny Lagoon, Obitochynaya Spit and Krivaya Spit. In the mid-1990s, there were large colonies at Kuyanlitsky and Alibay Lagoons in the Odessa region (Siokhin & Grinchenko 1988, Siokhin 2000a).

### Jarylgachsky Bay

In 1929, Jarylgach Island was included in the Black Sea Reserve. Here there were about 100 breeding pairs of Pontic Gulls (Kistaykovsky 1957). In the last 70 years, the number of pairs breeding on islands in Jarylgachsky Bay has remained relatively stable. Some increase was observed in the 1980s and 1990s, when the population reached 3 500-3 900 pairs (Ardamatskaya 2000), and at the beginning of this century, there were about 4 500 pairs in this area (Ardamatskaya *et al.* 2000).

### Black Sea Biosphere Reserve

When Jarylgach Island was excluded from the Black Sea Biosphere Reserve (in 1951), the Pontic Gulls moved onto islands in Tendra Bay, where the numbers increased to 3 100 pairs (Sabineevsky 1958). At the beginning of the 1950s, the main colonies were located on Babin Island. In 1956-1958, Pontic Gulls were eradicated from islands in Tendra Bay, as they posed an appreciable threat to other bird species nesting on the islands (Sabineevsky 1958).

Since the end of the 1950s, the main breeding colonies in the Black Sea Biosphere Reserve have been located on Konsky and Krugly Islands in Yagorlitsky Bay. In 1984-1986, the number of pairs on Konsky Island varied between 2 000 and 3 500 (Trubka 1986, Rudenko 1992). On Krugly Island, there were between 200 and 500 pairs. During the 1990s, the number of Pontic Gulls in the Black Sea Biosphere Reserve increased to 5 000 pairs. The numbers breeding on islands in Tendra Bay have increased from 50-60 pairs in 1990 to 1 500 pairs in recent years. Other colonies are located on Orlov Island and New Island

Fig. 1. Breeding areas of the Pontic Gull *Larus cachinnans* and ringing sites in the south of Ukraine. 1 – breeding areas; 2 – ringing sites.

(Yaremchenko pers comm.). The total number of breeding pairs in the reserve in the early 2000s was about 4 000.

### Swan Islands (Lebayzhie)

The largest colonies of Pontic Gulls have always been on the Swan Islands. Here the numbers increased from 1 750 pairs in the 1950s (Kistaykovsky 1957) to 9 417 pairs in the early 1980s (Kostin 1983). During the 1980s, the population remained relatively stable at 10 000 pairs, but by the end of the 1990s, numbers had fallen by almost half to 5 000-7 000 pairs (Tarina *et al.* 2000).

### Sivash

There are large breeding colonies of Pontic Gulls in the Sivash. In the 1970s and 1980s, up to 2 000 pairs bred on Kitaj Island, up to 300 pairs on Martinaychy (Kostin 1983), 2 030 pairs on the Chongarsky Islands, and 5 500 pairs in eastern Sivash. There were also 2 500 pairs at Molochny Lagoon and 785 pairs on Krivaya Spit (Siokhin & Grinchenko 1988). In the 1990s, the total number of breeding pairs in the Sivash was over 14 000 (Siokhin 2000a).

According to the results of censuses in 1998, the total number of Pontic Gulls in the Azov-Black Sea region was 28 226 pairs (Siokhin 2000b). The relative stability in the total numbers of Pontic Gulls in Sivash and Karkinitsky, Jarylgachsky, Tendra and Yagorlitsky Bays in the Black Sea, despite considerable fluctuations in numbers at each of these sites, the synchronization of breeding, and the movements of individuals between colonies, have led to the conclusion that these colonies form part of a single Azov-Black Sea population (Sabinevsky 1958, 1966). This conclusion is supported by the fact that many of the breeding birds remain throughout the year in the Azov-Black Sea region, and there are no essential differences in the nomadic movements of birds from the various ringing sites. After breeding, birds from the various colonies are widely distributed along the coasts of the Sea of Azov and Black Sea, and also in the Danube, Don and Kuban regions.

## RESULTS AND DISCUSSION

### A brief history of Pontic Gull ringing in the south of Ukraine

The ringing of Pontic Gulls with metal rings began in the south of Ukraine, and in particular in the Black Sea Biosphere Reserve, at the end of the 1920s. In the reserve archives, there are recoveries of birds ringed on islands in Tendra and Yagorlitsky Bays in the Black Sea Biosphere Reserve, on the Swan Islands in Karkinitsky Bay, and on Kitaj, Martinaychy and Kuyuk-Tuk Islands in Sivash (Table 1). The presence of all this material is a legacy of the many ornithologists who have worked in the region, especially A.B. Kistaykovsky (1920s), M.I. Klimenko (1950s), B.V. Sabinevsky (1950s-1960s) and T.B. Ardamatskaya (1950s-1970s) in the Black Sea Biosphere Reserve and Sivash, and Yu.V. Kostin and N.A. Tarina on the Swan Islands.

An analysis of the results of gull ringing in the Black Sea Biosphere Reserve during the period 1944-1950 was undertaken by Klimenko (1950, 1951, 1953), and later by Sabinevsky (1958, 1966), while Ardamatskaya (1977) produced a report on the migration of gulls including the Pontic Gull.

The author has been involved in the ringing of Pontic Gulls in the south of Ukraine since 1984. Since 1993, a colour-ringing

programme has been in operation under the co-ordination of Norman van Swelm (Ornithological Station Voorne, The Netherlands). About 2 000 nestlings have been colour-ringed since this programme began. An independent study of the migration of the Pontic Gull using ringing has also been carried out by the Melitopol Pedagogical University (Koshelev 2000).

The following analysis of the results obtained from the ringing of Pontic Gull chicks includes the results from both metal- and colour-ringing, and uses published material as well as recent unpublished material. In total, 1 169 Pontic Gulls ringed with metal rings have been recovered. Gull chicks were ringed in spring and summer, primarily in May and June. Seventy-six adult birds were ringed in April and May in 1984 and 1985, and eight adults were ringed in 1990. Colour-ringing of Pontic Gulls was carried out on Konsky and Krugly Islands in Yagorlitsky Bay and at Potievsky in Tendra Bay in the Black Sea Biosphere Reserve. In this paper, only the results obtained from colour-ringing during the five-year period 1999-2003 are discussed.

### Results from ringing with metal rings

Most recoveries, irrespective of age, were recorded as "killed by a hunter" (Table 2). A large proportion of the recoveries were recorded as "circumstances unknown", but the majority of these were probably birds killed by man. Over two-thirds of the recoveries (67.1%) were of birds recovered in their first calendar year. Somewhat fewer (19.2%) were of birds in their second and third year of life, and only 9.5% were of birds aged 4-6 years old (Table 3). The maximum age recorded was 21 years and seven months; this was a bird ringed as a chick in the Black Sea Biosphere Reserve in May 1954 and recovered in the Crimea in January 1976. The annual survival rate of Pontic Gulls increases after the birds have achieved an age of two years. However, the low recovery rates of older birds can also be explained by the loss of metal rings, which disintegrate with age (Ardamatskaya 1977).

### Post-fledging roosts and autumn migration

Most eggs hatch at the beginning of May, and the first young birds fledge in the first ten days of June. In the Black Sea Biosphere Reserve, the first young were seen on the wing on 6-8 June in 1984-1989 and on 28 May in 1990. The nesting sites are abandoned by the young gulls in the last ten days of August (25-31 August in 1984-1990s), and only a few young birds from late broods remain on the islands in autumn. There are only

minor differences in the basic phenology of the breeding season between the Swan Islands and Sivash (Kostin 1983, Siokhin & Grinchenko 1988).

Having abandoned the islands, the great majority of young birds from the Black Sea Biosphere Reserve spend the first two to three weeks within 3–5 km of their birthplace, forming large roosts on bay shores, alongside roads and in fields. By the beginning of August, and less often by the end of July, the young birds reach Tendra Island, where they disperse along the coast. Here the young birds congregate with adults in large post-breeding roosts (Rudenko & Ardamatskaya 1993; Fig. 2).

Young birds from the Swan Islands and Sivash, having abandoned their colonies, appear along the coasts of Karkinitzky Bay

**Fig. 3.** Distribution of autumn recoveries of Pontic Gulls *Larus cachinnans* ringed as chicks in the Black Sea Biosphere Reserve (1x), Swan Islands (2x), and Sivash (3x). and the Sea of Azov. Some weeks after ringing, some individuals migrate along the northern and eastern coasts of the Sea of Azov, and have been recovered 300–500 km from the place of ringing. A young bird ringed on the Swan Islands on 27 June was recovered a few days later on Krivaya Spit in the Sea of Azov, about 300 km away. Many birds ringed as chicks in May and June have been recovered in June and July between 50 and 500 km from the place of ringing, or even more (Fig. 3); of the 72 recoveries of birds in this period, only 11 (15.3%) were from within 50 km of the place of ringing. Some of the young birds undertake a long-distance migration in a north-westerly direction. For example, four gulls were observed one month after ringing on the River Neman in Byelorussia (825 km), and two birds, ringed on 23 May on the Swan Islands and 27 May in the Black Sea Biosphere Reserve respectively, were recovered in Sweden (Fig. 4). The bird ringed on 27 May was recovered in Sweden as early as June. Some young birds move south-west, reaching the Danube Delta and coasts of Romania and Bulgaria (one recovery) in June and July, while others migrate in an easterly direction, e.g. a young gull reached Cimlyansky water storage basin (850 km from the place of ringing) by 26 July.

The majority of recoveries of birds in their first calendar year have been in the month of August, and this is also the peak month for recoveries of adults (Fig. 5). The distribution of recoveries of

**Fig. 4.** Distribution of foreign recoveries of Pontic Gulls *Larus cachinnans* ringed as chicks or adults in the Black Sea Biosphere Reserve (1x), Swan Islands (2x), and Sivash (3x). Month of recovery: 6–12 (June to December).

**Fig. 5.** Recoveries by month of Pontic Gulls *Larus cachinnans* ringed in the Black Sea Biosphere Reserve (1), Swan Islands (2), and Sivash (3). A: immature birds in their first calendar year; B: adults. Month of recovery: I–XII (January to December).

young birds in August is similar to the distribution of recoveries in June and July (Fig. 3). The birds are widely dispersed along the northern coasts of the Black Sea and Sea of Azov from the Danube to the Don and Kuban in the Crimea. In the south-west, some birds reach the coast of Romania (260 km from the place of ringing). It appears that young birds reaching the Romanian and Bulgarian coasts in their first year of life prolong their nomadic wanderings in subsequent years, as there have been 12 recoveries of immature gulls from Romania and three from Bulgaria in various seasons in later years. There is also one recovery of an immature bird in August in the Chernovtsy region, indicating that a part of the population continues to migrate in a north-westerly direction towards the Baltic coast. Immature birds in their second year of life have been found in the port of Copenhagen in Denmark, over 1 700 km from the place of ringing. Other young birds follow the Don and Manich river valleys to Lake Manich (675-680 km from the place of ringing), and there has been one recovery further north-east in the Penza region, about 1 160 km from the ringing site.

The recoveries of young birds in September and October indicate that the great majority of birds remain along the shores of the Black Sea and Sea of Azov. Some birds continue to move in a north-westerly direction, reaching the coast of Denmark (Zealand) and Germany (Heligoland), while others move east as far as the coast of the Caspian Sea (two recoveries in the Astrachansky region, 1 160-1 170 km from the place of ringing). There have also been recoveries of young birds in September and October from Greece (1 250 km) and from Lake Brollos in lower Egypt (c. 2 500 km).

The recoveries of adults after the end of the breeding season and in autumn indicate that these birds disperse along the coasts of the Black Sea and Sea of Azov (Fig. 6). Field observations have revealed that adults and young birds migrate in mixed flocks.

**Fig. 6.** Distribution of recoveries of adult Pontic Gulls *Larus cachinnans* ringed as chicks in the Black Sea Biosphere Reserve (1x), Swan Islands (2x), and Sivash (3x). Month of recovery: 1-12 (January to December).

### Wintering period

During the wintering period (from the end of November to the end of February), most Pontic Gulls in all age groups remain within the Azov-Black Sea region in Odessa, Nikolaev, Kherson, Zaporozhye, Crimea, Donetsk and Rostov territories in Ukraine and Krasnodar Territory in Russia (89.0% of all winter recoveries;  $n = 163$ ). This region can be considered to be the centre of

**Fig. 7.** Distribution of winter recoveries of Pontic Gulls *Larus cachinnans* ringed as chicks in the Black Sea Biosphere Reserve (1 and 4), Swan Islands (2 and 5), and Sivash (3 and 6). 1-3 = first-year birds; 4-6 = immature and adult birds.

the wintering range of the Azov-Black Sea population of the Pontic Gull (Fig. 7). The recoveries suggest that most of the adult birds remain throughout the winter in this region. However, some immature birds winter on the coast of Romania, Bulgaria, Greece and Turkey (10.4% of recoveries), and one bird has been recovered in winter in Byelorussia.

### Spring migration period

The date of return of Pontic Gulls to their breeding grounds varies somewhat from year to year. In the Black Sea Biosphere Reserve, the main arrival of adults at the colonies usually occurs between 20 February and 10 March, but in severe winters with late springs, the arrival may be delayed until the second ten days in April. The adults arrive on the breeding islands in small flocks of between three and eight individuals. Egg-laying usually commences at the end of March or beginning of April. Immature birds remain dispersed along the coasts of the Sea of Azov and Black Sea south to Romania (Fig. 8). Thus, the distribution of immature Pontic Gulls in spring scarcely differs from that in autumn. The main concentrations (88.8% of recoveries) are in the Odessa, Kherson, Crimea, Zaporozhye and Rostov regions in Ukraine, and on the coast of Krasnodar Territory in Russia. However, some birds remain in the Baltic Sea, and there has been one recovery of an immature on the River Narva in Estonia in May.

Pontic Gulls ringed on islands in the Black Sea Biosphere Reserve have been recovered in May in the Rostov region, and birds ringed on the Swan Islands have been recovered at the height of the breeding season on islands in the Black Sea Biosphere Reserve. These recoveries indicate that there is some interchange of individuals between breeding colonies.

### Results from colour-ringing

In the period 1999 to 2002, 817 Pontic Gull chicks were ringed with red colour-rings. Reports of 20 of these birds have been

**Fig. 8.** Distribution of spring recoveries of Pontic Gulls *Larus cachinnans* ringed as chicks or adults in the Black Sea Biosphere Reserve (1x and 4x), Swan Islands (2x and 5x), and Sivash (3x and 6x). 1x-3x = adult birds; 4x-6x = immature birds. Month of recovery: 3-5 (March to May).

**Table 4.** Recoveries and re-sightings of Pontic Gulls *Larus cachinnans* colour-ringed as chicks at Yagorlitsky Bay, Konsky Islands, in the south of Ukraine in 1999-2002.

Date of ringing	Number of chicks ringed	Recoveries/re-sightings	
		Total	%
29.06.1999	430	15	3.5
13.07.2000	275	3	1.1
14.07.2001	100	1	1.0
28.07.2002	12	1	8.3
Total	817	20	2.4

received from the Kiev and Moscow Ringing Centres and Norman van Swelm (Table 4). Nine birds were reported in the year of ringing, seven in the following calendar year, two in the third year, and two in the fifth year. Sixteen of the birds were seen alive, and the number on the colour ring was read in the field; four birds were found dead. Three of these were found dead in the calendar year after ringing, although they were less than one year old (7-10 months). One bird was found dead four months after ringing. Most of the live birds were re-sighted in winter (seven) and summer (six).

Four of the birds were reported in Ukraine, and the remainder (17 re-sightings of 16 birds) were found in seven countries further west in Europe: Poland (6), Germany (3), Romania (3), Cyprus (2), Denmark (1), The Netherlands (1) and Bulgaria (1) (Table 5). Most of these birds were seen in natural habitats (on sea coasts, along rivers and at lakes), but two birds were found at rubbish tips in Poland, two birds were seen at Nicosia airport in Cyprus, and one bird was seen in the city of Berlin in Germany (Rudenko & Rudenko 2004).

## CONCLUSIONS

On the basis of evidence from the recovery of ringed birds, it can be concluded that there are no essential differences between the migration routes of Pontic Gulls nesting on islands in the Black Sea Biosphere Reserve and those nesting in the Sivash or on the Swan Islands (Lebyazhie). There appears to be regular inter-

**Table 5.** Distribution of recoveries and re-sightings, by country and month, of Pontic Gulls *Larus cachinnans* ringed in the Black Sea Biosphere Reserve in the south of Ukraine in 1999-2002.

change between these breeding populations, confirming the earlier conclusion of Sabinevsky (1966) concerning the uniform nature of the Azov-Black Sea population of the Pontic Gull. The bulk of the population is resident within the region, and this tendency to remain in the area appears to increase with age. Only young birds undertake long-distance migrations, migrating in two main directions: in a south-westerly direction to Romania, Turkey, Bulgaria and Cyprus, and in a north-westerly direction towards Poland, Germany, Denmark and The Netherlands. The movements of adult birds in autumn, winter and spring are largely confined to the limits of the Azov-Black Sea region.

## ACKNOWLEDGEMENTS

I would like to thank all the generations of ornithologists in the Black Sea Biosphere Reserve who have taken part in ringing of Pontic Gulls on islands in the Azov-Black Sea region. Special thanks go to Dr Tatiana Ardamatskaya for giving me the opportunity to analyse the recoveries resulting from her field work and that of Dr Boris Sabinevsky. I would also like to thank Norman van Swelm for enabling me to participate in the Pontic Gull colour-ringing programme, and Gerard Boere for encouraging me to prepare this paper.

## Modelling survival and movement probability of Little Tern *Sterna albifrons* at a post-breeding moulting site: the effect of the colony of origin

Giacomo Tavecchia<sup>1</sup>, Nicola Baccetti<sup>2</sup> & Lorenzo Serra<sup>2</sup>

<sup>1</sup>IMEDEA – UIB/CSIC, 21, c. M. Marques, 07190, Esporles, Spain.

Tavecchia, G., Baccetti, N. & Serra, L. 2006. Modelling survival and movement probability of Little Tern *Sterna albifrons* at a post-breeding moulting site: the effect of the colony of origin. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 560-561.

Safeguarding the main stopover or moulting sites for migratory birds along each flyway has long been long recognised and is a high priority in general strategies for bird conservation. These sites act as 'spatial funnels', attracting individuals dispersed over vast areas giving a unique opportunity to obtain a snapshot of the population at a larger scale. Moulting areas are usually sites with low predation pressure and abundant food resources that meet the high energy demands of feather replacement. The location of moulting areas and the extent to which they attract individuals from different breeding areas are often unknown, but have important consequences for population dynamics and conservation strategies.

In 1990, a large post-breeding roost of Little Terns *Sterna albifrons* was discovered at Venice Lagoon, Italy. This species is in decline throughout its European range and is threatened by human activities (del Hoyo *et al.* 1996). Recaptures of ringed birds suggested that the moulting area at Venice Lagoon attracts adults and juveniles from an area encompassing the entire east Adriatic coast (Cherubini *et al.* 1996). A large number of breeding colonies are within this range, hosting a total of about 6 000 pairs, the highest of any European country for this species (Fasola *et al.* 1989, Muselet 1997).

The extent to which the breeding colony of a bird's birth influenced the probability of it reaching the moulting site was investigated by combining information collected from multiple breeding colonies with that obtained at the moulting site. Moreover, the capture-recapture data provided the opportunity to estimate Little Tern post-fledging and annual adult survival probabilities for the first time.

The capture-recapture information collected between 1990 and 1997 came from two main sources, a) birds ringed as chicks on the main Adriatic breeding colonies and b) juveniles and adults captured after the breeding season on a roosting site in the Venice Lagoon near the moulting area. Survival probability was estimated by maximum likelihood procedure from individual encounter histories (Lebreton *et al.* 1993). The local survival parameter is the product between the local survival probability and a movement probability, called here "survival/movement" as a residual of these two components. A total of 12 185 capture-recapture histories were analysed.

The best model describing these data assumed a negative relationship between the survival/movement parameter and the distance of the colony of birth for juveniles. However, this relationship disappeared in adults, whose survival was considered constant. The average annual adult survival/movement probability was 0.899 (95% confidence interval: 0.963-0.836). Juvenile survival between June and September was 0.601 (95%

confidence interval: 0.287-0.850), calculated assuming that all juveniles born near the roosting site would actually visit it in their first winter. First-year survival was estimated to be 0.578 (95% confidence interval: 0.737-0.418).

The results suggest that the moulting area could act as a 'population funnel' within a system of moult migration that involves birds breeding up to 500 km away. However, other unknown moulting sites must exist within the Southern Adriatic Sea, given that a large proportion of Southern birds did not use the Venice Lagoon moulting site, that could be important for the conservation of the species.

The survival/movement parameter in juveniles varied according to birth location, being negatively related to the distance from the moulting site. The effect of the distance on survival cannot be disentangled from the probability of reaching the site. However, the most likely explanation is that distance affected the movement probability. In contrast, the average value of yearly local survival/movement was constant and very similar to the survival estimate found for other species of terns (Spendelov *et al.* 1995; del Hoyo *et al.* 1997). This suggests that individuals that have visited the moulting site at least once tend to visit it again, with a similarly high probability, regardless to their location of birth. Fixation upon the moulting site would probably be achieved the first time they visit it as juveniles, consistent with the general mechanism of site fixation (Ketterson & Nolan 1990).

The northern Adriatic Sea is a particularly productive area due to the large fresh-water input from the Po and other rivers, combined with the mixing effect caused by strong winds and tidal movements. Nearly 5% of birds born at the range limits of the site's breeding catchment are estimated to moult in the Venice lagoon. This further emphasises the importance of moulting sites but also suggests that other similar sites are likely to attract the majority of birds originating from southern areas of the Adriatic Sea, but their catchment ranges are not known. Patches of rich waters coupled with coastal lagoons have been found along the south-eastern coasts of the Adriatic Sea, but whether any of these sites are used as moulting areas by Little Terns, especially by individuals coming from Italian colonies is, currently, unknown (Tavecchia *et al.* 2005).

## Greater Flamingo *Phoenicopterus ruber* ringing at Lake Uromiyeh, I.R. Iran

Sadegh Sadeghi Zadegan

Department of Environment, Pardisan Eco-park, Wildlife Bureau, Tehran, I.R. Iran. (email: sadeghizadegan@abtidi.net)

Zadegan, S.S. 2006. Greater Flamingo *Phoenicopterus ruber* ringing at Lake Uromiyeh, I.R. Iran. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 562-563.

Uromiyeh Lake (483 000 ha) is a large, shallow, hypersaline lake with numerous islands and extensive fringing brackish to saline marshes, in a large internal drainage basin in the uplands of northwestern Iran. The lake is of great importance as a breeding area for many species of waterfowl, notably Greater Flamingo *Phoenicopterus ruber* and is protected as a National Park and Ramsar site. This note describes the results of the ringing programme started in 1970.

Large breeding colonies of the Greater Flamingo were first located in 1965 and 1966 (Fig. 1). Crude estimates place the total flamingo population on Lake Uromiyeh at 10 000-12 000 in 1965 and 1966, while aerial censuses of the breeding colonies in 1971-72 put the population at 15 000-20 000 breeding pairs, with an additional 5 000-10 000 non-breeders present (Scott 1973). Numbers appear to be increasing slightly, with perhaps as many as 25 000 breeding pairs in the last decade. In Iran as whole, wintering flamingo populations are estimated at 85 000-160 000 individuals.

The Flamingo Ringing Project at Lake Uromiyeh started in 1970, and has continued annually from early July to late August in most years. In 1970, 2 250 flamingo pulli (chicks) were neck-banded with blue collars and 242 adults were ringed with metal leg-rings. Since 1970 only metal leg-rings have been used, and

by the end of the 1999 breeding season, a total of 30 002 birds had been marked (leg rings and collars). A colour ringing program was initiated in 1999, starting with 295 pulli. Data are summarised in Table 1.

By the end of December 2002, 216 recoveries (0.72 %) had been reported from 28 countries, including Morocco, Sudan, Ethiopia, Somalia, Azerbaijan, Kazakhstan, India, Sri Lanka and Iran (Table 2). This demonstrates a very wide post-juvenile dispersal of flamingos that had not hitherto been suspected. The adult birds from the Lake Uromiyeh colony, however, seem to winter almost entirely in central Fars and along the coast of Persian Gulf and Oman Sea.

The rate of recovery increased until 1974 (1.23%), but from 1975 this has steadily decreased to 0.72% in 1999. This indicates that metal ringing is not a suitable method for marking flamingos, and we should explore more effective methods such as satellite tracking and colour ringing. From 689 adult ringed birds only 7 have been recovered (three from Iran, two from Kazakhstan, one from Egypt and one from the UAE), and those between 10 months and 15 years after ringing. It seems that ringed adults survive better than ringed chicks. Only two colour rings have been recovered, both in Khue Dubai in 2002 and 2005.

Fig. 2. Recoveries of ringed Greater Flamingos *Phoenicopterus ruber* by age groups (in months).

Fig. 2 shows recovery periods varying from 1-162 months. A total of 99 recoveries (46.3%) occurred 1-6 months after ringing, and 113 recoveries (52.8%) 1-9 months after ringing, showing a high mortality during the juvenile period, caused perhaps by the following:

- until five months, chicks do not have enough strength to fly, and therefore cannot escape enemies;
- chicks are not familiar with threats and are easily injured;

- differences in migration routes - adults are thought to winter mainly in Iran and juveniles outside Iran; and
- recovery data show that although flamingos are a protected species, they are widely hunted, and most recoveries come from shot birds.

## The Sivash Bay as a migratory stopover site for Curlew Sandpiper *Calidris ferruginea*

Sergei V. Khomenko

Schmalhausen Institute of Zoology, National Academy of Sciences of Ukraine, Vul. B. Khmel'nitskogo, 15, Kyiv-30, MPS, UA-01601, Ukraine. (email: khomenko@izan.kiev.ua)

Khomenko, S.V. 2006. The Sivash Bay as a migratory stopover site for Curlew Sandpiper *Calidris ferruginea*. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 564-567.

### ABSTRACT

During migration periods the Sivash Bay of the Azov Sea supports up to 1.5% of the world population of Curlew Sandpiper *Calidris ferruginea* (c. 66 000 – 120 000 birds). In spring most birds pass through in the first ten days of May. They stopover for four to five days during which they accumulate as much as 41% of extra body mass. Curlew Sandpipers' main prey during this time is Brine Shrimp *Artemia salina*, whose distribution is restricted to the hypersaline waters of the Sivash. Feeding upon Brine Shrimps is highly profitable: spending 79% of foraging time, with pecking rates of 90 per minute, birds are able to gain 4.3 g of reserve tissue daily. The flight range of birds departing from the Sivash in spring is estimated at 2 – 2 500 km. In autumn, Curlew Sandpipers leave for wintering grounds located all over the African continent with sufficient fat reserves to travel 4 – 4 500 km. Ringing recoveries link this stopover site with staging areas in the Mediterranean, Baltic and East-Atlantic. Birds breed in the Taimyr Peninsula, although morphometric data suggests that some birds may come from areas further east.

### INTRODUCTION

Compared with the East-Atlantic flyway, stopover sites of waders in wetlands around the Mediterranean, Black and Caspian Seas, the Afro-Eurasian continental flyway corridor, remains rather poorly studied. Curlew Sandpipers show a clear preference for this continental flyway corridor in both spring and autumn (Eliot *et al.* 1976, Wilson *et al.* 1980). This paper summarizes results of several studies on Curlew Sandpiper in the Sivash Bay (Khomenko *et al.* 1999, Dyadicheva *et al.* 1999).

### METHODS

Counts and mist-netting of Curlew Sandpipers were carried out during regular expeditions of the Azov-Black Sea Ornithological Station to the Sivash Bay (S Ukraine, SE Europe) between 1992-1998. By 1998, a total of 6 400 Curlew Sandpipers were ringed and 79 long-distance recoveries (0.6%) obtained in the Southern Ukraine (including the Sivash). Spatial coverage of counts varied between years, the most complete censuses being carried out in May 1993, 1996 and August 1998. Since the periods of catching and ringing varied between years, all data from 1992 to 1998 was pooled by five day periods (Bertold's pentads) to analyze the seasonality of morphometrics, body mass dynamics and moult (19 pentads,  $275 \pm 424$  birds per pentad analyzed). Only samples  $\geq 20$  adult birds were included in the analyses providing totals of 3 313 birds in spring and 1 414 birds in autumn. Birds were measured, weighed and aged according to standard methodologies (Prater 1977; pre-print by H. Schekkerman 1990). Plumage characteristics were described according to Chernichko (1988). The average wing to bill ratio was calculated for each sample to identify sex ratios (Khomenko & Dyadicheva 1999).

Time budgets were determined by activity scanning (184 hours of observations, six activities distinguished; for details see Khomenko *et al.* (1999). The average daily body mass gain was calculated by comparing the expenditure (BMR + activity costs + moult) and income (consumption of food per unit of time \* energy equivalent \* assimilation coefficient of the prey) of the energy budgets according to a standard evaluation procedure (Dolnik 1982). The production of 1 g of reserve tissue was considered to cost 34.2 kJ (Verkuil *et al.* 1993). The maximum flight distance (MFD, km) was calculated as the formula:  $MFD = 95.447 \cdot$

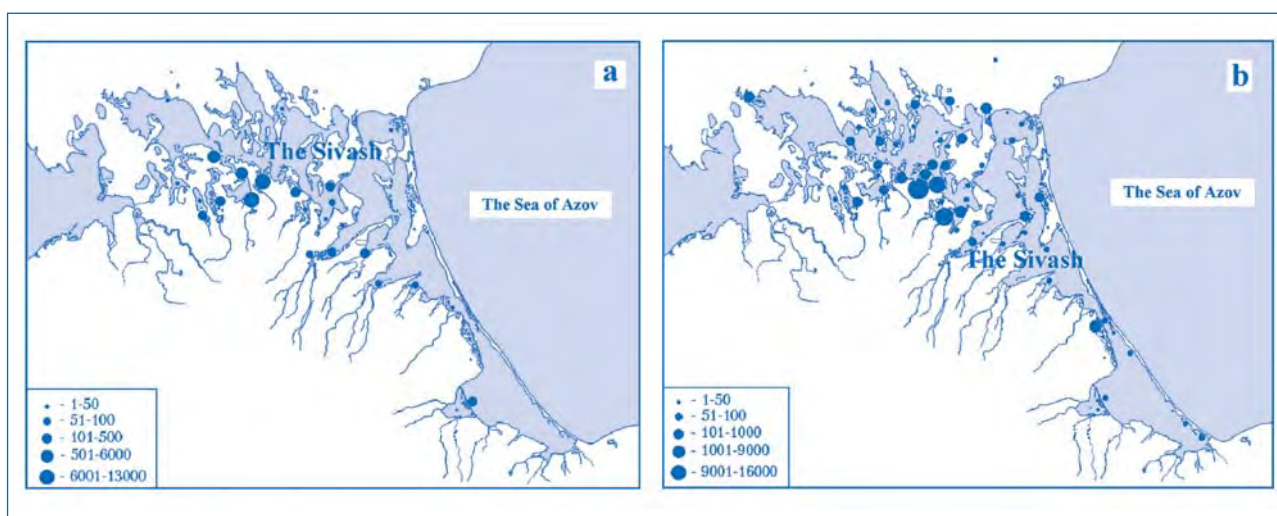

Fig. 1. Distribution of Curlew Sandpiper *Calidris ferruginea* gatherings in the Sivash according to absolute counts carried out in 1990-1998. Only maximum figures for each counting locality are presented. a – spring, b – autumn.

$V(T^{0.302} \cdot M^{0.302})$ ; where  $V$  – flight speed (km/h),  $T$  – initial body mass (g),  $M$  – arrival body mass (g) (Gavrillov 1992).

## RESULTS

### Numbers, distribution and migration pattern

The largest gatherings of Curlew Sandpipers were found in the southern part of the country, where birds occur in most coastal wetlands. In the Sivash area, c. 33 000 and c. 72 000 birds were counted here simultaneously at the peak of spring and autumn migration respectively. Smaller numbers, totaling up to c. 10 000, were counted in autumn in the estuaries of the Azov-Black Sea coast (Dyadicheva *et al.* 1999). The largest concentrations in both spring and autumn were in Central Sivash (Fig. 1).

Seasonal trends in the wing/bill ratio (Fig. 2) indicate that males migrate earlier than females in both spring and autumn (Cramp & Simmons 1983). In spring migration, two waves can be distinguished; the first, around 10 May with a maximum c. 33 000 birds counted simultaneously and a second, five times smaller, around 22 May. The migration pattern suggests that most birds stay in the area for five to six days. Autumn migration, which begins with the arrival of males in mid-July, is more prolonged. Most males leave the area by 8 August. A pronounced peak in numbers is recorded around 20 August, when females replace males in the staging area. In autumn, males and females are estimated to stay for two to four weeks, with females tending to have shorter stopover periods than males.

Fig. 2. Timing of male (m) and female (f) stopover in the Sivash according to the wing/bill ratio dynamics.

### FEEDING ECOLOGY, PRE-MIGRATORY FATTENING AND FLIGHT RANGE

The habitat choice of Curlew Sandpipers in the Sivash (Fig. 2) clearly shows that birds prefer Brine Shrimps to other (mainly freshwater) prey species that are available (Khomenko *et al.* 1999). Contrary to many other waders (e.g. Zwarts *et al.* 1990) Curlew Sandpipers in both the Central and Eastern Sivash feed only during the daytime. Maximum feeding activity occurs in the morning (Fig. 3), during periods of maximum availability of Brine Shrimps. In the Central Sivash, Curlew Sandpipers foraged significantly longer ( $79.4 \pm 22.3\%$ ) than in the Eastern

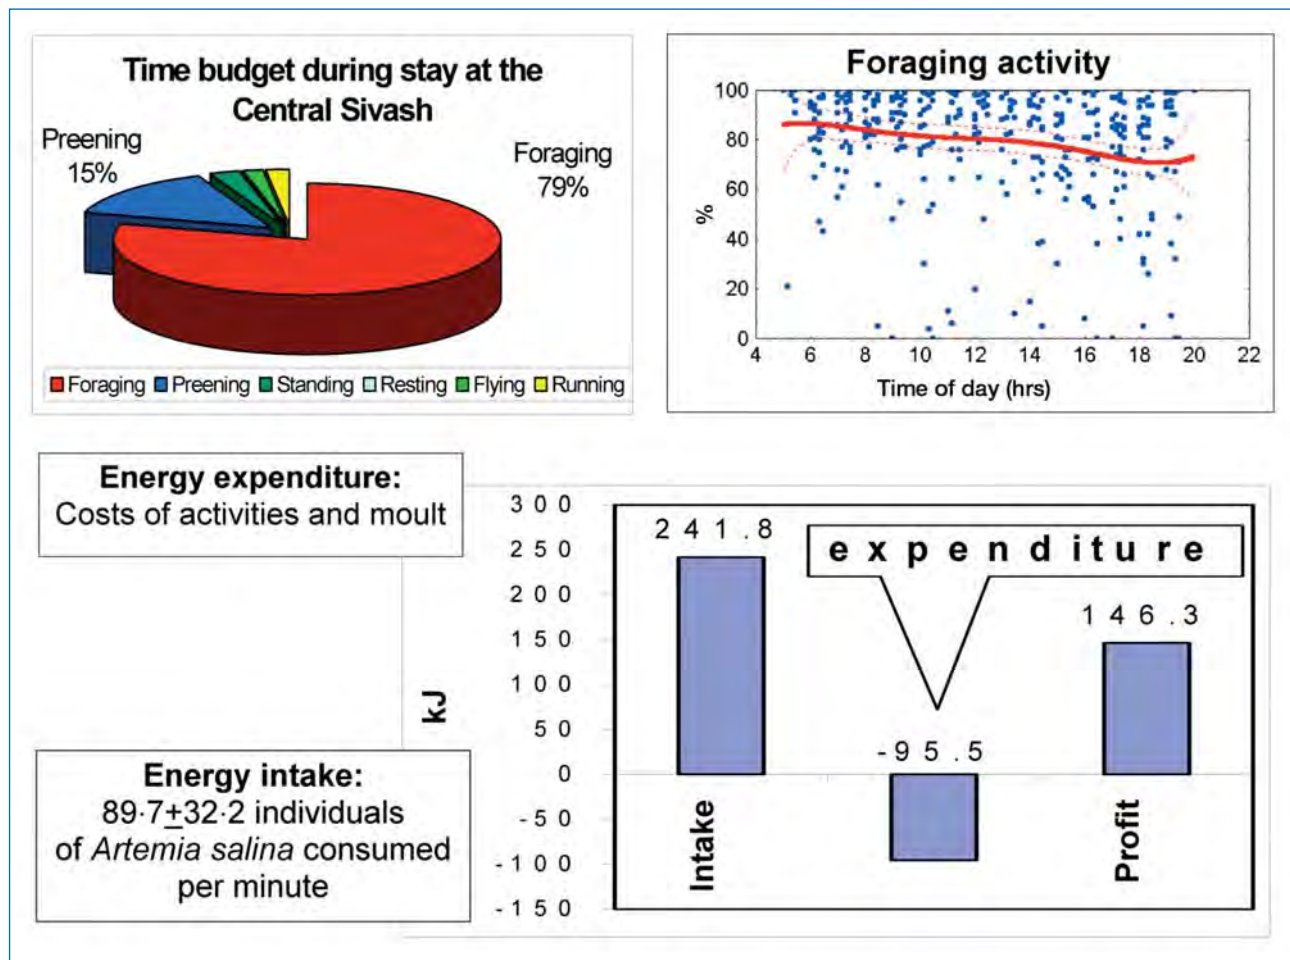

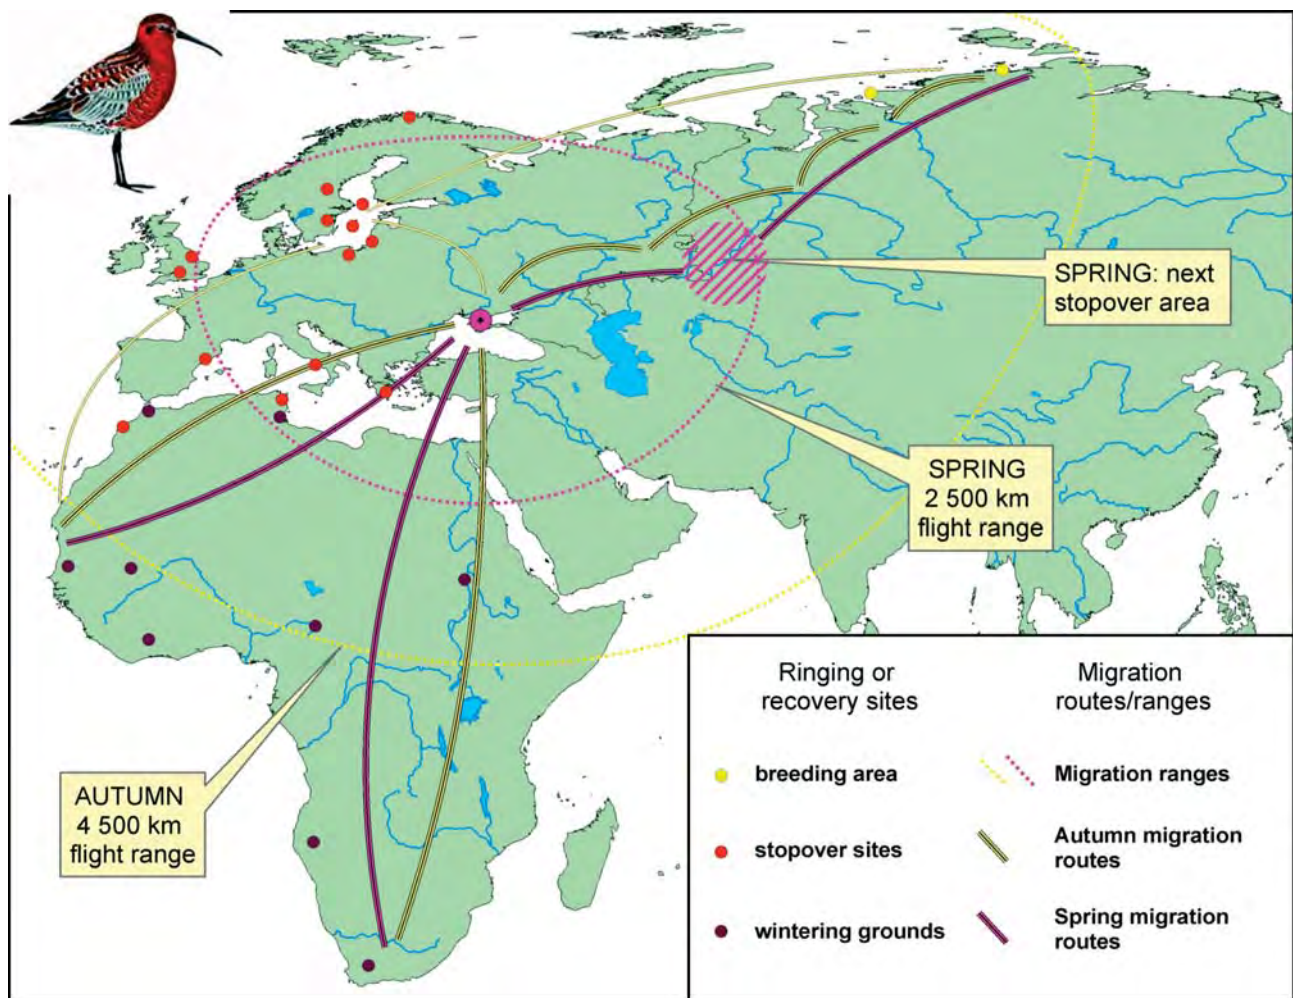

Fig. 3. Time and energy budgets of Curlew Sandpipers *Calidris ferruginea* foraging on Brine Shrimps *Artemia salina*.

**Fig. 4.** Recoveries of Curlew Sandpipers *Calidris ferruginea* ringed or recovered in the S Ukraine by seasons (wintering, migration and breeding) and scheme of migration routes and estimated flight ranges.

( $74.5 \pm 23.8\%$ ), mainly due to a decreasing time for resting from  $6.7 \pm 12.0$  to  $0.2 \pm 0.5\%$  (Mann-Whitney test,  $p < 0.01$ ).

Pecking rates of Curlew Sandpipers in the Central Sivash were measured ( $n=517$ ) to estimate the consumption of this prey per unit of time. It averaged  $89.7 \pm 32.2$  specimens per minute, which was significantly higher than in Dunlin (Mann-Whitney test,  $p < 0.01$ ). Energy intake was estimated on the basis of daily food consumption (Fig. 3). Dependent on the time spent foraging it varied from 180.8 to 273.8 kJ/day (average =  $241.8 \pm 32.5$  kJ/day). This fully compensated estimated daily energy expenditures leaving an average of  $146.3 \pm 38.4$  kJ/day ( $72.1$ – $185.5$  kJ/day) available for building up fat reserves. With this amount of energy Curlew Sandpipers were estimated to gain body mass at a rate of 2.1–5.4 g/day (on average  $4.3 \pm 1.1$  g/day). During the spring staging period, which is estimated to be no longer than five to six days (Khomenko *et al.* 1999), birds can gain as much as 33–41% of extra body mass. Their flight range should then be around 2 000–2 500 km, which is clearly not enough to go directly to the breeding grounds (Fig. 4). In autumn, average body mass is generally in the range of 70 to 78 g. The estimated flight range to the wintering grounds is approximately 4 000–4 500 km.

## DISCUSSION

Given the assessment of Curlew Sandpiper numbers in the Sivash it seems that the area is probably one of the most important

stopover sites for this species in the world. If the turnover rate is taken into account, according to our estimates up to 9% (c. 66 000 birds) of the African wintering population pass the area in spring and around 21% (c. 160 000 birds) – during autumn migration. These figures correspond to 0.5 and 1.5% of the world population of Curlew Sandpiper (Rose & Scott 1994). Nowhere else have such large concentrations of Curlew Sandpiper been recorded.

There is no doubt that large numbers of birds are attracted to the area by high densities of Brine Shrimps. Research has shown that Curlew Sandpipers using this food during pre-migratory fattening can gain body mass at a daily rate close to the maximum ever recorded (5.5 g/day, sedimentation fields in Bahrain, Hirschfeld *et al.* 1990). Therefore, fat reserves sufficient for flying some 2–2 500 km can be accumulated in an extremely short period of time (four to five days). It is important to stress the fact that most birds depart from the Sivash with 33–41% of extra body mass as early as mid-May, which is approximately one month before their arrival at the breeding grounds. They have one more stopover area on route to the breeding grounds, which is most likely to be located somewhere in the south of Western Siberia (Fig. 4).

The particular preference of Curlew Sandpiper for hypersaline environments has also been recorded in Hungary, where up to 61% of birds occurred in salt pans (Sterbetz 1993). This raises the question as to whether the species may be dependent on the

food resources of galinic water bodies during migrations via continental Eurasia. The exclusively diurnal feeding and high efficiency of foraging upon Brine Shrimps recorded in the Sivash clearly distinguish Curlew Sandpiper from other sandpiper species, and Dunlin in particular (Khomenko *et al.* 1999). These peculiarities of its feeding ecology suggest that birds do not just feed on Brine Shrimps by chance, but to a certain extent, specialize on such food. Moreover, it is known that saline water bodies (e.g. Manych-Gudilo, the Caspian coast, salt lakes of the south of Western Siberia) predominate in the areas Curlew Sandpipers pass through during migration to the breeding grounds and back.

Breeding grounds of Curlew Sandpipers ringed or recovered in S Ukraine are located in NW and N Taimyr (n=2), although analysis of morphometrics suggest (Khomenko *et al.* 1999) that a faction of smaller-billed birds may come from the areas to the east (up to the Lena River mouth). Wintering areas are apparently rather large and include N, W, S and Central Africa. Many recoveries (n=25) link S Ukraine and NW Europe (mostly Scandinavia and Baltic). Frequent re-trapping of birds between these two areas indicate that some Curlew Sandpipers using the East-Atlantic Flyway in autumn may move from NW Europe to S Ukraine via the Dnipro River valley just like Dunlins (Chernichko 1982). Another frequently used route links S Ukraine and the Mediterranean area (n=37). Two direct recoveries (in Spain and Italy) indicate a south-western movement in autumn. The seasonal distribution of recoveries suggests that birds use the Mediterranean flyway both during spring and fall migrations. The distribution of ringing recoveries suggests a wide wintering range of birds passing the Sivash (Fig. 4). Also the pattern of connections between the area and other stopover sites along the East-Atlantic flyway (as well as wintering and breeding grounds) seems to be more complicated than originally thought (Eliot *et al.* 1976, Wilson *et al.* 1980). The most likely migration routes taken by Curlew Sandpipers staging over in the Sivash are shown in Fig. 4. The scheme proposed by Eliot *et al.* (1976) and Wilson *et al.* (1980) can be accomplished by combining the Baltic – Black Sea route (which is apparently used by birds during autumn passage to the southern African wintering grounds) and the supposed Black Sea – south of Western Siberia route (which brings birds to the next stopover area on route to the breeding grounds).

Although both the Central and Eastern Sivash have already been designated as Ramsar sites, the future development of agricultural irrigation poses a serious threat to Curlew Sandpipers. A large-scale discharge of irrigation and drainage waters would freshen the saline lagoons and reduce availability of halophytic Brine Shrimps. Therefore, efforts should be made to safeguard this unique stopover site from the threat of possible desalination which would help to protect migratory populations of Curlew Sandpiper at a global scale.

## 4.5 Migration and flyway atlases. Workshop Introduction

**Jacquie Clark**

*British Trust for Ornithology, The Nunnery, Thetford, Norfolk, IP24 2PU, UK.*

Clark, J. 2006. Migration and flyway atlases. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 568.

Over one hundred years of bird ringing have provided a wealth of ringing recoveries. Much of this information has only incidentally been used in studies of single species or in depth population studies. Recently a few countries have produced bird migration atlases in which the results of bird ringing play a major rôle.

This workshop provided an overview of the present atlases; the various methods used to present the available ringing data integrated with information from other sources to give international overviews of the distribution and movements of waterbirds.

### INTERNATIONAL COLLABORATION

Whilst a number of migration atlases have been published, most only cover a subset of bird species, and almost all produced to date are based on ringing and recovery data from single countries (as for example, described by Dobrynina & Kharitonov for Russian waterbirds). There is a strong need for atlases using data from all countries, within a continent or sub-continent (for example, as noted by Oschadleus for southern Africa), in a flyway, or best of all, based on the biology of the birds.

Spina & Clark of EURING demonstrate how ringing schemes from different countries can collaborate productively, but there is still a long way to go.

### BROADENING THE TECHNOLOGICAL BASE OF INFORMATION

Most analyses for the atlases published so far are based on recoveries of metal rings. We need better integration with such data, of other data from colour-ringing and similar individual marking, telemetry, stable isotope analyses and genetic markers.

### COMBINING RINGING AND COUNT DATA

Systematic analyses for atlases confirm the value of ringing studies in assessing the conservation status of breeding, wintering and stop-over sites within the context of whole flyways.

Systematic analysis of data on waterbird ringing recoveries should continue to be a priority so as to give a better assessment of distributional limits of biogeographical populations. This work should be encouraged on a co-operative, international basis, and integrated with reviews of waterbird survey and census information. Such integration of count data with ringing data will allow the assessment of the conservation status of such sites even more clearly, and to better understand how each species uses the parts of its entire range.

### FLYWAY SCALE ATLASES

The mapped depiction of the geographic limits of the different biogeographical populations of waterbirds has long been seen as a conservation priority. Indeed, IWRB organised a whole international symposium in 1976 on the subject of mapping waterbird distributions, at which was discussed a proposal for an atlas of wetlands and waterfowl so as to map flyways and key sites for ducks, geese and swans. As discussed by Delany & Scott, this

George Atkinson-Willes pioneered IWRB's initial mapping of European waterbird distributions. Modern technology has vastly enhanced the capability to organise spatial information and modern bird atlases are using increasing sophisticated analytical methods. Photo: Wildfowl & Wetlands Trust.

project was eventually realised fifteen years later by Scott & Rose with their 1996 *Atlas of the distribution of African and West Eurasian Anatidae* — a land-mark publication by Wetlands International summarising existing knowledge. However, since then there has been slow progress in developing population atlases for other waterbird taxa, although a major publication on waders is currently in preparation.

### DEVELOPING ANALYTICAL TECHNIQUES

Systematic analyses of ringing data are needed for five reasons:-

1. Describe the distributional patterns of birds in space, how these vary seasonally, and long-term changes in distribution and movements.
2. Reliably distinguish the patterns of different populations, ages and sexes.
3. When ringing data are computerised, modern computing technology provides immense analytical power. Techniques such as geographical information systems expand this beyond the more obviously statistical methods.
4. Various analytical methods have been developed for ringing data and there is active progress in developing further methods; this must continue.
5. The major need is to overcome biases associated with geographical variation in reporting rates and with method of recovery. We need to overcome the impacts of these biases on the apparent differences in migration of different populations, ages and sexes.

## EURING: its role in migration and flyway atlases

Spina, F. & Clark, J. 2006. EURING: its role in migration and flyway atlases. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 569-573.

### ABSTRACT

Knowledge of the complex biological systems represented by migration routes is best obtained through the study of individually marked birds. The oldest and most widespread technique to follow the movements of birds is ringing. In Europe, EURING (The European Union for Bird Ringing) has ensured that ringing and recovery data are collected and stored in a standardized manner in its EURING Data Bank (EDB). These data can be used to perform large-scale analyses of the geographical distribution of flyways, seasonality of movements and ecological requirements of waterbirds migrating within the Palearctic and between Europe and Africa. This paper gives a brief review of the ringing and recovery data available for waterbirds in the EDB, and suggests some ways in which these data might be used, particularly in the compilation of migration atlases. EURING continues to improve the EDB, and offers its long-term expertise to assist in the analysis of recoveries of ringed birds on a flyway scale.

### INTRODUCTION

Migratory birds freely cross political boundaries and represent a natural heritage belonging to the international community. Sound conservation and management policies need to be based on a large-scale approach, involving many countries and also different continents. For species which are hunted, this implies the need for shared international legal instruments to ensure common actions and prescriptions in terms of habitat management and harvesting. Important examples are offered by the EU Wild Birds Directive 79/409 and the African-Eurasian Migratory Waterbirds Agreement (AEWA) under the Convention on Migratory Species of Wild Animals (CMS).

Knowledge of the complex biological systems represented by migration routes (including breeding, moulting, migration stopover and wintering areas) is best obtained through the study of individually marked birds. The oldest and most widespread technique to follow the movements of birds is ringing (also known as banding).

The original aim of bird ringing was to describe the routes used by birds during their migrations. A century after the first ringing activities were carried out, scientific bird ringing remains a highly versatile and extremely efficient research and monitoring technique. As well as identifying the movements of birds and the location of their breeding and wintering grounds in all continents, ringing has allowed the investigation of many aspects of bird biology, behaviour and demography which can only be analysed if individuals can be identified.

In Europe, EURING (The European Union for Bird Ringing, [www.euring.org](http://www.euring.org)), a network of 38 national ringing schemes, has ensured that data are collected and stored in a standardized manner. EURING maintains the EURING Data Bank (EDB),

which constitutes an invaluable asset for analysts by bringing together reports of ringed birds that were either ringed or subsequently reported (recovered, recaptured or re-sighted) anywhere in Europe. These data can be used to perform large-scale analyses of the geographical distribution of flyways, seasonality of movements and ecological requirements of waterbirds migrating within the Palearctic and between Europe and Africa. This information can assist in objective decision making, to ensure that appropriate site protection and sustainable hunting guarantee the favourable conservation status of the various species.

### MIGRATION ATLASES AND THE ANALYSIS OF RINGING DATA

A series of recently produced national migration atlases and a geographical index of the contents of the EDB provide practical examples of the potential for analysis of ringing recoveries to serve as a tool for the management of migratory birds. The analytical approaches which were adopted in these atlases and the strategy adopted by EURING to stimulate further large-scale applied analyses of ringing data were the subject of a session devoted to migration and flyway atlases at the Waterbirds around the world Conference.

The migration atlas for Britain and Ireland (Wernham *et al.* 2002) is based on an impressive sample of recoveries that have been accumulated over almost a century, and offers interesting examples of novel analyses. Frequency distributions of the distances moved by ringed birds allow the migratory tendency of a species and the differential migration of sub-populations of that species to be investigated and quantified. The historical coverage of data also offers a unique opportunity to describe temporal changes in migration routes as a possible consequence of global climate change.

The influence of global change on bird migration patterns is also shown by some of the analyses performed on another huge sample of recoveries, held at the Bird Ringing Centre of Russia and illustrated by Sergei Kharitonov, based on analyses carried out with the late Inna Dobrynina (Dobrynina & Kharitonov, this volume). The importance of having continuous coverage of ringing activities over many years, and hence long-term sets of recoveries, is illustrated by species such as the Red-breasted Goose *Branta ruficollis*. Until the 1970s, the main winter quarters of this species were located in the south-west corner of the Caspian Sea, but in the early 1970s, the entire population moved to the north-west corner of the Black Sea, and since the late 1990s, some birds have begun to spend the winter along the north coast of the Black Sea and around the Sea of Azov (Dereliev, this volume). Such complex patterns of movements also emphasize the need for international legislation to take account of the geographical distribution of birds and to respond

to any changes. Without adequate monitoring, significant changes in the network of important areas for a particular species (a crucial component of sound international conservation policies) may be missed.

This is especially true when huge geographical areas are involved, as shown by the data on recoveries held at the SAFRING Ringing Centre at the Avian Demography Unit, University of Cape Town, South Africa, and published in a series of atlases (e.g. Underhill *et al.* 1999). During the boreal winter, the southernmost latitudes of the African continent are home to a number of species that breed thousands of kilometres away to the north, in the highest latitudes of the Palearctic. The problems affecting birds which spend parts of their annual cycle in areas so far apart and pass across a large number of countries, often with very diverse legislation, during their migrations are a great challenge for bird conservation, and can only be evaluated through methods that involve marking birds individually, such as ringing.

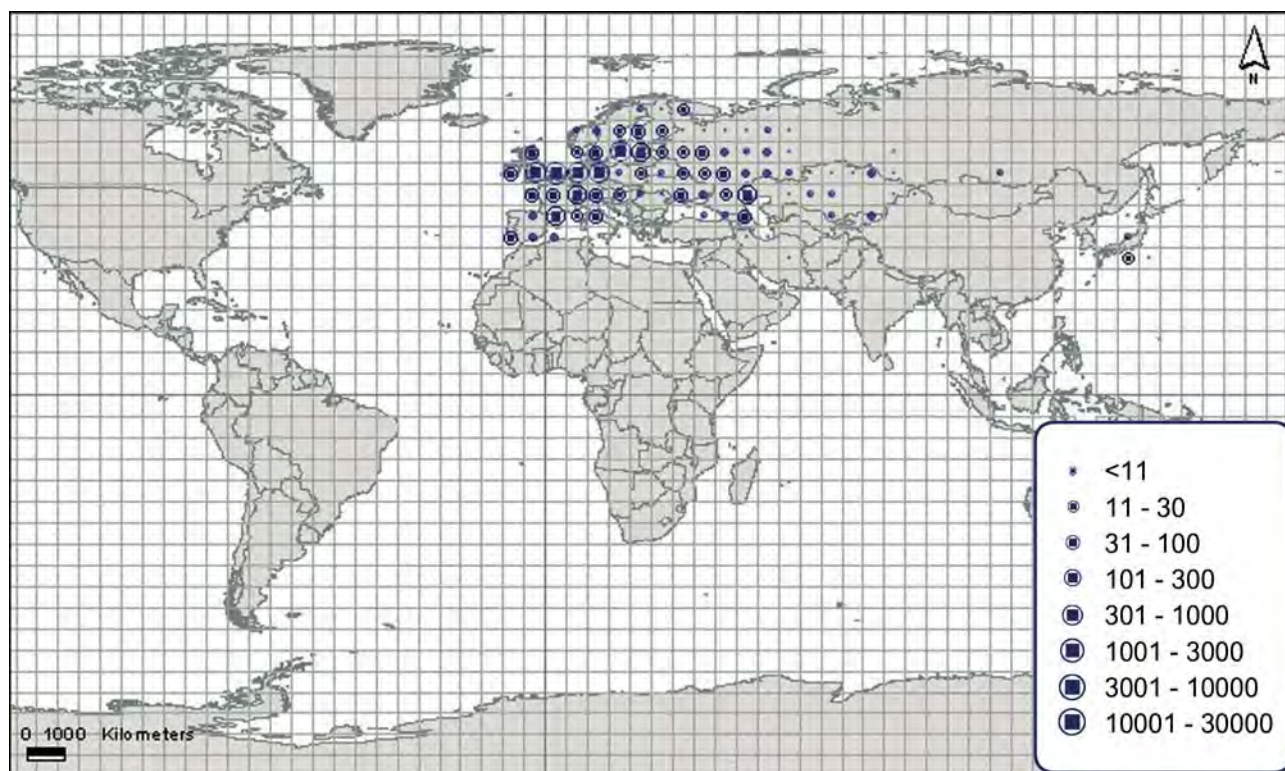

As many waterbirds congregate in a relatively small number of sites outside the breeding season, they are also regularly monitored by direct counts. The International Waterbird Census (IWC), co-ordinated by Wetlands International, covers a huge geographical area and a large number of species. This long-term project has provided numerical estimates of populations not only at the species level, but also at the level of biogeographical populations, and has contributed to the publication of a series of atlases (Delany & Scott, this volume), the first of which was the Atlas of Anatidae Populations in Africa and Western Eurasia (Scott & Rose 1996). These very important atlases show the geographical boundaries of the flyways followed by each of the different populations of a species. It is clear that in the integrated management and sustainable harvesting of migratory waterbirds, consideration has to be given both to the number of individuals of a given species and to the different populations funneling along their respective flyways.

**Table 1.** Recovery data available for analysis in the EURING Data Bank for some AEWA species.

EURING code	Scientific name	Live recoveries	Dead recoveries	Total recoveries
05820	<i>Larus ridibundus</i>	105 707	82 087	187 794

#### THE ROLE OF EURING

An ideal development in the compilation of migration atlases would be represented by an atlas integrating data on the distribution of waterbirds based on counts with data from the recoveries of individually marked birds. In order to provide better access to the contents of its unique data bank (EDB) and to stimulate such integrated analyses, EURING has produced a geographical index of the 2.7 million coded and computerized recoveries available for 426 species of birds. The EDB contains large data sets for many of the waterbird species covered by the AEWA (Table 1), and

**Fig. 1.** Ringing data available for the Mallard *Anas platyrhynchos* in the EURING Data Bank, by 5° grid square.

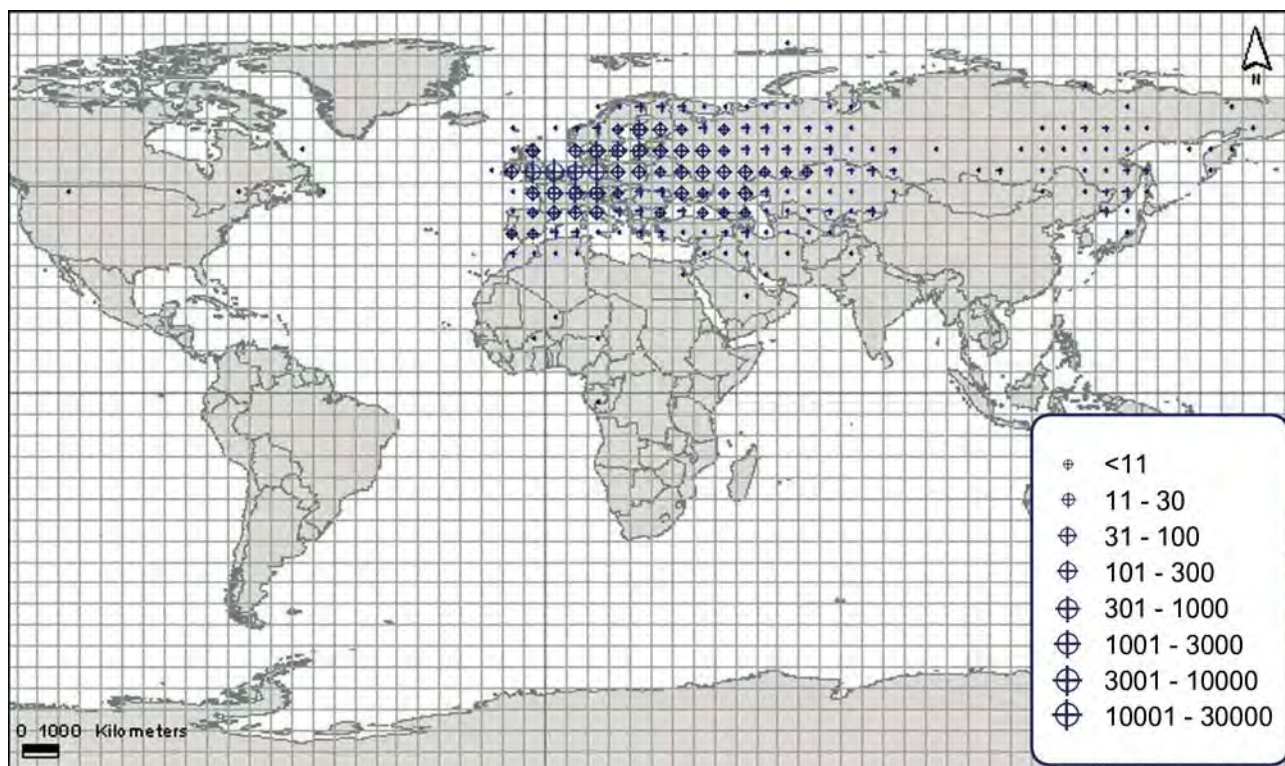

Fig. 2. Recovery data (dead recoveries only) available for the Mallard *Anas platyrhynchos* in the EURING Data Bank, by 5° grid square.

**Table 2.** Number of recoveries of the Mallard *Anas platyrhynchos* in the EURING Data Bank per decade. A distinction is made between birds recovered dead and those recaptured alive or re-sighted.

Time period	Records of dead recoveries	Records of live recaptures/re-sightings
Pre 1940	373	1
1940-1949	1 839	14
1950-1959	12 820	1 333
1960-1969	20 430	1 315
1970-1979	13 943	1 372
1980-1989	9 762	1 368
1990-1999	1 979	1 784
Post 1999	245	505

these are available for analysis. The EURINDEX project has been accomplished with the involvement of the NIOO in Heteren, The Netherlands, the INFS in Bologna, Italy, and the BTO in Thetford, UK; the results were published in July 2004 on EURING's web site (<http://www.euring.org/edb/index.htm>). The index is structured on a grid of 5° longitude x 5° latitude, and shows the amount of data available for each of the grid cells. Two maps showing the number of birds ringed and the number of dead recoveries, respectively, are presented for a total of 173 species with over 500 lines of data available (see examples for the Mallard *Anas platyrhynchos* in Figs. 1 & 2), while for another group of 160 species, a further two maps show the geographical distribution of ringing and live recaptures/re-sightings, respectively.

Summary tables also give the amount of data available per decade, starting from before the 1940s, and make a distinction between dead recoveries and live recaptures/re-sightings (Table 2);

this is important when planning analyses of long time-series, as the composition of the samples may change over time through changes in human/bird interactions (e.g. through changes in the finding circumstances). The contribution of data by each ringing scheme with over 500 recoveries is also reported (Table 3).

Although the AEWA covers a huge range of countries, it is apparent from the distribution of ringing/recovery data points in the EURINDEX maps that the geographical boundaries of the Agreement do not necessarily match those of the populations involved in migratory movements within the AEWA region. For example, the distribution of the recoveries of Eurasian Wigeon *Anas penelope* (Fig. 3) and Northern Pintail *A. acuta* (Fig. 4) includes the whole of Eurasia east to the Pacific coast. This suggests that further analyses are required for a better understanding of the complex flyways involving AEWA species and the Agreement area. As regards Africa, the geographical distribution of recoveries of the Sandwich Tern *Sterna sandvicensis* (Fig. 5) confirms that the boundaries of the Agreement area should extend to the southernmost latitudes of this continent.

Ringing recoveries are the best available source of information for the analysis of survival rates. This is especially important when considering the complex issues relating to the sustainable harvest of waterbirds, for which survival rates need to be taken into account. EURING can also make an important contribution in this respect. Through its analytical meetings, where statisticians and ornithologists work together for the better use of CMR (capture/mark/recapture) data, new models have been developed and are now available for the derivation of reliable survival estimates.

## CONCLUSION

EURING continues to maintain and improve its data bank, the EDB, and offers its long-term expertise to assist in the analysis

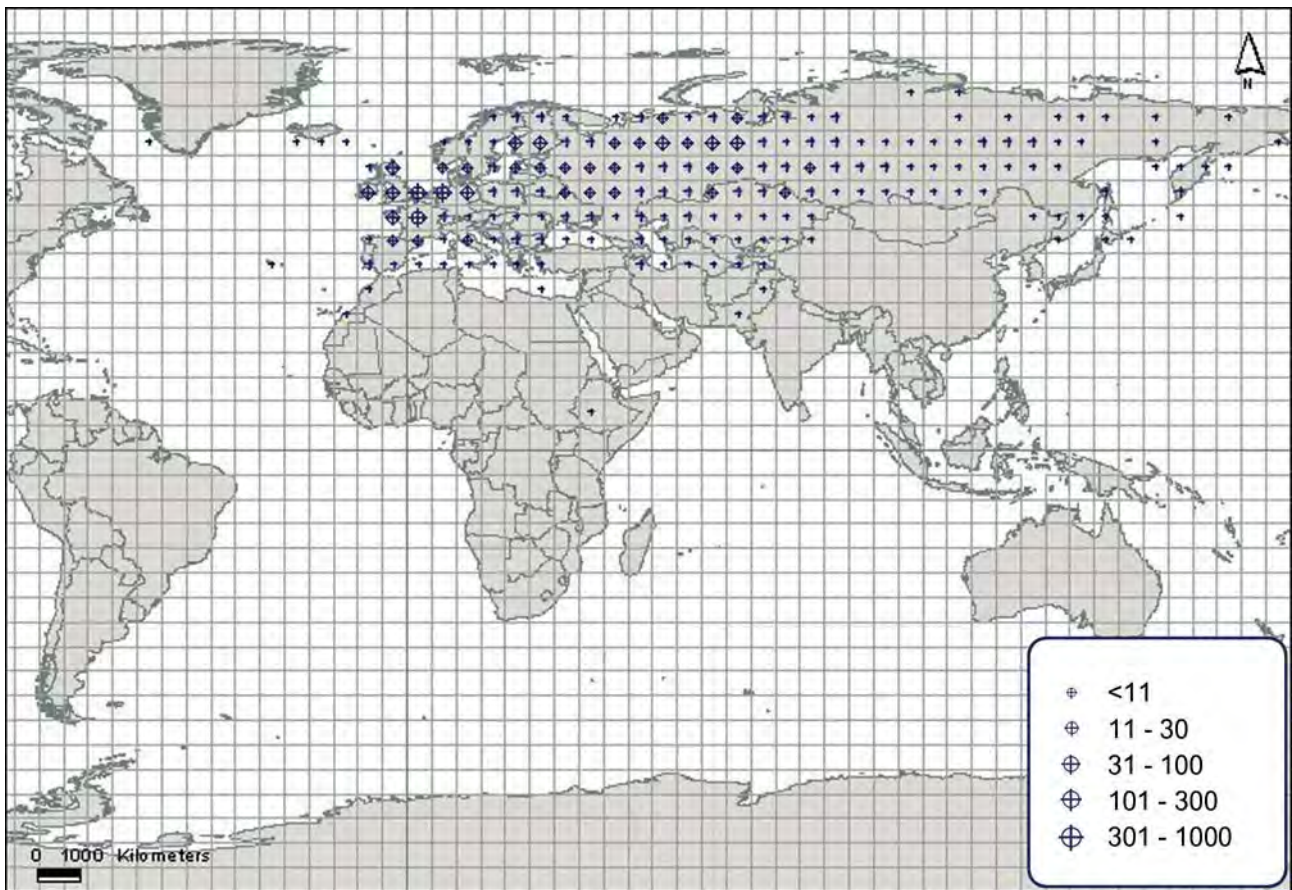

Fig. 3. Recoveries of the Eurasian Wigeon *Anas penelope* in the EURING Data Bank, by 5° grid square.

of recoveries of ringed birds on a flyway scale. The EURING information should aid decision makers (e.g. the AEWA Secretariat, European Commission and national governments) in establishing appropriate controls on factors such as the timing of hunting seasons, to ensure the sustainable use of waterbird resources for the benefit of biodiversity conservation and all sectors of society.

### ABSTRACT

Waterbird conservation takes place increasingly at the level of flyways of individual biogeographical populations. Wetlands International provides triennial updates of waterbird population estimates at global level on behalf of the Ramsar Convention on Wetlands. Practitioners using these estimates as the basis of waterbird conservation policies and plans need to know which estimates to apply in which geographical areas, and Wetlands International has produced a series of Flyway Atlases to facilitate this process. The *Atlas of Anatidae Populations in Africa and Western Eurasia* was produced in 1996 on behalf of the Secretariat of the African-Eurasian Migratory Waterbird Agreement (AEWA). This was followed by atlases of Anatidae and cranes in East Asia, which form the basis of the Asia-Pacific Migratory Waterbird Conservation Strategy site networks for Anatidae and cranes. *Goose Populations of the Western Palearctic* followed in 1999, and work on an *Atlas of Wader Populations in Africa and Western Eurasia* is currently underway. Plans for future atlases include volumes covering all the other waterbird populations included in AEWA, and interactive presentation on the AEWA web-site will be established. Modern developments in electronic media have opened up new possibilities for presentation which are being explored during production of the Wader Atlas.

### INTRODUCTION

Waterbird conservation takes place increasingly at the level of flyways of individual biogeographical populations. The concept of a flyway as the geographical area used by the migratory population of a species during every stage of its life cycle is well-established. Flyways were first described in Eurasia for a number of duck species by Isakov (1967), who developed the concept to embrace more generalised "flyways" which are used by a number of species with similar geographical ranges and migration habits.

When attempting the conservation of any species, it is essential to have as much information as possible about the numbers of individuals that exist, where they are found, and whether their numbers are decreasing, stable or increasing. Since 1994, Wetlands International has provided this information at global level for about 870 species recognised as "waterbirds", which are divided for the purposes of conservation into about 2 200 "populations". The first edition of the Wetlands International publication *Waterbird Population Estimates* was published in 1994 (Rose & Scott 1994), the second in 1997 (Rose & Scott 1997) and the third in 2002 (Wetlands International 2002). A fourth edition is in press at the time of writing (Wetlands International in press). An important policy instrument supported by this publication is the Ramsar Convention on Wetlands. Wetlands of International Importance (so called "Ramsar sites") are recognised under this international agree-

ment using nine criteria. Criterion 6 states that any site regularly holding 1% of a waterbird population qualifies as a Wetland of International Importance.

In order to know which sites hold 1% of a population, it is necessary to have an estimate for the total size of the population (which is provided by *Waterbird Population Estimates*), and also to know the geographical limits of each population. The geographical information provided about each species in *Waterbird Population Estimates* comprises a map of global distribution at species level together with verbal descriptions, which are necessarily brief, of the geographical range of each population during the breeding and non-breeding seasons. Practitioners using these estimates as the basis of waterbird policies and plans need to know precisely which estimates to apply in which geographical area. The information in *Waterbird Population Estimates* is not sufficient to enable detailed understanding of the population boundaries of each species. For this purpose, detailed maps showing the population boundaries of each species are required. In response to this need, Wetlands International is producing a series of Flyway Atlases which are the subject of this paper.

### WETLANDS INTERNATIONAL'S ATLASES OF WATERBIRD POPULATIONS

Wetlands International has produced three atlases of waterbird populations. The first to be published was the *Atlas of Anatidae Populations in Africa and Western Eurasia* (Scott & Rose 1996). This identified "biogeographical populations" for all 61 species of Anatidae which occur regularly in Africa and Western Eurasia, and shows the limits of these populations in a series of maps. This atlas was followed by a similar *Atlas of Key Sites for Anatidae in the East Asian Flyway* (Miyabayashi & Mundkur 1999) and an *Atlas of Key Sites for Cranes in the North East Asian Flyway* (Chan 1999). A related publication, *Goose populations of the Western Palearctic: A review of status and distribution* (Madsen *et al.* 1999) provided much greater detail for the 23 populations of nine species of geese (*Anser* spp. and *Branta* spp.) occurring in Europe and western Asia. Wetlands International is now working on the largest and most ambitious atlas to date – an *Atlas of Wader Populations in Africa and Western Eurasia* (Delany *et al.* in prep.).

Scott & Rose (1996) and Delany *et al.* (in prep.) cover the region of the African-Eurasian Migratory Waterbird Agreement (AEWA), and provide crucial technical information needed for conservation of waterbird populations under this agreement. Miyabayashi & Mundkur (1999) and Chan (1999) do the same for the Asia-Pacific Migratory Waterbird Conservation Strategy (APMWCS), forming the basis of site networks under the strategies for Anatidae and cranes, respectively.

For each species, the maps in these publications show the breeding range, the boundaries of each biogeographical popula-

tion (the total geographical range within which each 1% threshold applies) and key sites (i.e. sites that regularly hold >1% of the population). Also presented is a list of key sites for each species with details of counts, and this information is summarized in a site gazetteer, by country, combining information from all species. The species texts provide interpretation of the maps and tables and relevant background information about each population. An important concept running through all these atlases is that of sites forming a network.

## METHODS

The data and information used in the compilation of atlases of waterbird populations come from a number of sources. The most important single source is the International Waterbird Census (IWC), initiated in Europe in 1967 and now involving more than 15 000 waterbird counters (most of whom are voluntary bird-watchers) in over 100 countries in all parts of the world except North America. Each year in January, this network undertakes detailed, standardised counts of between 30 and 40 million waterbirds, details of which are sent to Wetlands International and stored on the IWC database.

These count data provide the information needed to estimate the numbers of many populations, to identify the geographical ranges at species level, and to identify the key sites used by the populations. Important information on the movements of birds in these populations comes largely from the results of bird ringing and other migration studies.

**Fig. 1.** The four main geographical populations of Anatidae in Western Eurasia as identified by Isakov (1967).

**Fig. 2.** Population boundaries of the Red-breasted Goose *Branta ruficollis* (from Scott & Rose 1996).

Millions of birds have been ringed in the past 100 years, and published information is available about the movements of most waterbird species (e.g. Spina & Clark, this volume). These published data provide a sound basis for the separation of many waterbird populations, but they usually relate only to birds ringed and/or recovered in a single country (e.g. Underhill *et al.* 1999, Fransson & Pettersson 2001, Bakken *et al.* 2003). One of the aims of EURING is to facilitate international-level analyses of data relating to birds ringed in Europe, but all except the most generalised data are inaccessible to third parties. It is therefore still difficult to conduct large-scale analyses which include data collected by both counting and ringing activities at international level.

## TYPES OF BIOGEOGRAPHICAL POPULATION

Various types of “biogeographical populations” have been recognized in *Waterbird Population Estimates* and the flyway atlases, and these are best demonstrated and explained by using examples from Wetlands International’s publications.

Isakov (1967) first presented biogeographical population boundaries for Anatidae in Western Eurasia (Fig. 1). In 1974, at an international conference at Heiligenhafen, Isakov offered his “Thoughts on an Atlas of distribution of waterfowl and wetlands”. These biogeographical populations are still recognised today, and form the basis of many of the populations in the Anatidae Atlas of Scott & Rose (1996). The approach fits well with the Convention on Biodiversity’s “Ecosystem Approach” because the flyway of each population encompasses the entire ecosystem that it uses. Isakov’s populations were supported by

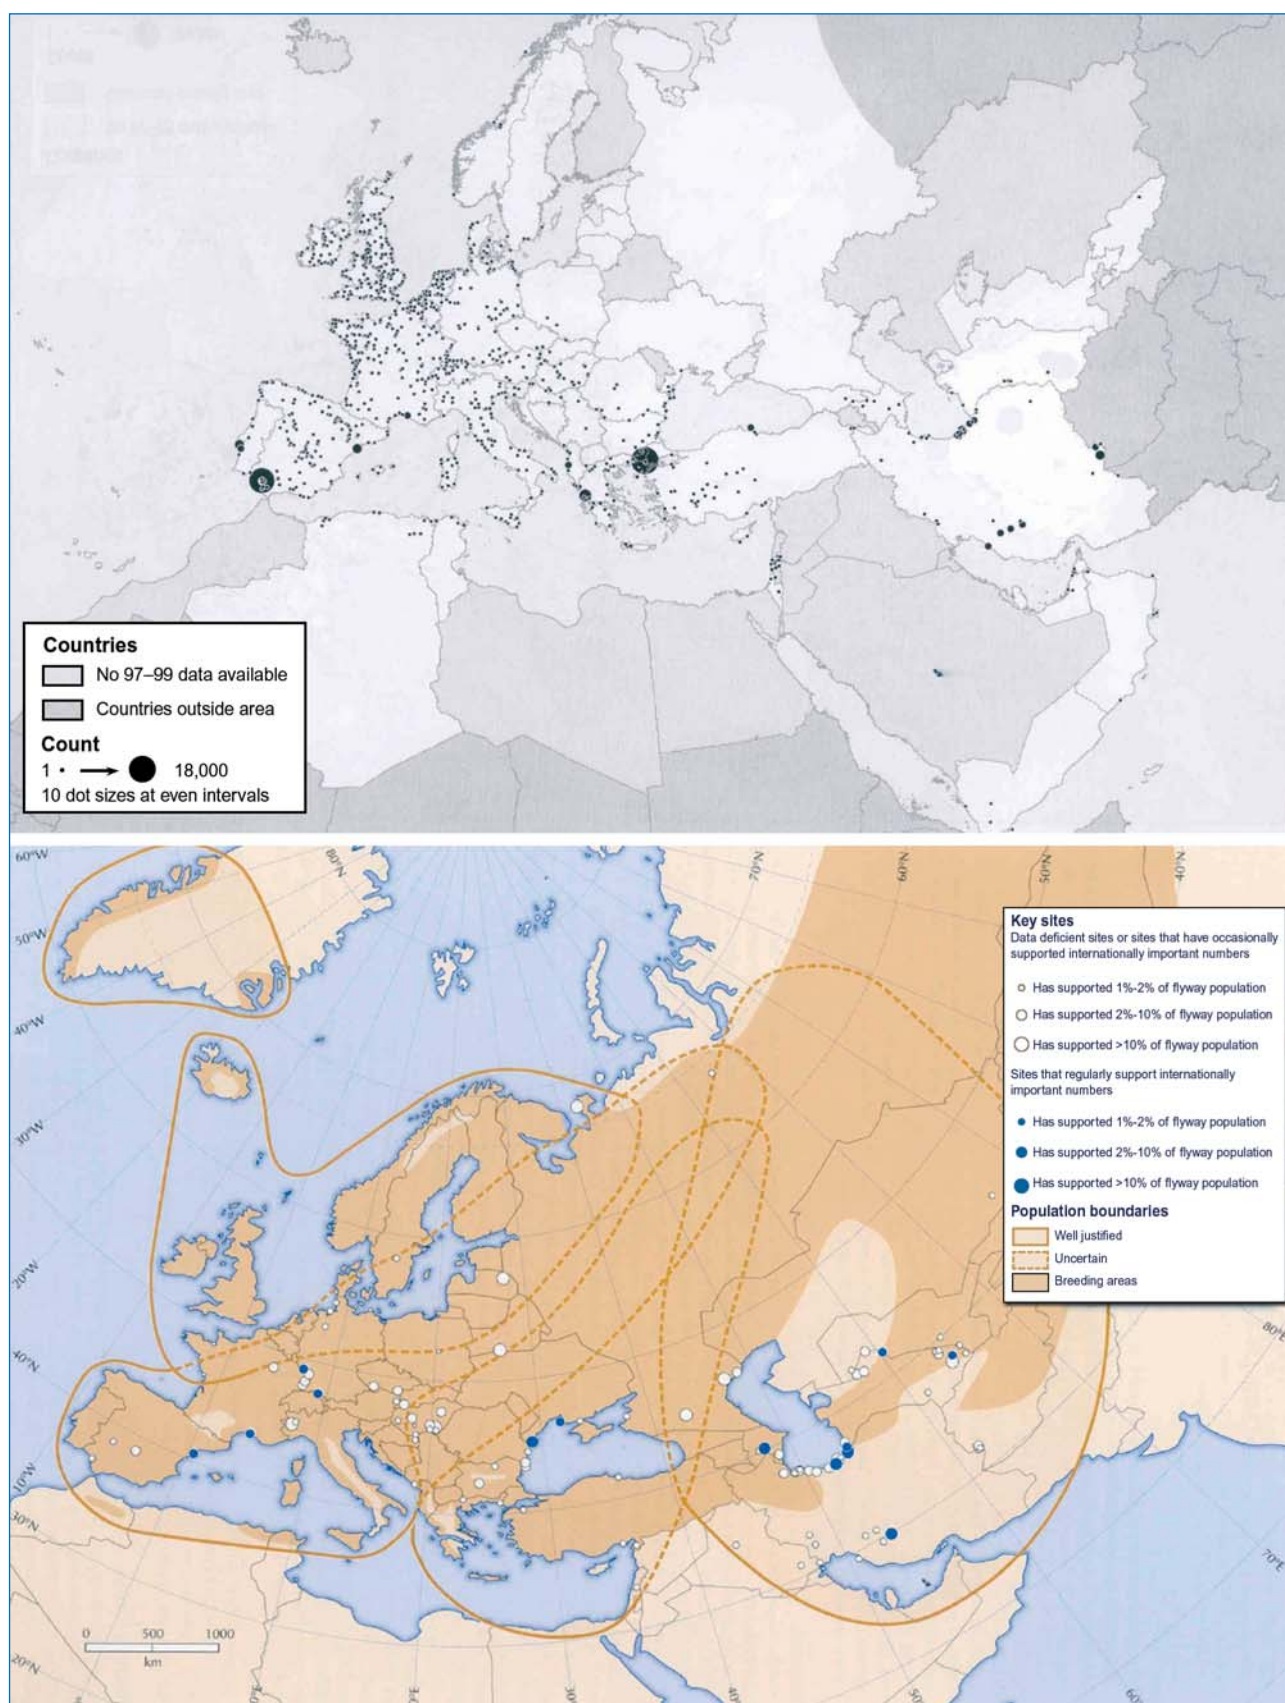

**Fig. 3.** Winter distribution of the Whooper Swan *Cygnus cygnus* in Europe, 1997-1999, as revealed by IWC counts (Gilissen *et al.* 2002), and population boundaries established by Scott & Rose (1996).

Shevareva (1970) who analysed 10 600 recoveries of ducks ringed in the former USSR and confirmed the basic geographical populations for the Mallard *Anas platyrhynchos*, Common Teal *A. crecca*, Northern Pintail *A. acuta*, Eurasian Wigeon *A. pene-lope* and Garganey *A. querquedula*.

The simplest type of waterbird population is illustrated in Fig. 2. The Red-breasted Goose *Branta ruficollis* is a monotypic species with a relatively small population. The migration routes and key sites are quite well known (although information is still lacking on key spring staging areas). There is only a single

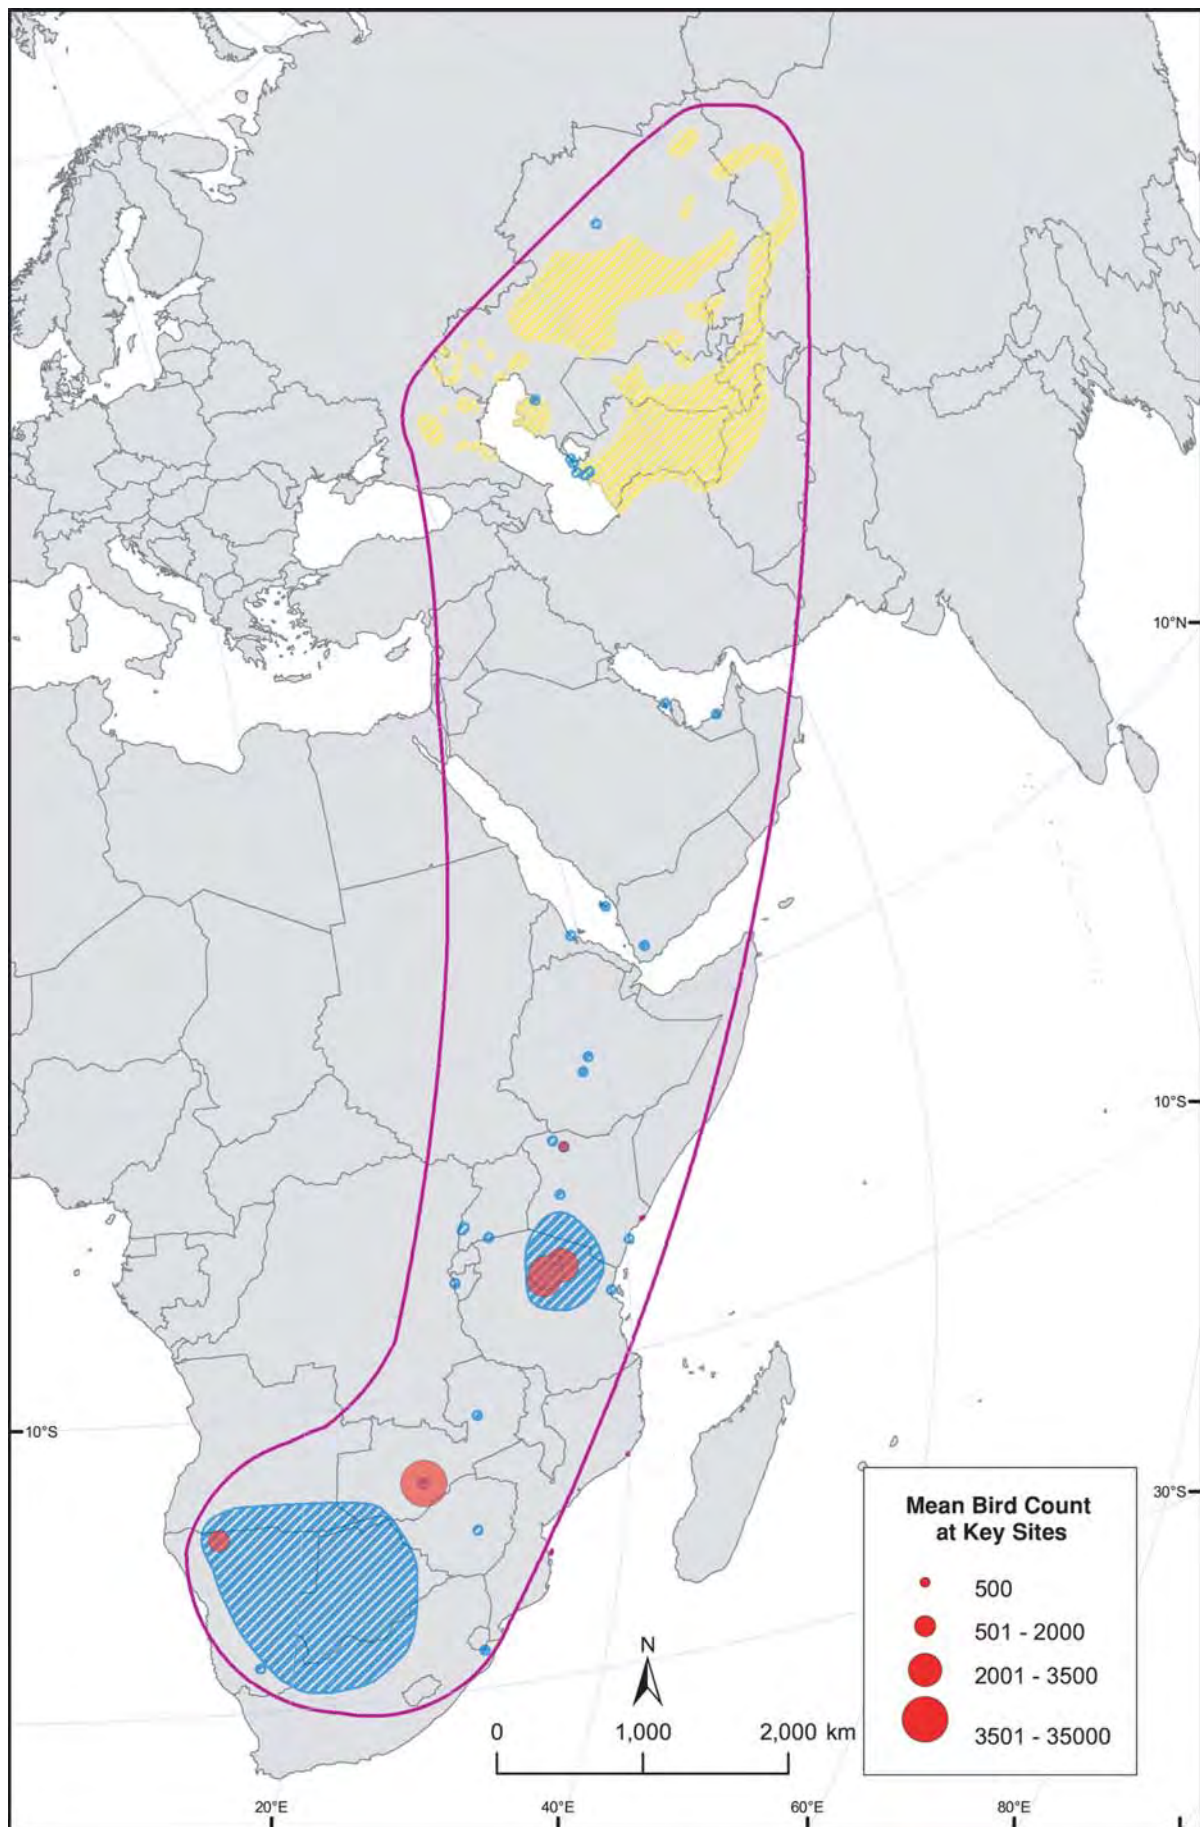

**Fig. 4.** Winter distribution of the Mallard *Anas platyrhynchos* in Europe, 1997-1999, as revealed by IWC counts (Gilissen *et al.* 2002), and population boundaries established by Scott & Rose (1996).

population, the geographical limits of which comprise the entire range of the species.

A similar approach can be used for many polytypic species,

where each subspecies occupies a different flyway. This type of population division is used for the Red Knot *Calidris canutus* which has six subspecies, each of which occupies largely sepa-

rate breeding and non-breeding ranges, although in some cases, two subspecies use the same sites during migration.

Fig. 3 shows another type of population division. The Whooper Swan *Cygnus cygnus* is a monotypic species divided into five populations on the basis of geographically separate wintering ranges. Fig. 3 shows four of these populations; a fifth occurs in East Asia and appears in Miyabayishi & Mundkur (1999). The lower map in Fig. 3 shows the distribution of Whooper Swans in Europe and western Asia in the three winters 1997-1999, plotted directly from IWC count data. The justification for the population divisions is clear, and is supported by published ringing data which show that birds wintering in Ireland and the UK breed in Iceland and comprise a discrete population, while the other three populations, identified on the basis of their geographically separated wintering areas, mix to a considerable extent on their breeding grounds in northern Russia.

The distribution and movements of many waterbird species are more continuous and complex, and do not allow ready division into populations on purely biological grounds. The most extreme example in the AEWA region is the Mallard. The range of this species in Europe, as plotted from IWC data collected in the three winters 1997-99, is shown in Fig. 4 above the population boundaries identified by Scott & Rose (1996). The range is nearly continuous, and movements are complex, with resident birds in western and central Europe being joined by migrants from the east in winter.

For the Mallard, Scott & Rose (1996) based the population boundaries on those proposed by Isakov (1967) and supported by Shevareva (1970), but they identified one additional population by splitting the Mediterranean population into western and eastern portions. Apart from the separate and distinct population breeding in Greenland, these "population boundaries" are not biologically very meaningful, and even with this division, very

few key sites are recognised for this species, which rarely forms very large concentrations. The Mallard is an extreme case, and division into populations using this "practical approach" based on "wintering regions" has been successfully undertaken for many species which cannot be reliably divided using a purely biological approach. Furthermore, it has often been found that the same "wintering regions" are appropriate for a number of species of waterbirds with similar habitat requirements and migration strategies, e.g. the North-west Europe, Black Sea/Mediterranean and South-west Asia regions for various dabbling ducks and diving ducks in Western Eurasia.

It is accepted that in most widespread and numerous species there is a considerable amount of overlap between adjacent "wintering populations" during the migration seasons and on the breeding grounds. However, under the "practical approach", the individuals wintering in a particular region are treated as a single population regardless of their distribution at other times of year. This approach was refined by Atkinson-Willes (1976, 1978) in the 1970s, then by Rüger *et al.* (1986), Monval & Pirot (1989) and others in the 1980s, before being used by Scott & Rose for the Anatidae Atlas in 1996. The approach is supported by ringing evidence, e.g. Perdeck & Clason 1980.

For many migratory species of waterbirds, particularly those that are widely dispersed outside the breeding season, far more is known about the breeding populations at northern latitudes than about the non-breeding populations at southern latitudes, where the birds may mix with sedentary populations of the same species and be indistinguishable to counters (e.g. some herons and egrets breeding in Western Eurasia and wintering in Africa). In such cases, population units have often been identified on the basis of the breeding populations within relatively well-defined geographical areas. As with populations identified on the basis of their wintering regions, such populations may mix with other popula-

**Table 1.** Definitions of “biogeographical population”.**Biological approach**

- The entire population of a monotypic species (e.g. Red-breasted Goose *Branta ruficollis*).
- The entire population of a recognized subspecies (e.g. the six subspecies of Red Knot *Calidris canutus*).
- A discrete population of a migratory species or subspecies that rarely if ever mixes with any other population of that species or subspecies at any time of the year (e.g. the population of Whooper Swans *Cygnus cygnus* breeding in Iceland).
- A regional group of sedentary, nomadic or dispersive birds with an apparently rather continuous distribution and no major gaps between breeding units sufficient to prohibit interchange of individuals during their normal nomadic wanderings and/or post-breeding dispersal (e.g. the Madagascar population of Hottentot Teal *Anas hottentota*).

**Practical approach**

- The individuals of a migratory species or subspecies which spend the non-breeding-season (“winter”) in a particular, discrete geographical region (e.g. the populations of Mallard *Anas platyrhynchos* in Western Eurasia). There may, however, be a considerable amount of overlap between two adjacent populations during the migration seasons and on the breeding grounds. The “wintering” regions used by these population units should:
  - a) be large and varied enough for the “populations” to stay within their boundaries for the whole winter;
  - b) be bounded by unsuitable habitats, or by zones in which birds are absent; and
  - c) include the migration routes leading to them.
- The individuals of a migratory species or subspecies which spend the breeding season in a particular, discrete geographical region (e.g. the European breeding population of Eurasian Woodcock *Scolopax rusticola*). There may, however, be a considerable amount of overlap between two adjacent populations during the migration seasons and on the non-breeding (“wintering”) grounds.

tions of the same species at other times of the year. For a number of species with extensive breeding ranges in Western Eurasia, two populations have been identified – a European breeding population and a West Asian breeding population, separated by the Ural Mountains. In many species, this practical approach appears to have some biological validity as evidence from ringing suggests that the bulk of the individuals breeding western of the Urals migrate south-west to spend the non-breeding season in western and southern Europe and West Africa, while birds breeding east of the Urals spend the non-breeding season mainly in the Middle East and eastern and southern Africa.

While much of the emphasis in the flyway atlases has been given to identifying “flyways” for migratory populations of waterbirds, an attempt has also been made to identify “populations” of sedentary or nomadic species which would be appropriate for conservation management purposes. Scott & Rose (1996) gave some consideration to this matter, and identified

Flyway populations of Sanderlings *Calidris alba* will be mapped in the forthcoming Wader Atlas to be published in 2007. Photo: Paul Marshall.

population units on the basis of degree of isolation from other populations of the same species in relation to the known extent of the dispersive and/or nomadic movements of the species. They defined such populations as “a regional group of sedentary, nomadic or dispersive birds with an apparently rather continuous distribution and no major gaps between breeding units sufficient to prohibit interchange of individuals during their normal nomadic wanderings and/or post-breeding dispersal”.

The various types of “biogeographical population” that have been adopted in *Waterbird Population Estimates* and Wetlands International’s flyway atlases are summarized in Table 1.

**Wader Atlas**

The latest in the series of Wetlands International’s atlases of waterbird populations is the *Atlas of Wader Populations in Africa and Western Eurasia* (Delany *et al.* in prep.), which is being produced jointly by the International Wader Study Group and Wetlands International. Work started on this atlas as long ago as 1998. It has weathered a number of organisational and financial crises and is likely to be finished in 2007.

The wader atlas includes all the information provided in earlier flyway atlases, but is based on a wider selection of data sources. Its maps have also been produced and presented using more modern, GIS software. BirdLife International have made data available from their IBA database to help identify key sites in periods not covered by the IWC (principally, spring and autumn migration). An example of a map from the Wader Atlas is provided in Fig. 5.

**DISCUSSION**

Atlases of waterbird populations produced by Wetlands International to date have covered those groups of species for which most data of high quality are available. In the late 1980s, the number of species included in the IWC was expanded from just “wildfowl and waders” to include all waterbirds. Now that these additional species have been counted for 15 years, enough data have accumulated to make it possible to prepare similar atlases for most other waterbird species in Africa and Western

Eurasia. The existence of the AEWA as a legally binding instrument, with 53 Contracting Parties in January 2006, has created a strong demand for high-quality published information about migratory waterbird populations which gives great impetus to this work in the AEWA region.

Fig. 6 shows the distribution of the Great Cormorant *Phalacrocorax carbo* in Europe in the three winters 1997-1999, as revealed by the IWC counts. The IWC data are now in place for this and many additional species, and a review of literature concerning ringing recoveries, combined with these data, will provide the basis for population atlases for these additional species in years to come.

Future analyses for migration atlases would benefit greatly from an ability to use data from bird ringing in direct combination with the waterbird count data in the IWC database. It is to be hoped that developments at EURING will make this possible in the not too distant future.

Modern approaches to the presentation of spatial data will broaden the scope and improve the accessibility of future atlases. It will be possible to present maps in hardcopy for ease of use, but at the same time to make them available electronically on CD ROM and web-sites. Electronic formats will allow users to go deeper into the data by selecting map layers which could include, for example, count data for selected species in selected geographical regions, and related environmental data sets such as those relating to climate and land use. Zöckler *et al.* (2003) presented ideas for future presentation of waterbird data using an interactive, web-based interface which would allow data and information from a number of different web-based sources to be integrated and queried in a so-called "web portal". These methods will offer considerable scope for future work which will provide insight into factors beyond the current need to know the geographical limits of populations.

## ACKNOWLEDGEMENTS

The basis of Wetlands International's work on waterbird numbers and distribution is the network of over 15 000, mostly voluntary, waterbird counters in more than 100 countries. We salute their skill and dedication. Thanks also to Jacquie Clark, Fernando Spina and Carl Mitchell for helpful discussions.

## The Russian waterbird migration atlas: temporal variation in migration routes

Inna N. Dobrynina & Sergei P. Kharitonov<sup>1</sup>

<sup>1</sup>Bird Ringing Centre of Russia, Leninskiy prospect, 86-310, 119313, Moscow, Russia. (email: ring@bird.msk.ru)

Dobrynina, I.N. & Kharitonov, S.P. 2006. The Russian waterbird migration atlas: temporal variation in migration routes. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 582-589.

### ABSTRACT

Ringing recovery data from the database of the Bird Ringing Centre of Russia were used for this analysis, which examines variation in the mean distance of ringing recoveries for various waterbirds over ten-year periods. Many species of waterbirds which inhabit inland wetlands show a consistent trend of increasing migration distance throughout the last century. Several species of ducks demonstrate a more complicated pattern, with the mean distance of recoveries first decreasing and then increasing, although the overall trend is for the migration distance to increase over the past century. In seaducks, the migration distance has remained relatively constant throughout the period under review. A comparable analysis for some passerines reveals that in some groups (e.g. thrushes) there has been a progressive increase in the length of the migration, while in others (e.g. finches), the mean distance of ringing recoveries has decreased. Some waterbirds undertake “non-migratory” movements in autumn, continuing to move in the direction of their spring migration after breeding or moulting. We propose that bird migration atlases should reflect the changes that have occurred in migration routes throughout the entire study period of bird migration. Non-migratory movements of birds in autumn can be regular, and should also be reflected in migration atlases.

### INTRODUCTION

By March of 2004, the Bird Ringing Centre of Russia held details of almost 200 000 recoveries of ringed birds, of which 78 000 (for 380 species and subspecies) were computerized. For 67 species (including 54 waterbirds), the full set of recoveries was already in

the computer database. The majority of recoveries are of birds found since 1926. These recoveries cover a huge territory incorporating the breeding areas and long, and sometimes quite sophisticated, migration routes (Fig. 1). In bird migration atlases, it is usual to present the recoveries of ringed birds in a geographical way (Brewer *et al.* 2000, Wernham *et al.* 2002, Bakken *et al.* 2003). Here, we would like to stress that in such atlases it is useful to consider not only geographical areas, but also different time periods, which should be presented separately. The main aim of this paper is to demonstrate the importance of this statement.

### Materials and methods

This paper was written on the basis of ringing recovery data taken from the database of the Bird Ringing Centre of Russia. The main parameter of the recoveries under analysis was the mean distance between the ringing location and recovery location. All available recoveries were used to calculate the average length of movement during a particular time period, and no distinction was made between birds ringed in Russia and recovered abroad and those ringed abroad and recovered in Russia.

We examined changes in the mean recovery distance for various waterbirds since 1926. In most cases, we used ten-year periods (decades) as the standard time period for sampling. In the following account, we discuss species on the basis of the fluctuations in the mean distance of their migration during the study period, rather than in systematic order.

For plotting the recoveries, we used the MapInfo-5.5 programme with an additional tool written by Sergei Kharitonov in Map Basic language and installed into the body of the MapInfo

**Fig. 1.** Ringing recoveries of Northern Pintail *Anas acuta* (left map; 6 775 recoveries) and Eurasian Wigeon *Anas penelope* (right map; 2 829 recoveries) in the database of the Bird Ringing Centre of Russia. Duck symbols indicate the recovery locations.

**Table 1.** Migration distances of the Eurasian Woodcock *Scolopax rusticola* in the four decades from 1951 to 1990.

Decade	Mean distance of recoveries (km)	Number of recoveries	Significance of change between decades	Significance of change since 1951-1960
1951-1960	1 519.5	23		
1961-1970	1 553.9	18	P=0.93	P=0.93
1971-1980	1 927.8	42	P=0.08	P=0.046
1981-1990	2 300.9	67	P=0.008	P<0.0001

**Table 2.** Mean distance of ringing recoveries of the Eurasian Woodcock *Scolopax rusticola* according to direction of flight.

Decade	Mean distance of recovery for north-south flights (bearing 315°-45° and 135°-225°)			Mean distance of recovery for east-west flights (bearing 45°-135° and 225°-315°)		
	Distance (km)	Number of recoveries	Significance of change from 1951-1960	Distance (km)	Number of recoveries	Significance of change from 1951-1960
1951-1960	1 458.9	12		1 585.5	11	
1961-1970	1 392.3	4	P=0.59	1 600.0	14	P=0.84
1971-1980	1 742.9	13	P=0.37	2 040.9	29	P=0.15
1981-1990	2 301.3	7	P=0.013	2 300.8	60	P=0.0015

programme. This tool allows lines to be drawn on a map between ringing locations and recovery locations. As a test for statistical differences, we used the Mann-Whitney test (Fowler & Cohen 1995).

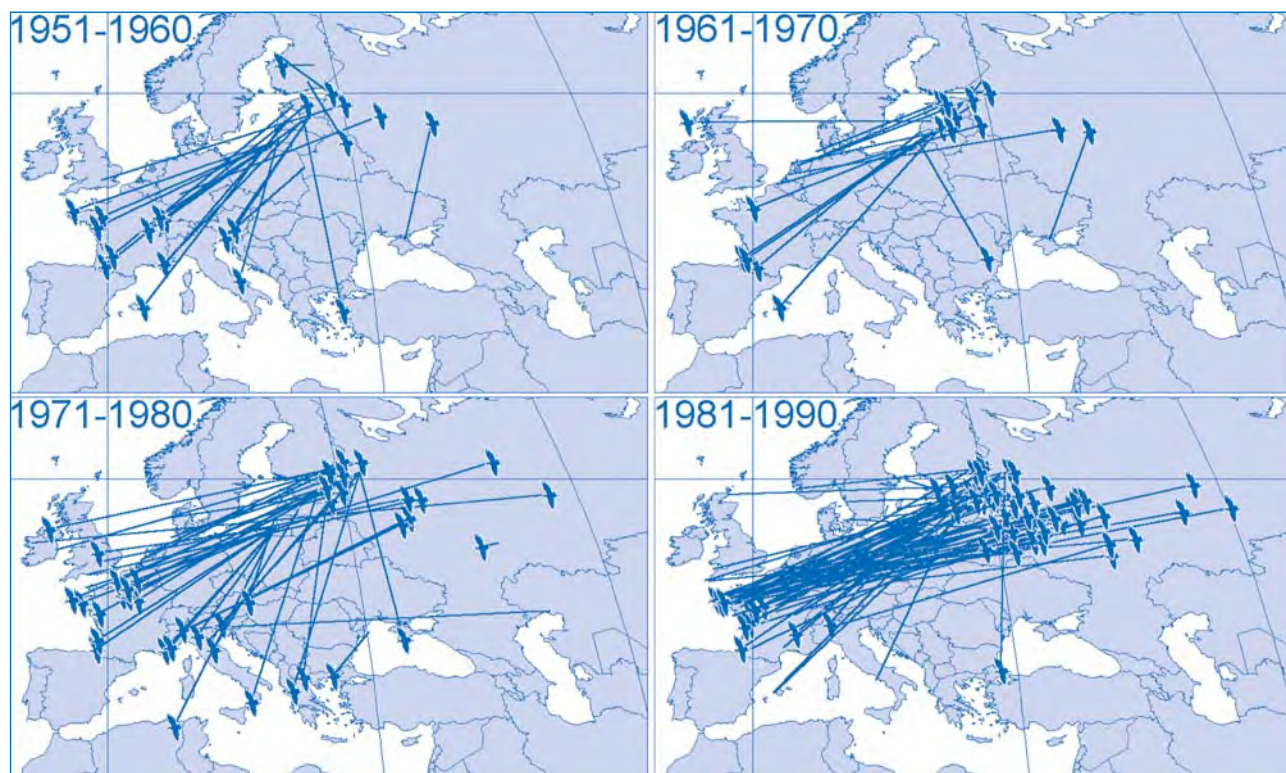

## RESULTS

### Variations in the recovery distances of waterbirds

The “classic” example of a species of waterbird making a major change in its migration route in recent decades is the Red-

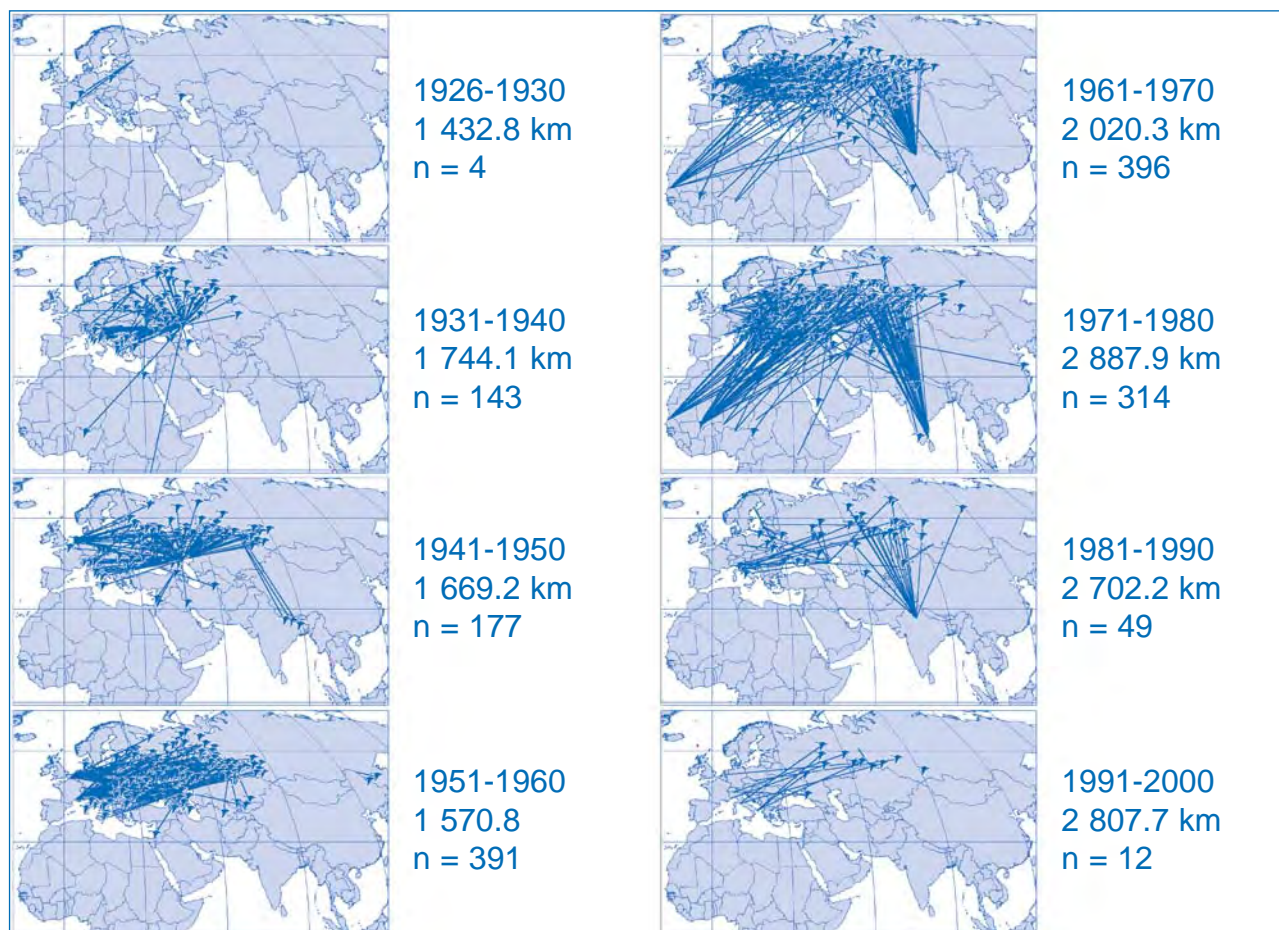

breasted Goose *Branta ruficollis*. Up until the late 1970s, this species wintered in the south-western corner of the Caspian Sea. The birds then suddenly changed their wintering grounds to the north-eastern corner of the Black Sea, mostly around Shabla and Durankulak lakes in Bulgaria (see review in Syroechkovski 1995). In the late 1980s, flocks of wintering Red-breasted Geese re-appeared in the Caspian region (Syroechkovski 1995).

Analysis of the average recovery distances in different groups of waterbirds during the eight decades from 1920 to 2000 has

**Fig. 2.** Recoveries of Eurasian Woodcock *Scolopax rusticola* ringed or recovered in Russia in the four decades from 1951 to 1990. Wader symbols indicate the recovery locations.

**Fig. 3.** Recoveries of Garganey *Anas querquedula* ringed or recovered in Russia by decade since 1926, with the average distance and total number of recoveries in each decade. Duck symbols indicate the recovery locations.

revealed interesting patterns of variation in the length of the migration. Several species that inhabit freshwater wetlands (Common Teal *Anas crecca*, Garganey *A. querquedula*, Common Snipe *Gallinago gallinago* and Common Coot *Fulica atra*), wet meadows (Northern Lapwing *Vanellus vanellus*) and moist places in the forest (Eurasian Woodcock *Scolopax rusticola*) show a consistent increase in the length of their migration route throughout the last century. This steady increase in the length of the migration is especially well pronounced in the Eurasian Woodcock (Fig. 2, Table 1). In this species, the increase is apparent both in terms of latitude and longitude (Table 2).

Another good example of an increase in length of migration is shown by the ringing recoveries of Garganey (Fig. 3). This increase is apparent even if we compare only those decades when most of the recoveries were in Europe (e.g. 1951-60 and 1991-2000;  $P=0.002$ ). A third example is provided by the Common Coot (Fig. 4). It can be seen from Fig. 4 that there has been a considerable increase in the recovery distances of birds ringed in India, with the recoveries shifting farther and farther north in each successive decade as the birds perform longer and longer journeys (differences are significant: between 1961-1970 and 1971-1980,  $P=0.0013$ ; between 1971-1980 and 1981-1990,  $P=0.0002$ ).

Several species of dabbling ducks (Northern Pintail *Anas acuta*, Mallard *A. platyrhynchos* and Northern Shoveler *A. clypeata*) and diving ducks (Common Pochard *Aythya ferina* and Tufted Duck *A. fuligula*) demonstrate a more complicated

pattern. The mean recovery distance first decreases, and then increases (Fig. 5). In the case of the Northern Pintail (Fig. 6), the mean recovery distance of birds ringed in the vast moulting area in the Volga Delta (Astrakhan Nature Reserve) decreased from 1 652.5 km in 1927-1940 ( $N=156$ ) to 1 372.4 km in 1941-1980 ( $N=1 215$ ;  $P=0.0015$ ).

A similar pattern of change has been observed in Black-throated Diver *Gavia arctica*. Eurasian Wigeon *Anas penelope* shows an almost constant mean recovery distance until the 1970s, then an increase; the Gadwall *A. strepera* and Caspian Tern *Sterna caspia* show a more or less constant distance until the 1950s, and then a sharp increase, while Common Goldeneye *Bucephala clangula* (a lake duck) shows a steady increase throughout.

In two seaducks, Common Eider *Somateria mollissima* and Steller's Eider *Polysticta stelleri*, the mean recovery distance has fluctuated in recent decades, although in the case of Steller's Eider, there has probably been some increase in the length of the migration in recent years (Table 3). Unlike most ducks, the Greylag Goose *Anser anser* shows a more or less constant mean recovery distance throughout the twentieth century.

#### Variations in the recovery distances of land-birds

For comparison, we carried out similar analyses for several species of passerines that are not associated with wetlands (Fig. 7). Song Thrush *Turdus philomelos* has shown almost no increase in mean recovery distance since the 1950s (1 899.3 km in 1951-1960,  $N=117$ ; 2 028 km in 1991-2000,  $N=66$ ;  $P=0.66$ ).

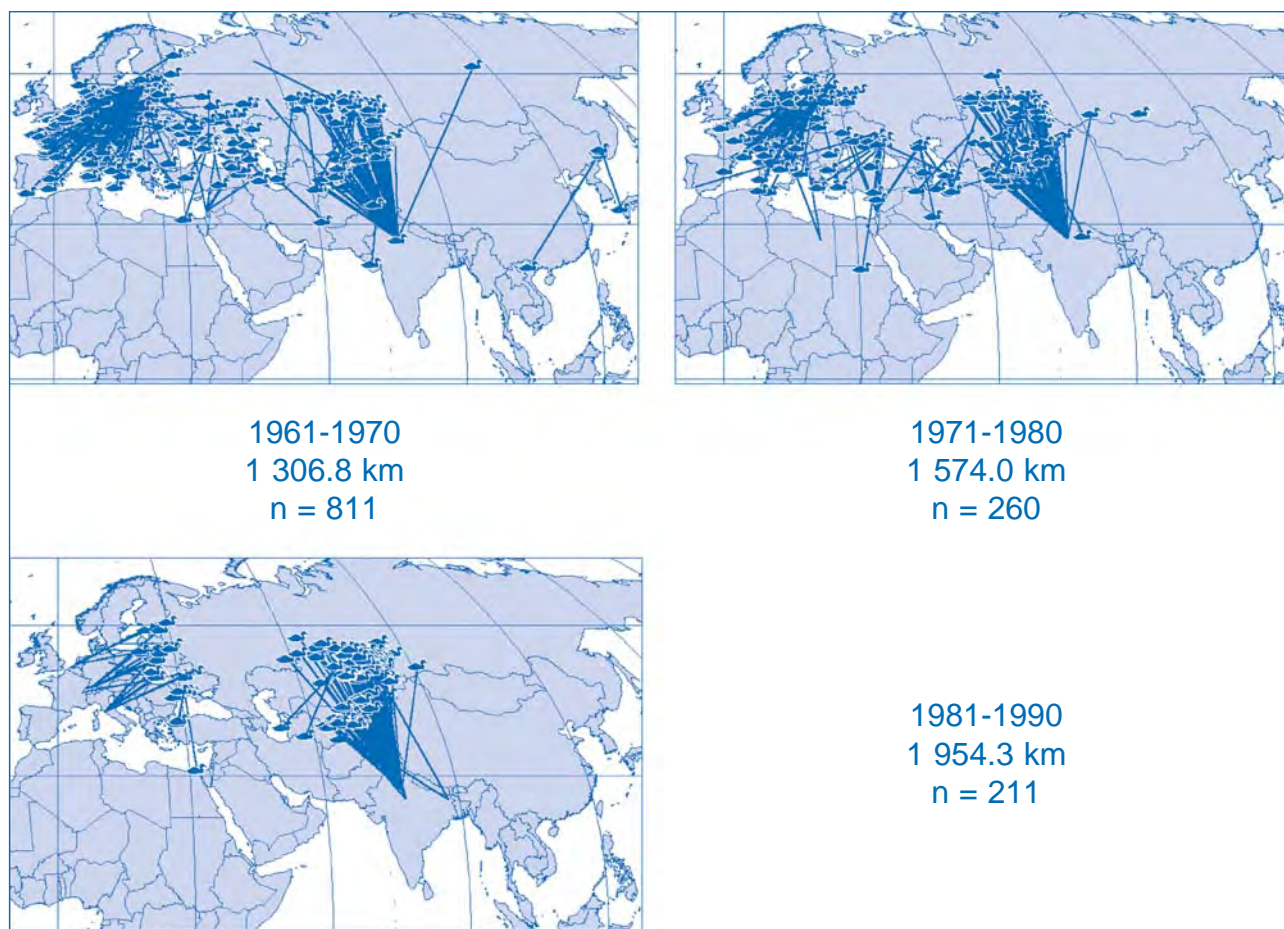

**Table 3.** Migration distances of the Common Eider *Somateria mollissima* and Steller's Eider *Polysticta stelleri* in the five decades from 1951 to 2000.

Decade	Common Eider			Steller's Eider		
	Mean distance of recoveries (km)	Number of recoveries	Significance of change from 1951-1960	Mean distance of recoveries (km)	Number of recoveries	Significance of change from 1961-1970
1951-1960	780.9	6				
1961-1970	498.1	19	P=0.36	2 516.7	43	
1971-1980	419.9	27	P=0.08	3 078.4	84	P=0.001
1981-1990	629.7	4	P=0.46	2 718.7	17	P=0.5
1991-2000				3 335.6	308	P<0.0001

In Redwing *T. iliacus* and Fieldfare *T. pilaris*, there has been a significant increase in the mean recovery distance since the 1950s: in the Redwing, from 1 899.3 km in 1951-1960 (N=61) to 2 886.3 km in 1991-2000 (N=38,  $P=0.0084$ ); and in the Fieldfare, from 1 946.9 km in 1951-1960 (N=103) to 2 860.2 km in 1991-2000 (N=26,  $P=0.007$ ). In the Brambling *Fringilla montifringilla*, the recovery distance showed a decreasing trend from the 1950s until the 1980s (1 771.4 km in 1951-1960, N=110; 1 305.4 km in 1981-1990, N=48;  $P=0.0005$ ), and then a probable increase in the 1990s (1 305.4 km in 1981-1990, N=48; 1 501.8 km in 1991-2000, N=25;  $P=0.37$ ). The Chaffinch *F. coelebs* shows a similar pattern, but with the decrease continuing in the 1990s (1 578.4 km in 1951-1960, N=360; 1 016.6 km in 1991-2000, N=101;  $P<0.0001$ ).

#### “Non-migratory” movements

Some waterbirds undertake lengthy movements in addition to their normal spring and autumn migrations. These movements usually take place after the breeding season and during the protracted autumn migration season. After the breeding season has ended, or in the event of breeding failure, some waterbirds use the time before the onset of the autumn migration to move elsewhere. In some species, the pattern of these post-breeding movements can be quite regular. These “non-migratory” movements have an interesting peculiarity in that the birds follow the spring migration routes. While the normal direction of the autumn migration in eastern Europe and Western Siberia is to the south, south-west or west, the non-migratory movements in autumn are to the north, north-east or east.

**Fig. 4.** Recoveries of Common Coot *Fulica atra* ringed or recovered in Russia in the three decades from 1961 to 1990, with the average distance and total number of recoveries in each decade. Duck symbols indicate the recovery locations.

**Fig. 5.** Mean distances of ringing recoveries for three dabbling ducks (Northern Pintail *Anas acuta*, Mallard *A. platyrhynchos* and Northern Shoveler *A. clypeata*) and two diving ducks (Common Pochard *Aythya ferina* and Tufted Duck *A. fuligula*) ringed or recovered in Russia by decade since 1926. The Y-axis gives the mean distance of recovery in km.

The movements of Black-headed Gulls *Larus ridibundus* in a non-migratory direction are well known as a result of studies by Jānis Vīksne in the Baltic States (Vīksne 1968). Black-headed Gulls ringed in the Baltic States have been recovered up to 506 km away in a non-migratory direction. Such movements also take place in central Russia, where movements of up to 370 km have been recorded (Fig. 8). Similar movements have been found in Gadwall which, after finishing the moult, may move as far as 300 km in a non-migratory direction.

The database of the Bird Ringing Centre of Russia contains three recoveries of Common Snipe which made non-migratory movements, travelling 984, 986 and 2 445 km, respectively (Fig. 9). In addition to these direct recoveries, a comparison of ringing and recovery dates in different parts of Europe indicates that, during the autumn migration, Common Snipe from eastern and middle Europe initially move far to the east or north-east (Kharitonov 1998). Later in the year, these birds turn back and migrate in the “normal” autumn direction, i.e. to the west and south-west. It seems that a considerable part of the European population of Common Snipe first moves in a north-easterly direction in autumn (Kharitonov 1998). Further support for these findings is provided by additional data from Paulauskas & Svazas (2002).

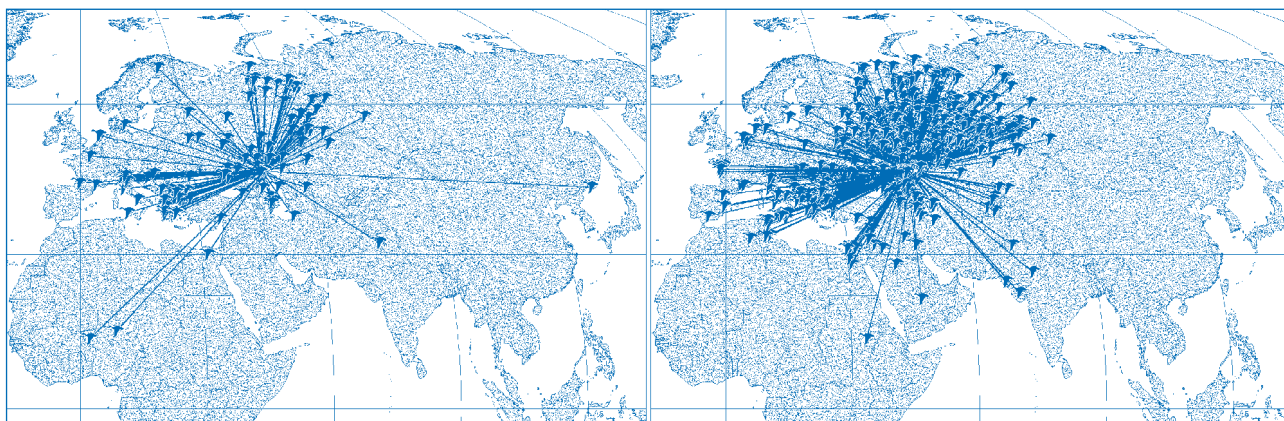

**Fig. 7.** Mean distances of ringing recoveries of three thrushes (Redwing *Turdus iliacus*, Song Thrush *T. philomelos* and Fieldfare *T. pilaris*) and two finches (Brambling *Fringilla montifringilla* and Chaffinch *F. coelebs*) ringed or recovered in Russia by decade since 1950. The Y-axis gives the mean distance of recovery in km.

## DISCUSSION

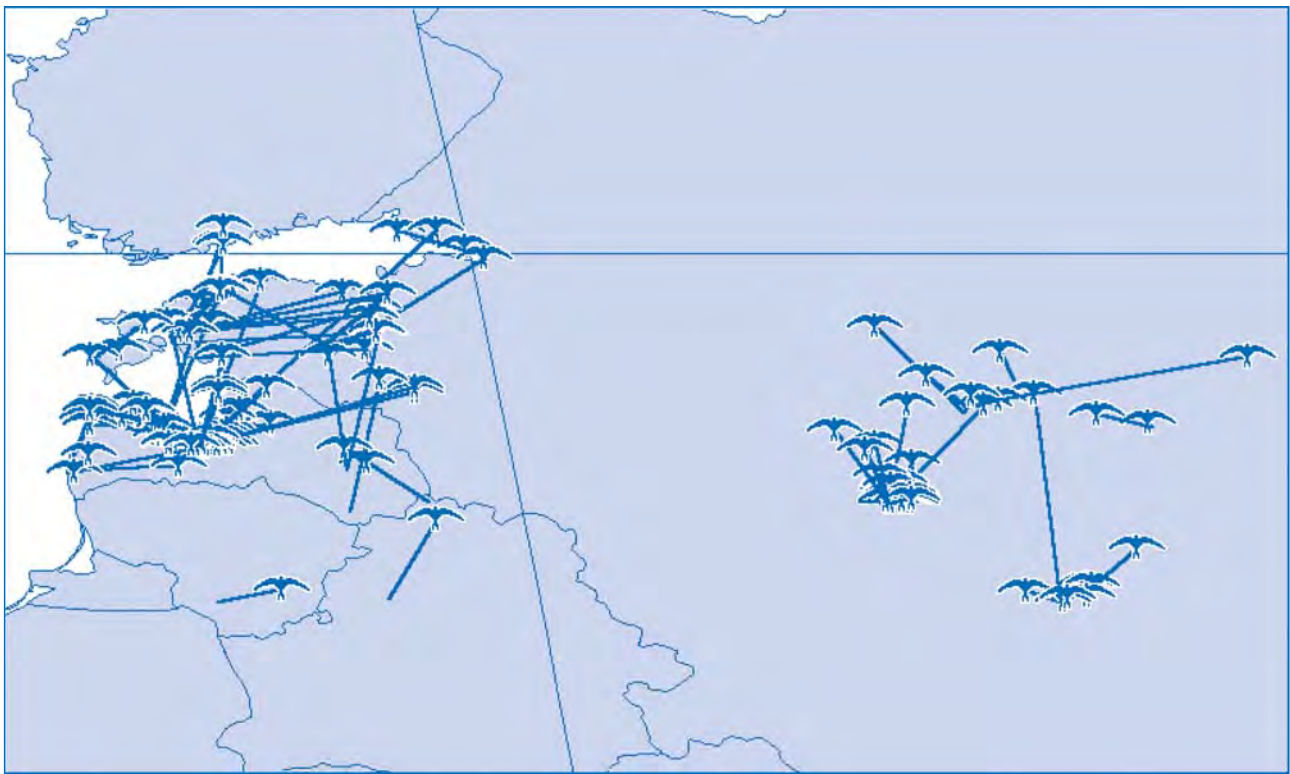

In this study, we have found several interesting changes in the migration routes of waterbirds. However, studies based on the recoveries of ringed birds are always open to the question: to what extent do the ringing recovery data reflect the real movements of birds, and to what extent are they biased by regional and temporal differences in the reporting rate by humans. In order to prove our findings, we must take into account a variety of factors that could bias the results.

The most common objection to ringing recovery data is that the pattern of recoveries reflects the distribution of hunters, rather than the distribution of the birds. One way to test this is to compare the distribution of the recoveries of two closely related species in the same area. The database of the Bird Ringing Centre of Russia provides a good possibility for such a comparison because we can perform the comparison in the very sparsely populated areas of central and eastern Siberia. If we plot the recoveries of Northern Pintail on a map, we can see an obvious gap between the Japanese and North American population and the European, African, Central Asian and Indian populations (Fig. 1). It could be argued that this gap is not real, and is caused by the low numbers of hunters in central Siberia. However, if we plot all recoveries of Eurasian Wigeon, we can see many recov-

**Fig. 6.** Recoveries of Northern Pintail *Anas acuta* ringed in the moulting area in the Volga Delta in 1927-1940 (left map) and 1941-1980 (right map). Duck symbols indicate the recovery locations.

**Fig. 8.** Autumn movements of Black-headed Gulls *Larus ridibundus* in a northerly or easterly direction in the Baltic States and central Russia. Gull symbols indicate the recovery locations.

eries exactly from this “gap”. Therefore, the gap for Northern Pintail is real, and not biased by the distribution of hunters. Similarly, the recoveries of Eurasian Wigeon show a gap between the birds wintering in Japan and all other wintering populations. This gap is also real, because there are many recoveries of Northern Pintail within it (Fig. 1).

The second common objection to ringing recovery data is that the distribution of hunters might change through time. To investigate this possibility, we looked more closely at the well pronounced and highly significant increase in the length of the migration route of the Eurasian Woodcock from 1971-1980 to 1981-1990. To check for a possible change in the distribution of hunters, we analysed the distances over which letters containing bird rings had been posted to reach the Ringing Centre, i.e. we analysed the distance from Moscow to the recovery location for all species of birds in 1971-1980 (10 587 letters from the former USSR) and 1981-1990 (13 444 letters from the former USSR). The average distance for letters in these two decades decreased significantly from 2 080.5 km in 1971-1980 to 1 743 km in 1981-1990 ( $P < 0.0001$ ). This situation is quite understandable, given that the economic situation was deteriorating in the 1980s, postage costs were increasing, and people were sending fewer letters from remote areas. However, in spite of the decline in numbers of letters from remote areas, the mean recovery distance of the Eurasian Woodcock clearly increased. We therefore conclude that the increase in length of the migration route is real, and is not caused by a change in the distribution of hunters or their reporting habits.

A third possible problem might arise as a result of the establishment of new bird ringing locations in successive decades. Such a problem might affect the recoveries of Garganey (Fig. 3), since many new ringing locations appeared in Africa during the study period. However, for this species, we made a special

comparison restricted to recoveries within Europe and only during the two decades 1951-60 and 1991-2000, when the European ringing locations were about the same (see above).

As regards specific ringing locations, we should stress that the trend in length of migration route observed at a particular ringing location might be the opposite of that observed in the population as a whole. A good example of this is provided by the Northern Pintail. Although the average recovery distance of Northern Pintail from the important ringing site in the Volga Delta decreased significantly between 1927-1940 and 1941-1980 (see above), the overall trend in this species was one of increase, with the mean recovery distance increasing from 1 834.9 km in 1926-1940 ( $N=263$ ) to 2 197.7 km in 1941-1980 ( $N=5\,702$ ;  $P < 0.0001$ ).

On the basis of these analyses, we conclude that there was a real increase in the length of the migration routes of many waterbirds of freshwater habitats throughout the last century. A probable reason for this tendency for migration routes to increase in length in each successive decade is the progressive shrinkage of wetlands and other moist areas in Europe and northern Asia. It seems that many areas are getting drier. Almost no changes were found in the migrations of seaducks, probably because these birds use marine habitats rather than inland water-bodies, and are therefore unaffected by the loss of wetland habitat.

It is not clear why, in several duck species, the length of the migration route first decreased and then increased. However, the overall trend in these species is increasing, because the initial decrease in the length of the migration route was less than the subsequent increase.

Global warming might be affecting land-birds such as the Chaffinch and Brambling. In these two species, the trend is the opposite of that for many waterbirds, with the length of the migration route decreasing during the last century. These

Fig. 9. Autumn movements of Common Snipe *Gallinago gallinago* in a northerly or easterly direction. Wader symbols indicate the recovery locations.

species, and probably many other passerines, are evidently spending the winter closer to their breeding grounds.

This analysis has revealed that the migration patterns of birds can change significantly even during the relatively short period when bird ringing activities have been carried out. The causes of these changes are poorly understood, but could include climate change and related factors.

In some species, it appears that the breeding and/or moulting areas are not really the terminal points of the birds' spring migration. In autumn, some birds continue their "spring migration" after breeding or moulting. There is evidence that some Gadwall, before migrating to their wintering grounds, first visit their previous breeding sites (Kharitonov 2002).

## CONCLUSIONS

In waterbirds that inhabit freshwater wetlands, lakes or other inland water-bodies, the length of the migration routes has been progressively increasing during the last century. Birds which live in more stable water conditions (e.g. seaducks) do not demonstrate this gradual increase in their migration routes.

As a result of this analysis, we recommend that efforts be made to identify periods in which significant changes in the length of migration routes have occurred. The dynamics of migration routes should then be reflected in bird migration atlases in order to define the places where species should be protected. It would also be worthwhile in migration atlases to indicate the non-migratory movements of waterbirds in late summer and autumn, especially when this pattern of migration is characteristic of a population. This type of movement might be particularly important for rare and vulnerable species. As regards the widespread increase in lengths of migration routes during the twentieth century, here we simply try to draw atten-

tion to this interesting phenomenon. Further and more detailed studies are clearly required.

## ACKNOWLEDGEMENTS

We would like to thank all staff members of the Bird Ringing Centre of Russia who computerize the ringing recovery data. The work was performed with the support of a grant from the Russian Fund of Fundamental Investigations (Grant No. 01-04-48382).

(email: dieter@adu.uct.ac.za)

Oschadleus, H.D. 2006. Logistics of a migration atlas project for a small ringing scheme: the waterbird migration atlas of southern Africa. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 590-594.

### ABSTRACT

By 1999, there were 11 656 recoveries of waterbirds recorded in the database of the South African Bird Ringing Unit (SAFRING). Producing a review atlas of ringing recoveries within a relatively small ringing scheme entailed several challenges. One of these was a time constraint: less than a year was available for completion of the atlas in order to meet the publication deadline of two international meetings. The biggest challenge related to data systems and a range of data integrity issues. In the previous year, SAFRING had converted all recovery data from mainframe multi-files to a consistent database, but was still fine-tuning the new database system. Other problems that were overcome included limited numbers of staff (volunteers were recruited to help with data checking), finances and the analysis and writing of the species texts.

### INTRODUCTION

There is a need to summarize and review the recoveries obtained from bird ringing to make the information widely available, especially information on survival rates and migration routes. Several ringing schemes around the world have begun to produce "migration atlases" which typically analyse bird ringing data by species, e.g. the BTO migration atlas for Britain and Ireland (Wernham *et al.* 2002), the Norwegian atlas (Bakken *et al.* 2003) and the Swedish atlas (Fransson & Pettersson 2001). The South African Bird Ringing Unit (SAFRING) produced its first review of ringing recoveries for raptors and owls (Oatley *et al.* 1998). This was followed by a similar review for waterbirds (Underhill *et al.* 1999), which covered about seven times as many recoveries as the review for raptors and owls, and presented much new information. Producing this review atlas within a relatively small ringing scheme posed several challenges. These challenges and how they were overcome are discussed in this paper.

### METHODS

By 1999, there were details of 11 656 recoveries of 101 species of waterbirds in the SAFRING database. These data were analysed and published for the first time in "A Review of Ring Recoveries of Waterbirds in Southern Africa" (Underhill *et al.* 1999). This review is limited to species of waterbirds occurring in southern Africa. Only species in the families listed as waterbirds by Rose & Scott (1997) were considered. These include pelicans, cormorants, herons, storks, ibises, flamingos, ducks, cranes, waders, gulls and terns. The review considered only those species for which there was at least one ringing recovery available in the SAFRING database. For each species, the atlas provides text, tables with details of the most significant and interesting recoveries, and maps and other graphics. As an

example, the information provided for the Sanderling *Calidris alba* is reproduced in Figs. 1, 2 and 3.

### RESULTS

#### Challenge 1: Funds

The cost of running the project was covered by SAFRING. Each recovery was printed on one page, but to save costs, this paper was later re-used on the second side, and then recycled. Six paid student volunteers were trained to check these pages against the original ringing schedules and recovery letters. The analyses and the writing of species texts were undertaken by four authors on an unpaid basis. The publication costs were sponsored.

#### Challenge 2: Data system and data integrity

Recovery data had previously been entered onto a mainframe computer. At one point in time, a substantial number of correct records had been deleted and the incorrect records intended for deletion had survived. A structured database (Paradox™) was designed for a PC computer. The mainframe data were collated, checked for integrity, and added to the database. Additional problems with the early ringing data, i.e. for the period 1948-1975, were as follows:-

- different numerical age codes were used at different stages by different ringers. The original SAFRING age codes were modified, with currently-used codes officially adopted on 1 October 1974 (Elliott 1974). It is, however, unclear whether all ringers made the change to the new age codes exactly on that date. The lesson to be learned is that if codes are changed, the new codes should be distinguishable from the old ones;
- data were submitted on hand-written cards, not on standardized forms, and as a result, some data (e.g. age) were sometimes omitted;
- no identification numbers were allocated to ringers;
- some records were lost when the scheme was moved to a new location; and
- the nearest town was entered as the ringing site, rather than the geographical co-ordinates of the site.

The data are also affected by scheme issues (as described in Oatley *et al.* 1998):-

- the return address on rings was changed;
- recoveries of foreign birds are not all received by SAFRING; and
- a large body of recapture and resighting data is held by ringers.

#### Challenge 3: Analysis and species texts

For each species, standard maps and tables of all the recovery records were produced to aid write-ups by species experts.

Fig. 1. Extracts from the *Review of Ring Recoveries of Waterbirds in Southern Africa* (Underhill *et al.* 1999), showing the table of interesting recoveries for the Sanderling *Calidris alba*.

Fig. 49. Ringing and recovery sites of Sanderling.

## 281 Sanderling

### *Calidris alba*

The Sanderling has a fragmented breeding distribution in the northernmost zone of the tundra; it breeds most extensively in northeastern Canada and Greenland with a series of isolated populations from the Taimyr Peninsula eastwards to Yakutia, Russia. It migrates to most of the world's coastlines between c. 60° N and the southern limits of South America, Africa and Australia. In southern Africa it is almost exclusively coastal. The timing of scattered inland records, which peak in September to November (Penry 1994 for Botswana; Tree 1999b for Zimbabwe), suggests that these are mainly young birds on their first southward migration. Throughout its nonbreeding range, it occurs at sandy beaches, wave-cut platforms, and sheltered bays and inlets with a sandy or muddy substrate. The highest densities in southern Africa are found on the west coast, especially in central Namibia, the Northern Cape and the Western

Cape. The population visiting southern Africa has been estimated to be 78 000 in Namibia and South Africa, and at least 5000 in southern Mozambique (Summers *et al.* 1987b; HBW3 520; ASAB1 422–423; Parker 1999).

The provenance of birds reaching southern Africa is currently considered to be Siberia and all recoveries have been interpreted to fit this hypothesis, although it had long been suggested that Sanderlings breeding in Greenland also occur (e.g. Summers 1976; Summers *et al.* 1987a; Hockey & Douie 1995; ASAB1 422–423). Arrival starts in September and departure is in April and early May, with the eastern and southern coasts having been vacated by March. Considerable numbers of young nonbreeders remain through the southern winter.

2916 Sanderlings ringed have generated 32 recoveries of which 22 were made in Eurasia (Table 64, Fig. 49). In addition there are five recoveries on the southern African west coast of birds ringed in Iceland (7), Great Britain (two, e.g. 14), Tunisia (16) and Ghana (8). We interpret the pattern of the recoveries as follows. Eight birds reported between 6 August and 15

October (median date 6 September) from the Black and Caspian Sea region were adults on southward migration from Siberia. Four recoveries in England, Denmark (6) and France (two) between 25 July and 9 August (median date 3 August) and the control in Namibia of a Sanderling ringed in Ghana on 15 September (8) were on southward migration from Greenland. In support of this interpretation, we point out that there have been no recoveries from the intervening Mediterranean basin area during southward migration and that the median date of passage in the west was 28 days earlier than in the east. Breeding in Greenland is completed earlier than breeding in Siberia.

During northward migration, nine recoveries can be assigned to three areas. (A) Four recoveries between 15 and 28 May in France, England (two) and Iceland. We believe that these birds were migrating to Greenland. (B) Four birds in the central Mediterranean basin between 1 and 22 May (Tunisia (16), Malta (two, e.g. 11) and Italy (12)). These are likely to have migrated along the west coast of Africa to the Gulf of Guinea and then crossed the Sahara Desert, and belong to the Siberian population. (C) One recovery from the Caspian Sea on 31 May (3). This bird is likely to have been returning to Siberia via the east coast of Africa. There are three recoveries close to or on the Siberian breeding grounds on dates between 13 June and 2 July: two birds were recovered near Dikson, western Taimyr, and one in northern Taimyr (2, 4 & 15).

If the above interpretation of the migration routes of Sanderlings is correct, it suggests that many Siberian birds undertake a loop migration southwards along the east coast of Africa and northwards along the west coast. There are controls of ringed birds and several other strands of evidence to support this. Three controls show 'westward' movement within southern Africa, but are not within the same year: two birds caught on the same night, 22–23 September 1971, near Port Elizabeth, were controlled in the Western Cape on 30 December 1973 and on the central Namibian coast on 3 January 1977 (1), respectively, and a bird ringed in the Western Cape on 28 November 1975 was controlled in the same 3 January 1997 catch in Namibia. High reporting rates for Sanderling occur from September to January in southern Mozambique (Parker 1999); numbers at two sites in Algoa Bay, Eastern Cape, were highest from December to February (Martin & Baird 1987; Spearpoint *et al.* 1989), and reporting rates along the coastline of the Northern Cape and Namibia were highest in March, and densities along the Skeleton Coast, Namibia, were high in March (Tarr & Tarr 1987; ASABI 422–423). These observations also support the notion of loop migration.

Recoveries of Sanderlings ringed in the Western Cape, dated 15 December 1979 in Crete (13) and 24 February 1984 in the Black Sea (5), are far more likely to represent reporting dates (and not dates of death) than to be examples of birds that have changed their nonbreeding areas. They have been excluded from the argument above, but their dates suggest that they were delayed reports of recoveries made on southward migration a few months earlier.

The longest elapsed time between ringing and recovery was of a bird ringed as an adult in England on 17 May 1969 and controlled 7 y 8 m later in the Western Cape (14). One of the shortest elapsed times was of an adult ringed at Langebaan Lagoon on 22 April 1972, close to departure date, and recovered 52 days later, within the breeding range in Siberia, 12 715 km distant (2). The date of recovery, 13 June, is four days later than the mean arrival date in their arctic tundra breeding areas (Syroechkovski & Lappo 1994).

## 284 Ruff

### *Philomachus pugnax*

The Ruff has a large breeding range in Eurasia, from the Netherlands eastwards to Chukotka. It breeds from temperate latitudes to north of the Arctic Circle, with high breeding densities in forest tundra and in the shrub tundras subzone of Siberia. The entire population migrates in a southwesterly direction; the vast majority are in sub-Saharan Africa during the nonbreeding season. It occurs widely in the interior of southern Africa, with concentrations in the Okavango basin of Botswana, the central watershed of Mashonaland in Zimbabwe and the panveld region of the Free State, Gauteng and North West provinces of South Africa. Relatively few Ruff occur in coastal habitats. The provenance of Ruff visiting southern Africa appears to be eastern Asia (Tree 1985; HBW3 530–531; ASABI 424–425).

The Ruff occurs in marshy, short-grassed habitat but also feeds in pastures and stubble. It favours mesotrophic and eutrophic wetland conditions. Arrival in southern Africa commences in early August and continues to November. It is highly nomadic, moving in response to rainfall events which create or drown suitable habitat. Males depart mainly during February; females depart from late March to early May. Winter records

Fig. 3. Extracts from the *Review of Ring Recoveries of Waterbirds in Southern Africa* (Underhill *et al.* 1999), showing the text for the Sanderling *Calidris alba*.

Les Underhill and Vincent Parker wrote the texts for the orders Pelecaniformes, Ciconiiformes, Phoenicopteriformes, Anseriformes and Gruiformes. Tony Tree wrote the texts for most of the Charadriiformes, and Les Underhill wrote the remainder.

About 10 recoveries per species were illustrated in the publication. The selection aimed to provide a representative set of interesting recoveries, showing distances moved and elapsed times between ringing and recovery. The authors attempted to choose both birds with the longest elapsed times between recoveries, and those that showed rapid movement over relatively long distances.

Where there was sufficient information to show movement, the recoveries for a species were illustrated on a map at the appropriate scale for the species. The authors were unable to provide uniform summary statistics of distances moved and elapsed times between ringing and recovery, although this had been one of their objectives. The reasons are described in detail in Underhill *et al.* (1999). For example, for species such as the White Stork and the Palearctic terns, the SAFRING database consists mainly of records of birds ringed on the breeding grounds and recovered in southern Africa; statistics based on distances and elapsed times are then based on a fraction of the total database for these species, and are not useful. The discussions of distances and elapsed times therefore tended to be qualitative, rather than quantitative.

The first paragraph of each species text provided a brief description of distribution, habitat and the current understanding of movements. Species for which there was little previously published information on movements and migrations had longer texts, as did species for which new insights into patterns of movement were presented.

#### Challenge 4: Time constraint

The review was completed in less than a year, from the development of the concept to the dates of two important meetings in South Africa where the review was to be presented. These two meetings were the Sixth Conference of the Parties to the Convention on the Conservation of Migratory Species of Wild Animals, and the First Meeting of the Parties to the African-Eurasian Migratory Waterbird Agreement.

#### DISCUSSION

A large body of data on bird movements exists at SAFRING, but until recently, these data have not been readily accessible. The upgraded computer system made it possible to analyse results for any species, and this led to a review of the results obtained from the ringing of raptors and owls (Oatley *et al.* 1998), followed by a similar review for waterbirds (Underhill *et al.* 1999). It was the intention of SAFRING to produce such reviews annually to cover other species groups, but this has not yet happened.

For some waterbird species, the accumulated information is meagre. For other species, the body of data now available is sufficient for more detailed analysis than was possible in the review by Underhill *et al.* (1999). For many species, the information presented had never previously been summarized and made available; for most species, additional information has accumulated since the last review of that species' movements was published. For a few species, notably Ruddy Turnstone *Arenaria interpres* and Sanderling, additional information obtained while the review was being undertaken has led to a radical reassessment of their migration systems.

From a statistical perspective, the production of this review was a substantial exercise in data mining (Adriaans & Zantinge 1996). A major component of data mining is data verification. Oatley *et al.* (1998) described some of the problems associated with the checking of old SAFRING records; these apply equally to the atlas analysis. As far as the limitations of the preserved records allowed, recoveries were individually checked against the original ringing and recovery information. There were tight time constraints on the production of the 1999 review, and it was inevitable that, in spite of the authors' best efforts, some errors remained. However, the quality of the SAFRING database of waterbird recoveries has been enormously improved through the production of this review; ongoing maintenance will occur as SAFRING becomes aware of errors. Underhill *et al.* (1999) regarded the database to be adequately clean so that researchers can use the data for individual species for further analyses.

#### ACKNOWLEDGEMENTS

The main sponsors of SAFRING are the University of Cape Town, BirdLife South Africa and the Namibian Ministry of the Environment and Tourism. The National Zoological Gardens of South Africa, Pretoria, and especially Dr Ferdi Schoeman, act as a clearing house, and efficiently send the recovery information to SAFRING. Les Underhill and Marienne de Villiers provided helpful comments on an earlier draft. An anonymous reviewer helped produce a more concise paper.

Acknowledgements for the production of Underhill *et al.* (1999) are as follows. The publication costs were sponsored by the Department of the Royal Netherlands Embassy, Pretoria, and the South African Post Office. Giselle Murison, Simone Maharaj, Kevin McDonald, Tafadzwa Mhlanga, Lizzie Turner and Gill van Zijl assisted with the task of data cleaning. Rob Crawford (cormorants and terns), James Harrison, Phil Hockey (African Black Oystercatcher) and Terry Oatley commented on species accounts, and Sue Kuyper and Jane Underhill proof-read the text.

Lappo E.G., Tomkovich P.S. & Syroechkovski E.E. Jr. 2006. Progress on the 'The Atlas of the breeding waders of the Russian Arctic'. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 595-596.

In total, 75 wader species have been recorded in the Russian part of the Arctic. This paper describes progress to date on a new atlas of breeding waders of the Russian Arctic.

The authors are currently working with colleagues on 'The Atlas of the breeding waders of the Russian Arctic', which will present a series of maps illustrating the distribution of breeding wader species, abundance and breeding range. The last set of detailed maps of breeding wader distribution in the former USSR was published over 40 years ago (Kozlova 1961, 1962), and the new Atlas is planned to be the first publication to present detailed information on waders in the Arctic or treeless northern areas of Russia as well as on other species that have recently expanded into the Arctic.

For the purposes of the Atlas, we consider the Russian Arctic as a super region north of the Arctic Circle (European Russia, West Siberia, Taimyr, northern Yakutia, Chukotka) as well as other adjacent tundra-like northern treeless areas (islands and the coastal White Sea, extensive north-boreal bogs of West Siberia, Magadan Region, Kamchatka, northern Sakhalin Island). Our team has been involved in collecting original data in the Russian Arctic since 1988: of 56 wader species that breed in the Russian Arctic, 51 were chosen for detailed analysis of their ranges.

Data entered into the Access database include the species, study sites with geographical coordinates, information on timing

of observations, weather data, rodent/predator information, data on status of each species, breeding density in certain habitats, and a list of publications and data sources.

Data entry and editing are possible from within a single form, and there is a set of standardized queries and reports. Data have been entered from over 1 375 sources of information from 1 504 localities (Fig. 1), but data for nearly 22% of the sources, including those from museum collections, are not yet published. All data are currently being analysed.

The database is linked to ArcView software with the help of AccessLink, and this allows the production of maps of species distribution. All localities within the database can be reflected on the map, and in this way up to three breeding distribution maps for any wader species in the Russian Arctic can be produced. These maps can show breeding records (point coverage), breeding abundance (point coverage) and an extrapolated breeding range (polygon coverage). We are utilising a method of species breeding range extrapolation based on landscape and vegetation maps that has previously been used in Russia (Uspenski 1969, Brunov 1982, Lappo 1996, Tomkovich 1997), and is known as the method of "landscape extrapolation". This method is suited to the analysis of irregular and incomplete records of breeding and habitats. Preferences for breeding habitats are determined for each species, and the presence of birds in habitats within these landscapes is extrapolated to a group of

Fig. 1. Localities with published, unpublished sources and data from collections on waders breeding records in the Russian Arctic.

similar landscapes. Margins of the breeding range are digitized according to a landscape network with some extra limits added in accordance with the currently known breeding distribution. GIS (Geographic Information Systems) provide the possibility of using the method of landscape extrapolation by providing landscapes, topography, rivers and lakes, soils, and natural zonation as different layers on available maps in various combinations.

Maps of the breeding distribution of each species will be accompanied in the Atlas by a detailed account describing general species distribution, population structure, migration links and some key characteristics of the species biology. An extended English summary will be provided.

The available preliminary data show that ranges and numbers of majority of the Arctic waders were apparently stable during the 20th century. Surprisingly few wader species had negative trends in at least some of their populations. The number of species with changes in range is larger than those with changes in number, probably due to the almost complete absence of monitoring of these processes in the Russian Arctic. The prevalence of positive over negative trends in wader distribution can be partly explained by subjective factors: it is much easier to record range extension than range shrinkage. The majority (n=13) of the species actively spreading north, especially to western European Russia, West Siberia and the Far East, are of southern origin.

#### ACKNOWLEDGEMENTS

The Ministry of Agriculture, Nature Management and Fisheries of The Netherlands and the Royal Netherlands Embassy in

Moscow are supporting the project financially. We are pleased to acknowledge many people including those who assisted in obtaining original data in the field, and especially those who kindly provided us with unpublished information - Dr. Yuri Gerasimov, Petr Glazov, Viktor Golovnyuk, Vladimir Morozov and Grigory Tertitski. Dr. Mikhail Stishov created the database and ArcView links. Dr. Christoph Zöckler and Dr. Symon Blyth of the World Conservation Monitoring Centre (Cambridge, UK) have kindly provided the background digitised maps.

Hughes, B. 2006. Flyway management for species of conservation concern. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 600-601.

The Black-winged Pratincole *Glareola nordmanii* is globally threatened and the population is in rapid decline. An international species action plan has been developed under the auspices of the African-Eurasian Waterbirds Agreement. Photo: Sergey Dereliev.

For migratory species of conservation concern, common or complementary approaches to conservation at an international scale are necessary to ensure their survival throughout their annual cycle. The last decade has seen a number of initiatives to seek co-operation for single species of threatened migratory waterbirds at international or flyway scales. As summarised by the following papers; some of these initiatives have been more successful than others.

The workshop reviewed flyway management planning initiatives with the aim of deriving ‘best practice’, in particular those features of procedure or policy that lead to effective implementation and conservation delivery, and reached the following recommendations:

- **Plan Production.** Production of species action plans needs to involve all stakeholders, ideally through holding focused participatory workshops using an established structure.
- **Plan Structure.** Action plans need to be produced to an established format with clear, specific, measurable, attainable, and prioritised targets backed up by thorough annual work programmes and realistic funding plans. They should facilitate the monitoring and evaluation of subsequent implementation, linking threats, actions and measurable objectives.
- **Plan Endorsement/Affiliation.** Endorsement by relevant international institutions, conventions, agreements, conservation organisations and national governments is highly desirable, although this in itself does not determine success or failure.
- **Plan Implementation.** Action plan implementation needs to be based on the twin premises of sound science and collaboration. International plans need to be transcribed into national action plans so as to ensure government commitment and support. Ideally, national action plans should be enshrined in national legislation (e.g. to implement national biodiversity action plans). In many cases, local community involvement is critical for successful implementation, and specific recommendations on this issue should be included in action plans. Greater priority needs to be afforded to communication, education and public awareness activities. Where relevant, building network capacity to enable sound implementation should be an integral factor in the action planning process. The success of long-term implementation may be enhanced if there is measurable short-term progress, demonstrating the success of plans to key stakeholders and funders at an early stage.
- **Plan Review & Update.** Plans need to include a predetermined process for monitoring and regular update in order to

learn from past successes and failures, i.e. an appropriate feedback mechanism. Most importantly, plans should be viewed as “living” rather than “static” documents incorporating an iterative monitoring and re-evaluation process to refresh priorities in order to react to inability to achieve the ideal agreed objectives. If the other issues identified in this series of recommendations can be addressed, the only (but totally defeating) reason for failure may be the lack of flexibility in an action plan to deal with evolving constraints.

- **Species Recovery Team.** The existence and enthusiasm of a highly motivated, multi-disciplinary Species Recovery Team, comprising key individuals and bodies that will be involved in plan implementation, is critical to successful implementation. A dynamic coordinator with the long-term commitment and organisational backing to drive the implementation process is essential. Recovery Team spirit needs to be maintained through regular communication between members, for example through team meetings and list

servers. All Recovery Team members should be in agreement over the goal and priorities outlined in the action plan thus engendering a strong sense of plan ownership. Recovery Team members should be sensitive to cultural differences between Range States and of the effects of human and logistical capacity limitations on the timescale for plan implementation.

- **Plan Funding.** Existence of national or international funding instruments (e.g. EU-LIFE funding) increase the chance of successful implementation. However, Species Recovery Teams need to incorporate fund-raising expertise in order to make the most of these opportunities. Species Recovery Teams also need to exploit all possible ‘marketing’ opportunities.
- **NGO Involvement.** The wholehearted, and ideally financial, backing of national or international non-governmental organisations is probably the most crucial factor in determining the success or failure of Species Action Plans.

Communication, education and public awareness are all crucial elements to any species recovery programme. Awareness materials have been provided for use at crane breeding sites in Yakutia (Russia) as part of international crane conservation initiatives. Photo: Crawford Prentice.

# Saving Europe's most endangered birds: lessons to be learned from implementing European Species Action Plans

Nagy, S. & Burfield, I. 2006. Saving Europe's most endangered birds: lessons to be learned from implementing European Species Action Plans. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 602-607.

## ABSTRACT

In 1993, BirdLife International started the development of European species action plans in collaboration with Wetlands International. These action plans were endorsed in 1996 by the Ornithological Committee of the European Union's Directive on the conservation of wild birds and by the Standing Committee of the Bern Convention. In 2003, the European Commission commissioned BirdLife International to review the implementation of the plans in the 25 Member States of the European Union. This paper summarizes the results with special reference to waterbirds.

## INTRODUCTION

The concept of international species action plans was developed in the 1970s to protect threatened populations of certain North American waterbird species with special economic and social importance. The format for these plans was developed under the framework of the North American Waterfowl Management Plan (Heredia *et al.* 1996). The preparation of species action plans was also triggered by the U.S. Endangered Species Act. These plans were used as a basis for recovery efforts in the UK, Australia, New Zealand and several other countries. The requirement of the Convention on Biological Diversity to prepare biodiversity action plans provided further impetus for the preparation of species action plans.

In 1993, BirdLife International and Wetlands International drew up action plans for 23 species then considered to be globally threatened or near-threatened (Collar *et al.* 1994), with support from the European Commission and the Royal Society for the Protection of Birds (RSPB, BirdLife Partner in the UK). For each species, a workshop of experts and interested parties from range states was held to ensure that the latest scientific and practical information was available. Each workshop also provided an opportunity to discuss the merits of different conservation strategies and to develop recommendations based on the outcome of the discussion. In order to secure high-level stakeholder commitment, several drafts were circulated to experts and government agencies under the auspices of international conservation bodies.

In 1996, the first set of 23 plans was endorsed by the Ornithological Committee of the European Union's Directive on the conservation of wild birds, and by the Standing Committee of the Bern Convention. The plans were published in 1996 (Heredia *et al.* 1996). Almost one third of the species covered by action plans in this book were waterbirds, namely the Pygmy Cormorant *Phalacrocorax pygmeus*, Dalmatian Pelican *Pelecanus crispus*, Lesser White-fronted Goose *Anser erythropus*, Red-breasted Goose *Branta ruficollis*, Marbled Teal *Marmaronetta angustirostris*, White-headed Duck *Oxyura leucocephala* and Slender-billed Curlew *Numenius tenuirostris*.

Since then, many more action plans have been produced under the auspices of the Ornithological Committee, the Bern

Convention, and the relevant Memoranda of Understanding of the Convention on Migratory Species of Wild Animals as well as the African-Eurasian Waterbird Agreement (see Table 1).

In October 2003, the European Commission commissioned BirdLife International to review the implementation of the first 23 action plans in the 25 countries that are now Member States of the EU. In 2000, BirdLife International carried out a pan-European assessment of progress in the implementation of these action plans, based solely on the information provided by its Partner organizations (Gallo-Orsi 2001). This earlier report therefore provided some basis for comparison with the more recent EU-level assessment.

## MATERIALS AND METHODS

### Data collection

The latest review of the implementation of species action plans broadly followed the methodology already used in *Saving Europe's most threatened birds* (Gallo-Orsi 2001), in order to obtain indices which could be aggregated across the EU. The review took place in three stages. First, available information was collected for provision to national contacts (usually national BirdLife Partners). The main data sources at this stage were:

- BirdLife International's *Birds in Europe 2* database, which provided information on the current population size and trend of each species over the period of 1990–2000;
- BirdLife International's World Bird Database, which provided information on Important Bird Areas (IBAs) of global importance already identified for the species;
- the European Commission's Natura 2000 database, which provided information on Special Protection Areas (SPAs); and
- the EU LIFE Project Database, which provided information on LIFE projects.

In the second stage, the available information was sent to the national contacts, together with a questionnaire for each species relevant to their country. These questionnaires were based on the recommendations in the relevant action plans. The actions in each plan were converted into target statements, to enable measurement of progress in implementation. The correspondents were asked to:

- review and if necessary correct the available information (i.e. information on population size, population in IBAs and protected areas, existence of management plans, LIFE and other Community funding);
- report on measures taken in relation to each action;
- evaluate distance to target by assigning an implementation score;

**Table 1.** Species with international species action plans.

Species	Year of action plan approval	EU25 Threat Status	European Threat Status	Global IUCN Red List Category	1990-2000 EU25 breeding population trend	1990-2000 EU25 winter population trend	Which targets are achieved?	Revision / new plan in preparation
<i>Pterodroma madeira</i>	1995	Critically Endangered	(CR)	CR	Stable	-	Long

<sup>1</sup> Based on range contraction reported from Spain.<sup>2</sup> Subspecies were not evaluated separately by BirdLife International.

- estimate the size of the population affected by the measure; and
- estimate the response of the population.

Implementation scores ranged from 0–4 according to the level of progress towards the target:

- 0 Action not needed/not relevant;
- 1 Little or no work (0–10%) carried out (only piecemeal actions, without being part of a strategic approach);
- 2 Some work started (11–50%), but no significant progress yet;
- 3 Significant progress (51–75%), but target still not reached; and
- 4 Action fully implemented; no further work required except continuation of ongoing work (e.g. monitoring).

In the third stage, the information returned by these national correspondents was sent to the respective members of the Ornithological Committee's Scientific Working Group for checking (copies were also sent to the national representative on the Ornithological Committee).

The final responses were then returned to BirdLife for checking and analysis. Some scores were corrected if there were inconsistencies between the answer and the score, or if the action was not relevant for the particular country. When in doubt, replies were checked by consulting the compilers individually.

## EVALUATION

The evaluation of the action plans was based on two questions:

- To what extent have the recommendations of the action plan been implemented?
- Have the short-, medium- or long-term biological aims of the action plan been achieved?

### Implementation

Implementation was evaluated from the Implementation Scores assigned in the previous process. As explained above, these scores measure the distance to target. The overall level of implementation at national level was characterized by the National Implementation Score (NIS), which combines for each country the priority of the actions with the level of implementation. The NIS ranges between 1 and 4, where 1 represents little or no progress while 4 represents full implementation.

The overall implementation of the action plan was evaluated by calculating an Average Implementation Score (AIS) from the National Implementation Scores. In order to obtain a rough idea of the overall level of implementation of the action plans in a given country, an Average of National Implementation Scores (ANIS) was calculated for each Member State, based on the NIS of all the species occurring in the country.

### Effectiveness

The outcome of the implementation of the action plans was measured in relation to the short-, medium- and long-term aims set in the action plan (Table 2). On this basis, the following categories were distinguished:

- None of the aims was achieved;
- Short-term aims achieved;
- Medium-term aims achieved;

- Long-term aims achieved; and
- Status unknown.

## RESULTS

### Implementation

The level of implementation of the action plans varied markedly between Member States, with NIS ranging between 0 (for endemic species) and 2.69 (for White-headed Duck).

The highest efforts were directed towards Critically Endangered species such as Zino's Petrel *Pterodroma madeira* and Slender-billed Curlew, but no clear tendency was observed in other Red List categories (Table 3). The AIS for Vulnerable species was slightly higher than that for Near Threatened species. Interestingly, the AIS for the Endangered species was somewhat lower than for other Red List categories. Furthermore, a tendency towards higher level of implementation for waterbirds can be observed compared to other species.

The UK achieved the highest level of implementation, indicating the benefits of the UK Biodiversity Action Plan process. It was followed by some other countries where species are the subject of targeted actions, such as The Netherlands, Hungary, Portugal, Austria, France and Sweden. Although some regions of Spain also carry out excellent species conservation work, this is not reflected in the ANIS of Spain because the country's overall score was often reduced due to more limited actions in other regions.

The level of implementation in the ten new Member States was generally lower than in the existing fifteen Member States. This was probably due to the lack of EU funding instruments, such as LIFE-Nature, Interreg and agri-environmental programmes, during the decade preceding their accession to the EU. It also shows that much more assistance is needed in eastern European and African countries if a higher level of implementation of the action plans is to be achieved there.

An analysis of the distribution of LIFE-Nature funding revealed that this funding played a major role in the implementation of the action plans, especially in the Mediterranean Member States. Regarding waterbirds, LIFE-Nature funding played an especially important role in Greece (Pygmy Cormorant, Dalmatian Pelican, Lesser White-fronted Goose, White-headed Duck and Slender-billed Curlew) and Spain (White-headed Duck and Marbled Teal).

The European Union also played an important role in the implementation of the action plans through its conservation Directives. Article 5 of the Birds Directive provides a strong legal framework and guidelines for the Member States to give adequate legal protection to the action plan species, all of which are listed on Annex I of the Directive. However, it was reported in several cases (especially for raptors and waterbirds) that the enforcement of legal protection is still insufficient (e.g. Pygmy Cormorant and Dalmatian Pelican in Greece, and raptors in Portugal, Spain and Greece).

The obligations arising from Article 4 of the Birds Directive have also played an important role in the conservation of the action plan species. For most species, most or all of the IBAs are covered to some extent by SPAs, and the accession process has also accelerated the protection of key sites in the new Member States (Z. Waliczky *in litt.*). However, the results of this analysis also showed that the extent of SPAs and nationally protected areas tend to be much smaller than that of IBAs.

**Table 2. Recovery targets set in the international species action plans.**

Species Name	Aim of Action Plan
Zino's Petrel <i>Pterodroma madeira</i>	To increase the breeding population to at least 40 pairs by the year 2000.
Slender-billed Curlew <i>Numenius tenuirostris</i>	S: to prevent the extinction of the Slender-billed Curlew. M: to prevent any further decrease in the Slender-billed Curlew population. L: to secure a significant increase in the number of Slender-billed Curlews.
White-headed Duck <i>Oxyura leucocephala</i>	S: to maintain the current population and area of occupancy of the White-headed Duck throughout its range. M: to promote population increase within its current range. L: to promote expansion of the breeding population to other suitable areas. To prevent hybridization of the White-headed Duck by eradicating the introduced North American Ruddy Duck <i>Oxyura jamaicensis</i> in the Western Palearctic.
Spanish Imperial Eagle <i>Aquila adalberti</i>	To increase the numbers and distribution of the Spanish Imperial Eagle to a degree that will allow its reclassification as a species of least concern.
White-tailed Laurel Pigeon <i>Columba junoniae</i>	S: to conserve the population at no less than its 1985 level. M-L: to promote the expansion of its range.
Azores Bullfinch <i>Pyrrhula murina</i>	To increase the Azores Bullfinch population to 150-200 pairs by 2010. To extend the area of the laurel forest by 80 ha, reversing its continuing large-scale deterioration through the invasion of exotic flora.
Dalmatian Pelican <i>Pelecanus crispus</i>	S: to prevent any further declines below 1994 levels in the population size and distribution of the Dalmatian Pelican. M-L: to increase the population size of the Dalmatian Pelican to a level at which it no longer qualifies as a globally threatened species.
Lesser White-fronted Goose <i>Anser erythropus</i>	S: to maintain the current population in known areas throughout its range. M-L: to ensure an increase in the Lesser White-fronted Goose population.
Red-breasted Goose <i>Branta ruficollis</i>	S: to maintain Red-breasted Goose numbers at no less than 70 000 birds.
Marbled Teal <i>Marmaronetta angustirostris</i>	S: to maintain the current population and area of occupancy of the Marbled Teal throughout its range (based on 1985-94 figures). M: to promote population increase of the species within its current range. L: to promote expansion of the breeding population to other suitable areas.
Imperial Eagle <i>Aquila heliaca</i>	S: to maintain the numbers of Imperial Eagle throughout its present range. M-L: to ensure range expansion.
Lesser Kestrel <i>Falco naumanni</i>	S: to maintain all known breeding colonies at 1994 levels or larger. M-L: to increase the population size so that it no longer qualifies as a globally threatened species.
Great Bustard <i>Otis tarda</i>	S: to maintain the populations of the Great Bustard throughout its range. M-L: to enable population growth and range expansion.
Aquatic Warbler <i>Acrocephalus paludicola</i>	S: to maintain the current population throughout its range. M-L: to promote expansion of the breeding population to other suitable areas.
Fea's Petrel <i>Pterodroma feae</i>	S: to protect and maintain the breeding population of Fea's Petrel. M: to promote its expansion to all available habitat on the island of Bugio. L: to promote its expansion to all available habitat on Deserta Grande.
Pygmy Cormorant <i>Phalacrocorax pygmeus</i>	S: to prevent declines below 1994 levels of population size and distribution. M-L: to increase the population size to a level at which it no longer qualifies as near threatened.
Cinereous Vulture <i>Aegypius monachus</i>	S: to maintain and enhance the existing populations in Europe. L: to encourage the re-colonization of the former range.
Corncrake <i>Crex crex</i>	S: to prevent declines below 1994 levels in the population size and distribution of the Corncrake to enable it to be removed from the list of globally threatened birds. M: to ensure recovery of small breeding populations at risk of extinction.
Houbara Bustard <i>Chlamydotis undulata</i>	S: to maintain the range and population of the Canary Islands' Houbara Bustard at no less than the 1994 levels. M-L: to promote an increase in the population and range expansion.
Audouin's Gull <i>Larus audouinii</i>	S: to maintain the current population throughout its range. M-L: to ensure expansion of the species' range and numbers particularly in smaller colonies.
Dark-tailed Laurel Pigeon <i>Columba bollii</i>	S: to conserve the population at no less than its 1993 level. M: to promote the expansion of its range.
Madeira Laurel Pigeon <i>Columba trocaz</i>	S: to maintain the population at no fewer than 3 500 individuals. M: to ensure its continued increase towards occupying all suitable habitats. L: to enable re-colonization of areas of its former range through habitat restoration.
Blue Chaffinch <i>Fringilla teydea</i>	S: to conserve the range and populations at no less than the present level. M-L: to increase the Gran Canaria population to a level at which it is no longer classified as a near threatened species.

**Table 3.** Implementation of the international species action plans in decreasing order of Average Implementation Scores (AIS).

Species name	AIS
Zino's Petrel <i>Pterodroma madeira</i>	3.31
Slender-billed Curlew <i>Numenius tenuirostris</i>	3.21
Dalmatian Pelican <i>Pelecanus crispus</i>	3.05
Madeira Laurel Pigeon <i>Columba trocaz</i>	2.94
Lesser White-fronted Goose <i>Anser erythropus</i>	2.81
Cinereous Vulture <i>Aegypius monachus</i>	2.80
Marbled Teal <i>Marmaronetta angustirostris</i>	2.75
Great Bustard <i>Otis tarda</i>	2.55
Blue Chaffinch <i>Fringilla teydea</i>	2.51
Red-breasted Goose <i>Branta ruficollis</i>	2.47
Pygmy Cormorant <i>Phalacrocorax pygmeus</i>	2.44
Imperial Eagle <i>Aquila heliaca</i>	2.39
Aquatic Warbler <i>Acrocephalus paludicola</i>	2.39
White-tailed Laurel Pigeon <i>Columba junoniae</i>	2.38
Dark-tailed Laurel Pigeon <i>Columba bollii</i>	2.38
Fea's Petrel <i>Pterodroma feae</i>	2.27
Spanish Imperial Eagle <i>Aquila adalberti</i>	2.19
Corncrake <i>Crex crex</i>	2.14
Houbara Bustard <i>Chlamydotis undulata</i>	2.04
Audouin's Gull <i>Larus audouinii</i>	2.01
Azores Bullfinch <i>Pyrrhula murina</i>	2.00
White-headed Duck <i>Oxyura leucocephala</i>	1.87
Lesser Kestrel <i>Falco naumanni</i>	1.84

In most cases, there was not a large difference between the population recorded within IBAs and that within SPAs, although the data in the Natura 2000 database and the World Bird Database are not readily comparable. Some major gaps in the coverage of IBAs by SPAs were identified for some species, especially farmland birds, whereas the coverage for globally threatened waterbirds was found to be almost complete for the breeding populations. Coverage of the key stopover sites would require further investigation.

Although significant progress has been made in designating the key sites for globally threatened waterbirds as SPAs, much less progress has been made in preparing and implementing management plans. On the basis of the available information, only a small fraction of the sites was covered by management plans.

### Effectiveness

Assessing the population size, distribution and trends (BirdLife International 2004a) in relation to the short- (1-3 years), medium- (1-5 years) and long-term (1-10 years) aims set out in the action plans suggested that the status of the action plan species has generally improved since the drafting of the plans. For 15 species, at least the short-term targets have been achieved. For 11 of these, the medium-term targets have also been met, and in six cases even the long-term targets have been reached. It is also encouraging that a separate analysis found that Annex I species with species action plans did better than Annex I species without an action plan, based on their population trends (BirdLife International 2004b).

The group of species where the long-term targets were achieved includes two waterbirds with fairly concentrated populations: Pygmy Cormorant and Dalmatian Pelican. On the other hand, the group where even the short-term objectives of the action plan were not achieved also includes three waterbirds: Slender-billed Curlew, Lesser White-fronted Goose and Marbled Teal. The first two of these species are long-distance migrants, and the development of their populations is likely to be heavily influenced by factors operating on their breeding or wintering grounds outside the European Union.

Despite these results, it was not possible to detect any association between the AIS and the level of recovery. This is partly because AIS scoring was a qualitative measure that focused at the level of implementation of all actions relevant in a given country, and did not take into account the size of the population in that country. An example is White-headed Duck, where the AIS is fairly low because of poor measures in many potential White-headed Duck range states, even though effective measures in certain regions of Spain have contributed significantly to the increase of the population. In the case of Great Bustard *Otis tarda*, however, the positive effects of many ongoing conservation measures were reduced by the ongoing range contraction. Another factor contributing to the lack of association relates to differences in the species' biology and their reaction to changes induced by political and economic changes. For example, Corncrake *Crex crex* has responded positively to the reduced intensity of farming in the new Member States, despite the fact that little progress has been made towards targeted agri-environmental measures for it.

International action plans were drawn up to build consensus amongst the individuals and organizations involved in the conservation of the species. Therefore, an analysis was made to show whether species with a "champion" did better than those without. Of the 23 species, 16 had an organization leading on the species' conservation (e.g. species specialist groups, conservation teams or dedicated NGOs, such as the Black Vulture Conservation Foundation). In general, species with a "champion" reached a higher level of recovery target than species without one, although this difference was not significant.

### CONCLUSIONS AND RECOMMENDATIONS

This evaluation shows that the species action plans have played a positive role in improving the conservation status of Europe's most threatened birds, because Annex I species with action plans did better than Annex I species without action plans (BirdLife International 2004b).

In almost two-thirds of the action plan species (15 species), further population decline or range contraction in the EU has been stopped. In the case of 11 species, medium-term targets were also reached, and in six cases even the long-term recovery target was met.

The recovery of action plan species can be explained partly by the generally higher level of site protection, but also by their priority status for LIFE-Nature funding. LIFE-Nature was a major instrument in promoting the implementation of the action plans. Unfortunately, LIFE-Nature provided only project funding, and activities often ceased after the funding ended.

Apart from LIFE-Nature funding, species 'champions' have played a major role in promoting the implementation of the action plans. Their activities were supported partly by LIFE-Nature funds, but substantial amounts of private and corporate

funding were also mobilized through NGOs. However, the lack of a significant difference in the performance of species with and without “champions” suggests that government commitment to regulations, law enforcement, site designation and management is essential.

Research and monitoring to fill gaps in knowledge and to provide feedback about the effectiveness of measures also require stable funding. Collaborative arrangements at national level, involving different stakeholders, based on national action plans and supported by adequate funding, are necessary for effective species recovery. At international level, the European Union has played a major role, but for migratory species it is essential to expand the scope of the plans to cover the entire range of the species.

#### ACKNOWLEDGEMENTS

We thank Wetlands International and in particular Baz Hughes (WWT) for inviting us to present the preliminary results of our study in Edinburgh, and Gerard Boere for his encouragement and patience during the process of preparing the manuscript.

Micheál O’Brian (DG Environment) played an instrumental role in initiating this study and promoting the action planning process in the European Union. Our BirdLife colleagues Umberto Gallo-Orsi, Nicola Crockford, Canan Orhun, Marianne de Rijk, Stuart Butchart and Frans van Bommel all provided invaluable help in collecting and analysing the data.

Diagana, C.H., Dodman, T. & Sylla, S.I. 2006. Conservation action plans for the Black Crowned Crane *Balearica pavonina* and Black Stork *Ciconia nigra* in Africa. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 608-612.

### ABSTRACT

Conservation action plans have been drawn up for the Black Crowned Crane *Balearica pavonina* and Black Stork *Ciconia nigra* in Africa. The action plans present overviews of the species and their different populations, with a particular emphasis on status and threats. Key components of the plans are recommended actions for implementation. The conservation action plan for the Black Crowned Crane has already led to follow-on actions that contribute to implementation of the plan. Participation is essential in the action planning process.

### INTRODUCTION

The Black Crowned Crane *Balearica pavonina* is a resident of the Sahel and Sudan Savannah regions of Africa, ranging from the Senegal basin and Guinea-Bissau drainage in West Africa to the western Ethiopian Highlands and south-west Rift Valley in East Africa. The West African Crowned Crane *B. p. pavonina* occupies the western part of this range, from Senegal to Chad. The Sudan Crowned Crane *B. p. ceciliae* occurs in eastern Africa, with its largest concentration in Sudan (Walkinshaw 1964, 1973, Johnsgaard 1983). It is classified as Near Threatened (BirdLife International 2005). Current population estimates are 15 000 for *B. p. pavonina* (Dodman 2002) and 43 000-55 000 for *B. p. ceciliae* (Beilfuss *et al.* in press). Due to the rapid decrease of populations in certain areas and a lack of knowledge about status in other areas, the International Crane Foundation (ICF) and Wetlands International launched the Black Crowned Crane Programme in 1999 in order to determine the species' conservation status and to prepare an action plan for its conservation.

The Black Stork *Ciconia nigra* is a fairly widespread but generally scarce bird in Africa, where it occurs in three separate populations (Rose & Scott 1994). The estimate of the population breeding in south-west Europe and spending the northern winter in West Africa is the lowest of these, at 1 300-1 370 individuals (Wetlands International 2002). Whilst various projects and conservation programmes are underway for this population in south-west Europe, its conservation status is much less clear in West Africa, where awareness of the stork is also rather low. Results from recent initiatives, including some pioneering satellite-tracking programmes, have helped identify preferred migration routes and important sites in West Africa (Jadoul *et al.* 2003). The much larger population that breeds in central and eastern Europe and spends the northern winter in south-west Asia and sub-Saharan Africa north of the equator numbers around 19 500-28 000 individuals (Wetlands International 2002). Birds from this population cross into Africa at both the Straits of Gibraltar and the Sinai. Of 10 birds fitted with trans-

mitters in the Czech Republic between 1995 and 1999, six followed the south-west migratory route and four followed the south-east flyway into Africa (Bobek *et al.* 2001). There is also a resident population of Black Storks in southern Africa with an estimated population of 1 560-4 050 individuals, key countries being Zimbabwe, Zambia and South Africa (Dodman 2002). With the support of the Ramsar Convention Secretariat, Wetlands International has developed a preliminary conservation action plan for the Black Stork in Africa, focusing largely on West Africa.

### METHODS

#### Black Crowned Crane

Using resources from diverse sources, Wetlands International and ICF supported a range of activities aimed at ascertaining the status of the Black Crowned Crane across its range, and employed a full-time Black Crowned Crane Programme Co-ordinator in December 1999, based at the Wetlands International office in Dakar, Senegal. Preliminary activities included an analysis of gaps in information and a detailed questionnaire survey, whilst a wide range of field surveys were supported in twenty countries across the range. Over a two-year period, a total of 187 of 226 target sites were covered by field surveys or questionnaires, or both (Williams *et al.* 2003). Target sites included all sites known or suspected to harbour cranes, as identified from the African Waterbird Census database, previous reports and publications, and personal communication with survey participants.

The questionnaire surveys aimed to supplement and expand on the field surveys, and the questionnaires were widely distributed. Questions were asked on distribution, population size, status and movements, diet, breeding activity, threats, local attitudes, and legal protection concerning the Black Crowned Crane. Field and questionnaire survey data were analysed to develop population estimates for discrete "sub-populations" or "Crane Areas". The survey results were also used as the basis for developing the Conservation Action Plan, which was reviewed during a Round Table Discussion at the 10th Pan African Ornithological Congress in Uganda in 2000 (Williams *et al.* 2001). The action plan was published in 2003, whilst a technical poster and an awareness-raising poster (labelling the crane as the "Jewel of the Sahel") were also produced.

### BLACK STORK

The aim of the "Conservation Action for Black Storks in Africa" project was to determine the status of, and threats to, Black Storks in (West) Africa, initiate actions for their conservation, and build awareness of this charismatic migratory species in Africa. The

**Table 1.** Estimates by country of the Black Crowned Crane *Balearica pavonina* from 1985 (Urban 1987), 1994 (Urban 1996) and 2004 (after Beilfuss *et al.* in press).

<b>Species total</b>	<b>65 000-90 000</b>	<b>66 500-77 500</b>	<b>43 000-70 000</b>

main objectives were: to determine the conservation status of the Black Stork in (West) Africa; to identify key sites for, and threats to, the species in (West) Africa; to develop a conservation strategy (action plan) for (West) Africa; and to increase awareness of the Black Stork and importance of wetlands in West Africa.

As in the Black Crowned Crane programme, questionnaires were also used for developing the preliminary action plan, although no specific surveys were organized. Field data were mainly drawn from existing data held in the African Waterbird Census database, whilst information on migration and other aspects was obtained via parallel projects (e.g. Bobek *et al.* 2001, Jadoul *et al.* 2003). The preliminary study was carried out in 2002, priority actions were identified in 2003, and a preliminary action plan (consultation review) was produced in 2005. A poster was produced and presented at the Waterbirds around the world Conference in Edinburgh, UK, in 2004. A technical poster was also produced, and both posters are being distributed in Africa.

## RESULTS

### Black Crowned Crane

New population estimates were produced based on the surveys of 2000-2001, with 14 500 *B. p. pavonina* and >27 500 *B. p. ceciliae* yielding a global species estimate of >42 000 individuals (Williams *et al.* 2003). Population estimates have subsequently been revised and now stand at 15 000 *B. p. pavonina*

and 28 000-55 000 *B. p. ceciliae* (Table 1; Beilfuss *et al.* in press, Wetlands International in press). These figures are significantly lower than previous estimates of Urban (1987), Urban (1996) and Meine & Archibald (1996), mainly due to a substantial revision in the estimated population of the Sudan Crowned Crane (Table 1). Both populations were found to be in decline, with significant declines noted in Nigeria and Mali, whilst a hitherto largely undetected sub-population was discovered in Guinea-Bissau. A distribution map was drawn up, in which the discrete Crane Areas were identified. The action plan also detailed information on crane breeding ecology, habitat, feeding ecology, protection status, threats and local attitudes, and used this information to develop a set of recommended conservation actions, as detailed below.

### Recommended conservation actions for the Black Crowned Crane (from Williams *et al.* 2003)

- 1 Launch public awareness programmes for the Black Crowned Crane as a flagship species for wetland conservation.
- 2 Initiate case studies to find solutions to key threats facing the Black Crowned Crane.
- 3 Develop integrated management programmes for critical wetlands and catchments that support Black Crowned Cranes.

- 4 Advocate the designation of Black Crowned Crane sites as Wetlands of International Importance and the implementation of the Ramsar Convention on Wetlands.
- 5 Transfer the Black Crowned Crane from CITES Appendix II to Appendix I.
- 6 Strengthen the Black Crowned Crane network and working group to promote further research, monitoring and exchange of information.
- 7 Convene international and range-wide workshops to plan future conservation measures for the Black Crowned Crane.

Further specific actions were developed for each subspecies (Williams *et al.* 2003). Since the action plan was developed (in 2001, printed in 2003), Wetlands International and ICF have continued to work together to address the main recommendations of the plan. In particular, a number of specific case studies have been achieved and/or are still underway. These include:

- investigating the status of cranes and factors behind the live crane trade in Mali;
- investigating factors affecting breeding and movements of cranes in an area where wetlands have been converted to agricultural land in Senegal;
- surveys and conservation of cranes in the rice-growing zone of coastal West Africa from the Casamance of Senegal to Guinea, with a special focus on Guinea-Bissau;
- a survey and Participatory Rural Appraisal in selected communities in the crane's range in Nigeria.

### Black Stork

Key sites for Black Storks in West Africa were identified, including potential Wetlands of International Importance (sites that meet the Ramsar Convention's 1% criterion for the Black Stork), as well as other key (non-wetland) stopover sites. The main threats to Black Storks in Africa were also identified, and their conservation requirements determined. Awareness of the Black Stork was built into the African Waterbird Census network and other networks in Africa.

The Black Stork Conservation Action Plan is currently under technical review prior to publication. It presents information on the status of the three populations, their distribution and migration strategies, count data from the African Waterbird Census, habitat and ecology, breeding, threats and current conservation measures and legislation. In Africa, the main threats identified are the loss and degradation of habitat, hunting, and factors relating to inadequate legislation. Habitat degradation in West Africa is due to desertification, changing landscapes with agricultural intensification, and related factors such as pollution caused by the concentration of pesticides and other chemicals in wetlands. In eastern Mauritania, an important staging area for Black Storks, natural wetlands have been lost due to the building of dams and clearing land for agriculture, a trend that is likely to continue given current national policies directed towards food security (Shine 2003).

The main aim of the preliminary action plan is to prevent, in the short term, further degradation of wintering sites in West Africa through local community-based conservation initiatives, and in the long term, to augment the populations wintering in

West Africa through site restoration and the conservation of the stork's main habitats. The specific objectives of the plan are given below.

#### Specific objectives of the preliminary Black Stork Conservation Action Plan

- 1 Promote the restoration and conservation of suitable wintering habitat for Black Storks in West Africa.
- 2 Encourage the application of national and international legislation in favour of the protection of the Black Stork and its habitat, notably its wintering habitat in Sahelian Africa.
- 3 Regularly monitor the populations of Black Storks in Africa.
- 4 Initiate case studies to define threats to Black Storks in their winter quarters in Sahelian Africa and identify solutions to minimize threats.
- 5 Develop and launch a public awareness and education programme on storks in general and the need to protect their fragile habitats in Africa.
- 6 Strengthen co-operation between breeding and non-breeding zones (staging and wintering zones) of the Black Stork, especially through a network of managers of key sites for storks across their flyways.
- 7 Strengthen communication of the network.

The action plan further provides management options and measurable indicators for each objective and a series of "sub-objectives", and describes mechanisms for putting the plan into practice. The plan details specific recommendations for each of

the main wintering zones in West Africa, namely the western zone (Mauritania, Senegal and western Mali), the central zone (Mali), and the eastern zone (Burkina Faso, Niger, Benin, Nigeria, Togo and Ghana), as well as a buffer zone for staging areas in Mauritania.

#### DISCUSSION

There have been significant outputs from the follow-on projects launched since the development of the Black Crowded Crane Conservation Action Plan. These have included community awareness and training activities and related outputs; conservation awareness materials produced and locally distributed; site guardians appointed; site conservation agreements developed with local communities; and local training materials produced in Creole and other languages. Training has mainly focused on informing local communities about the importance and values of wetlands and about cranes and other waterbirds. The plan thus remains as a useful living conservation tool that is still under implementation. It has certainly acted as a stimulus for focusing and prioritizing further conservation action and for raising funds for these actions.

By contrast, the Black Stork Conservation Action Plan has not yet been completed, due to a prolonged review process, and no new specific follow-up actions have been developed. There is also a need to integrate further information and conservation priorities for the discrete population in southern Africa, for which further communications are also required. Nevertheless, the plan promises to be a useful document for prioritizing future conservation actions for this species, and for potentially expanding some components to embrace other storks in the region. Significant research is conducted on Black Storks in Europe, where this is widely regarded as a high priority species for conservation. There is much to be gained through a strengthened network for Black Stork conservation and exchange between partners in Europe and Sahelian countries of Africa. The series of international conferences on the Black Stork and the Stork, Ibis and Spoonbill Specialist Group of Wetlands International are positive vehicles for achieving this.

Conservation action plans are useful planning tools for focusing and prioritizing attention on species, in particular threatened species, for which concerted and co-ordinated action is often needed for their successful conservation. It may arguably be easier to raise funds and enthusiasm for the implementation of plans for charismatic or well-known species than for less-known or drab species. However, whatever the success in raising funds, clear and prioritized recommended actions are extremely useful, and will be widely respected if appropriate networks have been involved in drawing them up. The African-Eurasian Migratory Waterbird Agreement (AEWA) advocates the development of Species Action Plans, and has produced a number of plans under its technical series, e.g. UNEP/AEWA (2004). There are also specific national action plans in some countries, such as the Botswana Wattled Crane Action Plan (Motsumi *et al.* 2003). The BirdLife African Species Working Group and the Royal Society for the Protection of Birds (RSPB) have established a project to enhance the conservation of key bird species in Africa through the development and implementation of Species Action Plans. A key step in the BirdLife Species Action Plan approach is the organization of participative species action planning workshops (BirdLife International, no date). Participation is certainly a key

element in the success of developing and implementing action plans, and in their monitoring and evaluation.

## ACKNOWLEDGEMENTS

We would like to acknowledge the input of Emmanuel Williams and Rich Beilfuss, both co-authors of the “Status Survey and Conservation Action Plan for the Black Crowned Crane *Balearica pavonina*”, upon which parts of this paper are based. Other key collaborators in implementation of the Black Crowned Crane Conservation Action Plan are Bakary Kone, Idrissa Ndiaye and Joãzinho Sá. We particularly acknowledge the financial support of the Disney Wildlife Conservation Fund, the North of England Zoological Society, the Programme of International Nature Management of the Ministries of Agriculture, Nature Management and Fisheries (LNV) and Foreign Affairs (NEDA) in The Netherlands, and the Ramsar Convention Secretariat.

## Approaches to freshwater bird species conservation – Wattled Cranes *Bugeranus carunculatus* and Shoebill Storks *Balaeniceps rex* in Zambia

Hewitt Chizyuka

WWF Southern Africa Regional Program Office, No 10 Lanark Road, Belgravia, PO Box Cy 1409, Causeway, Harare, Zimbabwe.  
(e-mail: Hchizyuka@wwf.org.zw)

Chizyuka, H. 2006. Approaches to freshwater bird species conservation – Wattled Cranes *Bugeranus carunculatus* and Shoebill Storks *Balaeniceps rex* in Zambia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 613.

At first sight, there may not be many compelling reasons why freshwater bird species in their own right merit particular conservation efforts. However, many large conservation issues, such as habitat protection, management of certain important landscapes, water and wetland management issues and promotion of improved local livelihoods and tourism, can benefit from bird species conservation initiatives.

The World Wide Fund for Nature (WWF) has recently embarked on large-scale freshwater conservation initiatives in Southern Africa. A strategic decision has been made to implement freshwater management interventions that address conservation at river basin level and prominently factor in livelihood issues in order to promote the positive socio-economic progress of local communities while reducing the pressures that lead to ecological damage of these ecosystems.

Work is currently underway in the Kafue flats wetlands of Zambia to promote wise use of wetland resources, and special attention is being paid to the protection of habitats for the Wattled Cranes *Bugeranus carunculatus*, an endangered bird species in the area whose low numbers remain a matter of grave concern. According to the International Crane Foundation the future of Wattled Cranes in Africa depends on Zambia, which supports more than half of the global population in the country's major wetlands and flood plains, such as the Bangweulu Swamps and the Kafue Flats.

Recent surveys in countries previously thought to be strongholds for the crane – Botswana, Mozambique, Tanzania and especially Zambia – have indicated that populations of Wattled Cranes may now only be half previous estimates. Zambia's crane population was recently estimated at around 4 000 to 4 500 compared to 1985 estimates of around 11 000 and 1994 estimates of around 7 000 to 8 000. Loss and degradation of wetland habitat is the most significant threat to the Wattled Crane, and human encroachment into the habitat, dry season fires on the grassland plains and even harvesting of crane eggs for food have all been detrimental.

Breeding and feeding cycles of Wattled Cranes are linked to the natural flood cycles of rivers. Pairs begin nesting as flood waters start to recede following peak flooding since nesting in shallow waters protects the nests from predators and wildfires, but unfortunately not from man as the intensification of artisanal fishing activities in relatively shallow waters has resulted in increased disturbance and the loss of eggs. In the Kafue Flats, river regulation has had a very adverse impact on the cranes. Since the construction of the Itezhi Tezhi dam on the Kafue river, Wattled Cranes have experienced significant constraints to their breeding and feeding sites. The ICF estimates that during a year of normal flooding conditions, about 40% of Wattled Crane pairs

attempt to breed but when floods fail only about 3% of all pairs breed. The absence of floods also decreases tuber productivity, an important food source for cranes. Wattled Cranes are not the only victims: farmers and fishermen who depend on natural hydrological variations in river-floodplains for their livelihoods are also affected by river regulations which give rise to artificial flooding and drying. Throughout Southern Africa large dams have brought hardship for subsistence farmers and fishermen whose livelihoods depend upon the natural flow regimes of rivers. Altered flooding patterns have impacted on water supply, fuelwood, grasses for livestock grazing and fish stocks.

WWF is also working in the Bangweulu basin, also in Zambia, where they are seeking solutions to arrest the decline of the very rare Shoebill Stork *Balaeniceps rex*. This is one of the most rare and elusive birds in Africa and has lured many visitors to the swamps in hope of a sighting in one of their last remaining habitats. The biggest threat to this bird species has been loss of nesting sites due to human encroachment, flooding and occasional fires.

In both cases the conservation of these rare bird species is not only critical for biodiversity in the Kafue Flats and the Bangweulu basin but also for enhancing the livelihoods of local communities through eco-tourism.

# Co-ordinating conservation action across the Atlantic: development of a Flyway Management Plan for the East Canadian High Arctic Light-bellied Brent Goose *Branta bernicla hrota*

James A. Robinson

The Wildfowl & Wetlands Trust, Slimbridge, Gloucestershire, GL2 7BT, UK.

Present address: RSPB Northern Ireland, Belvoir Park Forest, Belfast, BT8 4QT, UK. (email: james.robinson@rspb.org.uk)

Robinson, J.A. 2006. Co-ordinating conservation action across the Atlantic: development of a Flyway Management Plan for the East Canadian High Arctic Light-bellied Brent Goose *Branta bernicla hrota*. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 614-618.

## ABSTRACT

The East Canadian High Arctic (ECHA) Light-bellied Brent Goose *Branta bernicla hrota* breeds in Canada's eastern Queen Elizabeth Islands and winters mainly on the coast of the island of Ireland. The key threats to the population are habitat loss/degradation, natural disasters, changes in the dynamics of native food species, and pollution. In light of the small number of countries involved, it has been deemed appropriate by the Range States to take an international approach to the conservation of the population, with the production of an International Single Species Action Plan (SSAP) within the framework of the Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA). The broad aim of this SSAP will be to restore the ECHA Light-bellied Brent Goose to a favourable conservation status. The SSAP is being developed using internationally agreed standards for identifying actions, and has been prepared specifically to facilitate the monitoring and evaluation of subsequent implementation, linking threats, actions and measurable objectives. The ECHA Light-bellied Brent Goose Working Group will oversee the implementation of the SSAP, and will comprise representatives of the five countries involved (Canada, Greenland, Iceland, Ireland and the UK), relevant international interest groups and several technical advisors.

## INTRODUCTION

Single species action plans are prepared and reviewed regularly for many species/populations of birds with an unfavourable conservation status. These plans address the status of the species/population, identify recovery options, and recommend management activities (Bell & Merton 2002). Targeted conservation activity for species and populations is essential to ensure that effective use is made of limited resources.

The East Canadian High Arctic (ECHA) population of the Light-bellied Brent Goose *Branta bernicla hrota* breeds in Canada's eastern Queen Elizabeth Islands; the great majority winter on the coastline of the island of Ireland, with smaller numbers in the Channel Islands and northern France (Fig. 1). The population comprises around 20 000 individuals in winter (Wetlands International 2002), and is listed under Category A (2) of the Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA) (see AEWA web-site). The AEWA has been developed under the Convention of Migratory Species of Wild Animals (CMS) and encompasses Europe, Central Asia, the Middle East and Africa. The Agreement covers 235 species of birds ecologically dependent on wetlands for at least a part of their annual cycle. Populations listed in Category A (2) are deemed to deserve the production of national action plans with a view to improving their overall conservation status.

**Fig. 1.** Global distribution of the East Canadian High Arctic Light-bellied Brent Goose *Branta bernicla hrota* (breeding areas – dark blue; non-breeding areas – grey; delimitation of flyway – hatched line).

In light of the small number of countries within the range of the ECHA Light-bellied Brent Goose, and given the history of co-operative international conservation and research initiatives, it has been deemed appropriate by the Range States to take an international approach to the conservation of this population, with the production of an AEWA International Single Species Action Plan (SSAP) which can also be used to frame conservation action in countries that are not Contracting Parties to the Agreement. The broad aim of the SSAP will be to restore the ECHA Light-bellied Brent Goose population to a favourable conservation status.

This paper describes the development of the SSAP for the ECHA Light-bellied Brent Goose, from the convening of an international workshop in autumn 2003 to the drafting of the plan itself in 2004, using the format for AEWA SSAPs developed by BirdLife International (BirdLife International 2002). The future success of the plan and its implementation are also discussed.

## PLAN DEVELOPMENT

### International workshop

The first international workshop for the ECHA Light-bellied Brent Goose was convened at the Wildfowl & Wetlands Trust (WWT) visitor centre at Castle Espie (on the shores of Strangford Lough in Northern Ireland) in autumn 2003. This workshop followed discussions between various stake-

holders across the flyway who were eager to see more targeted and secured conservation action for the population in the future. Much of the impetus came from the Irish Brent Goose Research Group, a small group of Brent Goose enthusiasts from Ireland and the UK including individuals from government departments, non-governmental organizations and research institutions, as well as amateurs. Without this group of keen individuals, it is unlikely that such rapid progress in the production of the plan would have been possible.

The workshop was designed to promote co-operation and exchange of knowledge between researchers and conservationists involved with the Brent Goose population. Experts attended from throughout the range of the population and, on the first day, gave various presentations on the biology of the species and its conservation requirements. On the second day, “wall-storming” sessions and discussions within small groups enabled the participants to identify the threats facing the population and the actions required to improve its conservation status. Workshop activities were designed to elicit contributions from all of the delegates present, to promote a sense of “ownership” of the SSAP at a very early stage in the process.

Bert Lenten attended the workshop on behalf of the UNEP/AEWA Secretariat, presenting a synthesis of the aims and objectives of the AEWA Secretariat and its ability to support the production and implementation of SSAPs. The workshop resulted in formal support for the production of an AEWA SSAP for this population of Brent Geese. The WWT (an international non-governmental organization based in the UK) agreed to undertake the work necessary to produce the plan, supported by funds from the Environment & Heritage Service (Northern Ireland) and the National Parks and Wildlife Service (Ireland).

### Threats analysis

The threats facing this population of Brent Geese were identified at the international workshop and derived using the interactive “wall storming” approach detailed in Robinson & Callaghan (2003). To ensure consistency between this and other AEWA SSAPs, all threats were identified according to categories listed in the IUCN Species Survival Commission’s Threats Authority files (see IUCN Species Survival Commission web-site).

The results of this analysis and additional research (e.g. Robinson *et al.* 2004) indicated that the ECHA Light-bellied Brent Goose faces various threats throughout its range. In order to prioritize conservation action to address these threats, the following scoring system was adopted:

- Critical - a factor causing or likely to cause very rapid declines (>30% over 10 years);
- High - a factor causing or likely to cause rapid declines (20-30% over 10 years);
- Medium - a factor causing or likely to cause relatively slow, but significant, declines (10-20% over 10 years);
- Low - a factor causing or likely to cause fluctuations;
- Local - a factor causing or likely to cause negligible declines; and
- Unknown - a factor that is likely to affect the population, but it is not known to what extent.

The main threats to the ECHA Light-bellied Brent Goose are listed in Table 1.

### Structure of the plan

After the international workshop, the WWT took the lead in producing the first draft of the SSAP. The first major section of the SSAP provides a summary of the best scientific information available on the population, its ecology, threats and conservation status (both for the population and its habitats in each of the Range States). Much of this information is provided in more detail in a recent review of the population (Robinson *et al.* 2004). The second major section, entitled “Framework for Activity”, identifies and defines the Goal, Purpose and Results of the SSAP, and sets targets and means of verification for its implementation.

The Goal is the higher level of objective to which the SSAP will contribute. Overall, the Goal of the SSAP will be to secure the favourable conservation status of the ECHA Light-bellied Brent Goose. The Purpose is the objective or effect of the plan. The five Purposes listed for the SSAP are to:

- end illegal and accidental shooting by 2014;
- ensure that permitted harvest levels continue to remain sustainable;
- provide protection and management of sufficient habitat across the range to support 25 000 birds (as measured in winter) by 2014;
- understand population dynamics fully by 2014; and
- understand fully the effects and impacts of currently unquantified threats by 2014.

The Results are the changes that will need to have been brought about by the plan if the Purpose is to be realized. Objectively Verifiable Indicators (OVIs) specify the meaning of the Results. They are designed to measure the impact of an activity, rather than the process undertaken to achieve it, and are measured by Means of Verification, which are time-bound. The Goal, Purpose, Results and Activities of the plan have been designed to be specific, measurable, agreed, realistic and time-bound. An example of the relationship between Purpose, Result, Objectively Verifiable Indicator and Means of Verification is shown in Table 2. Limited space here does not allow the listing of all the Results and Activities identified in the second draft of the SSAP.

The section of the SSAP entitled “Activities by Range State” identifies a series of activities for each country. The activities needed to achieve each Result are listed with their priority and urgency. Many of the required activities were identified at the international workshop and are linked directly to specific threats. The lists of activities are relatively short for each Range State and require achievable conservation action.

### A FRAMEWORK FOR IMPLEMENTATION

#### Creation of an International Species Working Group

The ECHA Light-bellied Brent Goose Working Group will act as the International Species Working Group (ISWG) for implementation of the SSAP, working under the auspices of the AEWA Technical Committee. This group will comprise representatives of each of the five Range States, representatives of relevant international interest groups including each of the relevant treaties (e.g. AEWA Technical Committee), and several technical advisors.

AEWA Range States will have a responsibility to monitor their national populations of the species and its habitat, to

**Table 1.** Relative importance of threats to the East Canadian High Arctic Light-bellied Brent Goose *Branta bernicla hrota* during the breeding and non-breeding seasons.

**Table 2.** An example of the relationship between Purpose, Result, Objectively Verifiable Indicator and Means of Verification.

Purpose	Result	Objectively Verifiable Indicator	Means of Verification
To end illegal and accidental shooting by 2014	Strict enforcement of species protection legislation across the range by 2008	By 2008, a measurable increase in the number of penalties issued to those infringing national and international legislation regarding the species and its habitat	<p>Within three years:</p> <ul style="list-style-type: none"> <li>All known incidences of illegal shootings investigated</li> <li>Guilty parties penalized according to national legislative requirements</li> </ul> <p>Within six years:</p> <ul style="list-style-type: none"> <li>Financial penalties for contravening national legislation</li> <li>Annual assessment of illegal shootings</li> </ul>

monitor the actions taken, including their impact on the species and its habitat, and to report on successes and problems. This should be undertaken by the National Species Working Groups (NSWG), as recommended by the AEWA Conservation Guidelines No. 1 (National Single Species Action Plans). To ensure that lessons are learnt and shared internationally, this information will be communicated to the ECHA Light-bellied Brent Goose Working Group and thus to other Range States, including via the relevant international treaties.

To improve action for the species, the ECHA Light-bellied Brent Goose Working Group will aim to catalyse and co-ordinate the collection of further information relevant to the conservation of the species, including details of size and distribution of the breeding population, migration habits, wintering range and ecology (e.g. habitat use and diet).

Thus, the work of the ECHA Light-bellied Brent Goose Working Group will include the following:

- Developing guidelines for population censusing and monitoring.
- Organizing a co-operative ringing programme.
- Developing guidelines for habitat management practices.
- Facilitating the development of a population model where this will be helpful to focus conservation effort (for example through identifying parameters for which improved data are most needed).
- Assisting in and co-ordinating the preparation of National Action Plans.
- Co-ordinating and facilitating exchange of information between Range States (NSWGs) and between the AEWA and the Range States.
- Collecting country data and annual reports on the implementation of the SSAP from the NSWGs.
- Monitoring implementation of the SSAP through the preparation of an annual international report by the ISWG.
- Organizing intermediate meetings with groups of Range States (training, emergency measures, etc.).
- Preparing and organizing the triennial review meeting between Range States.
- Preparing and submitting a review of the SSAP to the triennial meeting of the Range States and to the triennial Meeting of the Parties to the AEWA.

Detailed “Terms of Reference” based on the above description of activities will be prepared by the AEWA Technical Committee, and hopefully endorsed by the Range States to assist the ECHA Light-bellied Brent Goose Working Group with its work.

### Country actions

To assist in the implementation of the SSAP, it is hoped that each Range State will, as a minimum, commit itself to:

- Endorse the Terms of Reference of the ECHA Light-bellied Brent Goose Working Group.
- Endorse the SSAP.
- Establish a National Species Working Group.
- Report to the ECHA Light-bellied Brent Goose Working Group (through the AEWA Secretariat) on relevant issues in the country, at least by contributing information for the preparation of the annual report by the ISWG.

- Prepare a National Action Plan within one year, in co-operation with the NSWG and based on the International SSAP (see AEWA Conservation Guidelines No. 1).
- Implement the National Action Plan.
- Prepare a review of the National Action Plan every three to five years.
- Maintain and further develop adequately funded research and monitoring programmes to deliver key data.

A timetable for monitoring, evaluation and communication has also been developed and is an integral component of the SSAP.

### NEXT STEPS

In February 2004, the first draft of the SSAP was circulated among the participants of the international workshop and other experts and key stakeholders who were unable to attend. Comments received during the consultation period were used to improve the first draft, and a new draft was finalized in May 2004. This was submitted to the AEWA Secretariat which, in turn, has now circulated it among the key contacts identified by each of the relevant government departments in the Range States. The SSAP was formally adopted at the Third Meeting of Parties to the AEWA in October 2005. It is hoped that it will also be adopted by those countries within the range of the population that are not as yet parties to the AEWA (Greenland and Iceland). Beyond that, it will be the responsibility of the International Species Working Group to oversee and monitor implementation.

The process of developing the plan has been effective so far. The interactive nature of the international workshop and the use of an action plan format that a) uses agreed standards in the definition of threats and identification of required actions, b) is easily understood and used by the target audience, and c) follows a common format adopted by other international treaties, have promoted involvement from stakeholders. It remains to be seen how effective the SSAP will be, but the structure of the plan facilitates monitoring and evaluation of the implementation through indicators of “means” (e.g. production of reports) and “ends” (e.g. increases in goose numbers).

### ACKNOWLEDGEMENTS

This work would not have been possible without contributions from Ken Abraham, Dave Allen, Stuart Bearhop, Hugh Boyd, Sean Boyd, Bob Brown, Kendrew Colhoun, Kathy Dickson, Bart Ebbsing, Ian Enlander, Gudmundur Gudmundsson, Jim Hines, Richard Inger, John McCullough, Graham McElwaine, Kerry Mackie, Paddy Mackie, Mark Mallory, Oscar Merne, Ian Montgomery, James Orr, Alex Portig, Austin Reed, Tony Richardson, David Thompson, Matthew Tickner, Lynne Tinkler and Hugh Thurgate. Thanks also go to Bert Lenten and Yuki Itakura (both of the UNEP/AEWA Secretariat) and Lorraine Robinson who provided support during the preparation of the International Single Species Action Plan. Much of the text has been derived from BirdLife International (2002).

Dereliev, S.G. 2006. The Red-breasted Goose *Branta ruficollis* in the new millennium: a thriving species or a species on the brink of extinction? *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 619-623.

### ABSTRACT

The Red-breasted Goose *Branta ruficollis* is a globally threatened species breeding in the Russian arctic, migrating through Kazakhstan and Russia, and wintering in Ukraine, Romania and Bulgaria. In the 1960s, the single population of the species shifted its wintering range from the south-west Caspian Sea to the north-west Black Sea. Coinciding with this shift, the numbers were thought to have declined by about 50%, from 60 000 birds in the 1960s to 30 000 in the 1970s. A recovery in numbers was recorded as early as the beginning of the 1990s, and during the next decade the population increased to 88 000. Numbers then plummeted to only 23 000 in 2002, since when there has been a moderate recovery. Because of these rapid declines, the species' IUCN Red List category could be upgraded from Vulnerable to Endangered. Past and present conservation, research and monitoring activities throughout the flyway have achieved some results, but full implementation of activities has been hampered by constraints such as lack of human, logistic and financial capacity in the Range States. To improve the situation, it is necessary to review and update the International Species Action Plan for the Red-breasted Goose, and to launch a major project for the species throughout the flyway.

### INTRODUCTION

This paper focuses attention on the globally threatened Red-breasted Goose *Branta ruficollis*, its population history and particularly its current status, the extent of our knowledge, and the past and ongoing conservation, research and monitoring programmes. The main purpose of the paper is to review the present situation and outline the constraints and priorities for future work.

### METHODS

This paper is based mainly on information from published studies and reports, reviews, unpublished reports and theses, and the personal comments of a number of contributors.

### RESULTS AND DISCUSSION

#### Range and flyway

The Red-breasted Goose is a monotypic species occurring in central and western Eurasia (Fig. 1). Its breeding range is confined to the Russian arctic, where it occurs on three peninsulas in west-central Siberia: the Taimyr (c. 70% of the population), Yamal and Gydan (Madsen *et al.* 1999). The northern and southern limits of the breeding grounds are at about 73°N and 68°N, respectively. The eastern limit is generally considered to be in the Taimyr at 108-110°E. However, in the late 1990s,

Red-breasted Geese were discovered breeding in Yakutia, which extends the species' range to 114°E (Syroechkovskiy, Jr. 1999).

The first section of the migration route of the Red-breasted Goose is oriented in a south-westerly direction down the eastern side of the Ural Mountains towards Kazakhstan, along a "corridor" only 100-150 km wide (Hunter & Black 1996). In this section, there are several staging areas in the Ob River floodplains, the first of which is still north of the Arctic Circle. Further south, there are staging areas in the middle Ob near Khanty-Mansiysk and in the region between Surgut and the River Vakh. On reaching Kazakhstan, the geese stage at several sites in the north-western part of the country (Kustanay region): in the Tobol-Ishim forest-steppe, and in the watersheds of the Ubagan, Ulkayak and Irgizin rivers in the Kazakh uplands. From there, the orientation of the flyway turns westwards, and the next known staging sites are at the Manych-Gudilo Lakes and Velvskoye Reservoir in Russia, to the west of the northern end of the Caspian Sea (Scott & Rose 1996).

From these last known staging areas, the geese enter their wintering range. Most of the recent literature on the Red-breasted Goose gives the contemporary wintering range of the entire population as the west coast of the Black Sea. However, in the last few years it has been shown that under certain conditions some geese may spend the winter along the north coast of the Black Sea and even around the Sea of Azov. The most important wintering sites are the Shabla and Durankulak lakes in Bulgaria, the Razelm-Sinoie complex and Danube Delta in Romania, Sivash Lagoon and the deltas of the Danube, Dniester and Dnepr

Fig. 1. The range of the Red-breasted Goose *Branta ruficollis* (green polygon – breeding range; red dots – staging or wintering areas) (after Cramp & Simmons 1977, Syroechkovskiy, Jr. 1995, 1999).

**Fig. 2.** Maximum counts or estimates (where count data are not available) of Red-breasted Geese *Branta ruficollis* in their wintering areas or staging areas (Kazakhstan) for the period 1956–2004. (The winter of 1955/56 is listed as 1956, the winter of 1956/57 as 1957, and so on). (Sources: Uspenskiy & Kishko 1976, Hunter & Black 1996, Dereliev 1998, Tolvanen & Pynnonen 1998, Madsen *et al.* 1999, Dereliev 2000a, Dereliev *et al.* 2000, Hulea 2002, B. Ivanov *in litt.*, S. Yerokhov *in litt.*).

rivers and adjacent “limans” in Ukraine (Dereliev 2000a, 2000b, Dereliev *et al.* 2000, Hulea 2002, Rusev *et al.* 1998, 1999) and, in warm winters, even the Kuma-Manych Depression in Russia (E.E. Syroechkovskiy, Jr. pers. comm.). Recent observations have shown that the Red-breasted Goose, although showing much higher fidelity to coastal areas than other wintering geese such as the Greater White-fronted Goose *Anser albifrons*, can be found over 100 km inland.

The wintering range of the Red-breasted Goose has not always been as it is today. In the twentieth century, there occurred a significant westward shift in the winter quarters by about 1 800 km. Up until the 1960s, the entire population spent the winter on the south-west coast of the Caspian Sea, particularly in the Kizil-Agach area in Azerbaijan. In that decade, the entire population abandoned the Caspian coast and moved to winter on the Black Sea coast. The last observations of large flocks (25 000 birds) in Azerbaijan were in 1970. Already in the late 1960s, similar numbers of Red-breasted Geese were being recorded on the west coast of the Black Sea in Romania. Large flocks of Red-breasted Geese (15 000 birds) were first recorded in Bulgaria in the late 1970s. This major shift in wintering range has been attributed to reduced food availability in the south-west Caspian because of a change from cereals and rice crops to cotton and vineyards, habitat loss, excessive hunting pressure, and possibly some other unknown factors (Isakov 1979).

### Population history

Records prior to 1954 are scarce, but it is thought that the numbers of Red-breasted Geese were similar to, or larger than, those of today. The first reliable estimation of numbers comes from 1956, when 60 000 Red-breasted Geese were reported to winter in the Caspian region (Fig. 2). Between 1956 and 1967, the population was thought to vary between 50 000 and 60 000

individuals (Uspenskiy & Kishko 1976). Coverage in 1967 and 1968 was the best that had been achieved up to that time, and produced a total of 49 000 birds, equally divided between the Caspian Sea and Black Sea regions. From 1969 to 1990, however, the maximum numbers recorded in the non-breeding areas did not exceed 30 000 (Hunter & Black 1996). There are suggestions that the population might have crashed as a consequence of the birds being forced to leave their traditional, but degraded, winter quarters in the Caspian region, and/or because of the effects of DDT on populations of the Peregrine Falcon *Falco peregrinus*, which is known to protect nesting geese from Arctic Foxes *Alopex lagopus* (Vinokurov 1990, Syroechkovskiy, Jr. 1995). However, it has been suggested that this decline was less dramatic than has been supposed, and that the big difference in numbers was due to a lack of adequate monitoring in the newly established wintering areas (Syroechkovskiy, Jr. 1995, Hulea 2002).

In 1991, a total of 43 180 birds were counted – the first time that over 30 000 had been recorded since the end of the 1960s. This was followed by a count of 75 881 in 1993 – the highest population size ever recorded for the species. In the following few years, fluctuating numbers were recorded, but the overall trend was one of increase. Peak numbers of 88 000 were recorded in 1996 in the staging areas in Kazakhstan, and again in 2000 in the wintering areas (Tolvanen & Pynnonen 1998, Hulea 2002, S. Yerokhov *in litt.*). However, within a period of only two years, numbers in the wintering areas crashed by more than 70% to only 23 000 birds in 2002. Several hypotheses have been put forward to explain this rapid decrease: (1) a new shift in the wintering range; (2) insufficient coverage of monitoring in recent years; and (3) a genuine population decline. The first of these hypotheses has been the subject of much discussion, but there have been no signs of a return of birds to Azerbaijan

(Sultanov pers. comm.) or establishment of new wintering areas elsewhere. Although there was some reduction in monitoring efforts in Romania in 2001-2002, the International Waterbird Census (a mid-January count) was carried out in all the countries in the wintering range, and covered the major roost sites.

The hypothesis that there was a genuine decline in the population between 2000 and 2002 has received the greatest support. S. Yerokhov (pers. comm.) reported a rapid decline in the numbers of staging Red-breasted Geese in Kazakhstan over the same period, and this was confirmed by Tolvanen *et al.* (2001). In Bulgaria at least, food was very scarce in the winters of 2000/01 and 2001/02 because of the limited amount of winter cereals in these years. The Red-breasted Geese were forced to concentrate along roads to feed on spilled grain – an unprecedented situation. Starvation and the harsh winters most probably led to high mortality. These events coincided with poor breeding conditions in the tundra. Reports of the breeding seasons of 2000 and 2001 in the annual bulletin of the International Arctic Birds Breeding Conditions Survey (Soloviev & Tomkovich 2001, 2002) from most of the monitored localities on the Yamal, Gydan and Taimyr peninsulas indicated an absence or low numbers of lemmings and voles, numerous predators (Arctic Foxes), low density of breeding birds of prey (Peregrine Falcon and Rough-legged Buzzard *Buteo lagopus*), and unstable, dry and unfavourable weather conditions: all prerequisites for low breeding success of the Red-breasted Goose population. Other “traditional” adverse factors at staging and wintering areas, such as excessive hunting pressure and disturbance, could also have contributed to the population decline.

Counts of geese in the next two winters (2002/03 and 2003/04) indicate that there has been a gradual recovery in the population to about 52 800 birds. This might have been a consequence of improved breeding conditions due to higher numbers of lemmings and lower predation levels in 2002 (Soloviev & Tomkovich 2003), and improved conditions in winter due to better food availability.

The geometric mean of the number of birds recorded in the last four winters (2000/01 to 2003/04) is only 35 900. This compares with a geometric mean of 75 500 in the previous four winters (1996/97 to 1999/2000), and represents a decline of 52%.

The future of the Red-breasted Goose seems uncertain. All the available information indicates that this species is highly susceptible to rapid fluctuations in population size due to slight changes in environmental conditions. Recoveries from population crashes might not always be quick and successful. Some critical sites in the wintering range are under increased threat from infrastructure development due to growing investments in Bulgaria and Romania. Global climate change poses an even greater threat. Based on modelling of climate change, it has been predicted that between 67% (scenario with moderate temperature rise of 1.7°C) and 85% (scenario with extreme temperature rise of 5°C) of the breeding tundra habitat will be lost by 2070-2099 because of changes in the vegetation (Zöckler & Lysenko 2000).

### Conservation status

The Red-breasted Goose is a globally threatened species currently classified as Vulnerable according to B2a + b(iii) of the IUCN Red List criteria (BirdLife International 2004a). It was

also listed in the category Vulnerable in the 1994 and 2000 editions of the IUCN Red List, and was listed in the category Threatened in the 1988 edition.

The recently recorded decline ranges between >70% (from the highest count in 2000 to the lowest count in 2002) and 52% (from the mean numbers in 1996-2000 to the mean numbers in 2001-2004). Since this decline was observed over a very short period of time (less than 10 years), it meets IUCN Red List criterion A1a ( $\geq 70\%$  population decline) or A2 ( $\geq 50\%$  population decline), and the status of the species could therefore be upgraded to Endangered.

At European level, the Red-breasted Goose is classified as SPEC 1 (Species of European Conservation Concern, Category 1) due to its globally threatened status (BirdLife International 2004b).

### Conservation activities, research and monitoring

World-wide conservation activities for the Red-breasted Goose are co-ordinated through an International Species Action Plan, which was elaborated by the Wildfowl & Wetlands Trust on behalf of BirdLife International and published with the support of the European Commission, DG Environment (Hunter & Black 1996). This Action Plan was endorsed by the European Union through the Ornithological Committee as well as by the Bern Convention. Some of the Range States have developed their own National Species Action Plans.

In the autumn of 1996, an International Red-breasted Goose Working Group was established within the framework of the Wetlands International Goose Specialist Group. The Working Group consists mainly of experts from the species' range states, and has been chaired by the Bulgarian Society for the Protection of Birds (BSPB)/BirdLife Bulgaria.

Most of the conservation activities throughout the range of the Red-breasted Goose are in some way related to the protection of roosting sites. Many wetlands where Red-breasted Geese congregate during the non-breeding season are managed in accordance with management plans officially endorsed by the state, or are the subject of management plans currently under development. In addition, some existing protected areas are being extended.

Since the geese are dependent on winter cereals as a food supply during the winter months, purchase schemes have been implemented by NGOs in Bulgaria and Romania. The general idea is to create buffer zones of protected agricultural land around the wetlands or to establish secure feeding areas inland. These schemes are in direct competition with investors whose plans are to establish tourist infrastructure and facilities near and around the coastal lakes. Since the investors are able to afford much higher prices than the NGOs, these schemes are only partially successful and the threat of habitat destruction at the key sites remains very high.

Despite the efforts of state authorities and NGOs to control hunting, shooting is still a major problem in some countries. Although a protected species throughout its range, the Red-breasted Goose is still being shot because it forms mixed flocks with the huntable Greater White-fronted Goose. Some key roosting sites, although protected, are often in winter practically under siege by hunters, who approach critically close to the wetlands and sometimes even to the shoreline. This hunting not only results in some direct mortality of Red-breasted Geese, but also has an indirect negative impact on the population as a whole

because of the strong disturbance factor. Shooting causes disturbance not only at the roosting sites, but also in the feeding areas, which are unprotected. Hunting is also a problem in the staging areas, but the severity of this is often unknown.

In the last decade, there have been very few studies that have focused on the Red-breasted Goose and its habitat. In the second half of the 1990s, Dr. John Quinn carried out a detailed scientific study of the behavioural ecology of the Red-breasted Goose in arctic Russia as part of his PhD study at the University of Oxford (Quinn 2000). This research deals, among other issues, with the habitat choice of breeding geese and nesting associations of geese and birds of prey. The winter feeding ecology of the Red-breasted Geese in Romania was studied by Dr. Dan Hulea during his PhD study at the University of East Anglia (Hulea 2002). In addition to habitat selection, food availability and feeding preferences, foraging dynamics and crop damage, this study covers the numbers and regional movements of the geese. Research by the author (for the Bulgarian-Swiss Biodiversity Conservation Programme, BSPB/BirdLife Bulgaria and Sofia University) in Bulgaria in the second half of the 1990s focused on phenology and dynamics of numbers, distribution at roosting and feeding sites, age ratio and body condition, diet and crop damage (Derelev 2000a, 2000b).

The wintering range is currently the best monitored part of the species' flyway. Already by the end of the 1960s, with the start of the International Waterbird Census, most of the key sites were being covered with the aid of sporadic expeditions by western ornithologists. The first monitoring schemes to cover the entire wintering period commenced as early as the beginning of the 1990s. In Bulgaria, B. Ivanov (*in litt.*) attempted monthly counts at Shabla and Durankulak lakes for a period of three years in the early 1990s, and BSPB/BirdLife Bulgaria has been running a monitoring scheme of fortnightly counts since the winter of 1995/96. In this winter and the next, simultaneous monthly counts were carried out with Romania, and these were also attempted, with varying degrees of success, from 1998/99 to 2000/01.

The BirdLife Partnership launched a promising new initiative in the winter of 2003/04 as part of the activities of the International Red-breasted Goose Working Group. This initiative is known as the Red-breasted Goose Common Monitoring and Research Programme (RBGCMRP). Its general goal is to provide up-to-date information on the status of the species and its habitats, movements, ecology and conservation needs to facilitate the drawing up and implementation of adequate conservation activities. The initiative is co-ordinated by BSPB/BirdLife Bulgaria, and currently operates only within the wintering range (in Romania by SOR/BirdLife Romania and in Ukraine by UTOP/BirdLife Ukraine). In the first stage of the programme, it is planned to extend the scope of the simultaneous counts in the coastal wetlands in the three countries and to strengthen the programme. Later, it is planned to expand the programme to cover the entire range of the species. The programme receives financial support from RSPB/BirdLife UK in Romania and Ukraine, and from WWT in Bulgaria.

No special monitoring of the Red-breasted Goose has been carried out in the staging and breeding areas in recent years. However, there have been regular expeditions to Kazakhstan mainly by Finnish and Norwegian ornithologists supported by local experts. The main focus of these expeditions has been

staging Lesser White-fronted Geese *Anser erythropus*, but they have contributed invaluable data on the Red-breasted Geese there. The second notable monitoring scheme is the Annual International Arctic Birds Breeding Conditions Survey, which has been carried out since 1998 and provides important data from the breeding grounds.

### Constraints and priorities for the future

Whether the Red-breasted Goose will be a thriving species in the new millennium or a species on the brink of extinction largely depends on adequate conservation measures. The formulation and implementation of such measures should be backed by rigorous research and monitoring programmes. All of these activities suffer from the same constraints of lack of sufficient human, logistic and financial capacity. Even in the wintering range, where conservation, research and monitoring activities have been most concentrated in the last decade, such problems hinder effective implementation. The situation is most serious in Ukraine, where the geese occupy vast coastal areas but human capacity is not adequately developed. Similar constraints exist in Romania as well, and to a much lesser extent also in Bulgaria. The ongoing activities rely on small grants, which do not allow institutional development and the necessary increase in capacity. In the staging and breeding areas, we are facing an even more complicated situation. In some parts of the flyway ("white spots"), no information has been available for a number of years because of a total absence of projects and expert coverage.

Largely for the above-mentioned reasons, the International Red-breasted Goose Working Group has not yet been able to provide co-ordination of activities outside the wintering range. It is an unfortunate fact that the species' flyway stretches across five countries, all of which are either developing or in transition (OECD 2003). Thus, the governments are encountering difficulties in providing financial and other support for implementation of necessary activities as described in the International and National Species Action Plans. NGOs in these countries are not well developed institutionally and are financially unstable, depending almost entirely on external funding. In addition, the framework of the International Species Action Plan is not sufficiently operational to provide good guidance to implementers.

Short- and medium-term actions should be undertaken in order to overcome these handicaps. In the first place, the International Species Action Plan should be reviewed, updated and rewritten in the shorter AEW format, with a view to improving its usefulness at the operational level. A major part of the further implementation of the Action Plan should be carried out within the framework of a large-scale flyway project (GEF or similar). While supporting basic scientific research and the strengthening of ongoing monitoring and conservation activities, the project should focus mainly on human and institutional capacity building. Thus, firstly it would improve international co-ordination, and secondly it would have a catalytic effect on the development of networking throughout the flyway.

### ACKNOWLEDGEMENTS

I would like to thank several experts from the Range States – members of the International Red-breasted Goose Working Group – not simply for their contribution to this paper, but for their long-standing commitment to the conservation, research and monitoring of this remarkable species: Elchin Sultanov in

Azerbaijan; Dimitar Georgiev, Ivaylo Ivanov, Nicky Petkov and Viktor Vasilev in Bulgaria; Sergey Yerokhov in Kazakhstan; Dan Hulea, Attila Sandor, Alexandru Dorosencu and Eugen Petrescu in Romania; Evgeny Syroechkovski, Jr., Vladimir Morozov and Konstantin Litvin in Russia; and Ivan Rusev, Anatoly Korzyukov and Mykhailo Zhmud in Ukraine. I would also like to extend this acknowledgement to the donor organizations, RSPB (represented by Norbert Schaffer), WWT (represented by Baz Hughes) and other sponsors, for their invaluable support.

### ABSTRACT

The White-headed Duck *Oxyura leucocephala* is the only stiff-tail (Oxyurini) indigenous to the Palearctic. The global population, which was probably over 100 000 in the early twentieth century, has decreased to 8 000-13 000 individuals in 2002. In the Central Asian region, the details of the life cycle of the species and its precise migratory habits largely remain an enigma. As the region undergoes an extended periodic drying

cycle, there is a challenge of ensuring maintenance of wetlands in their natural condition, and ensuring allocation to these wetlands of regular water supplies, given that human impacts on wetlands increase from domestic, industrial and agricultural uses. The fate of the small population of White-headed Ducks that migrate to Pakistan remains in question. In 2003, Wetlands International undertook a comprehensive survey and collation of information to ascertain the status and conservation needs of the

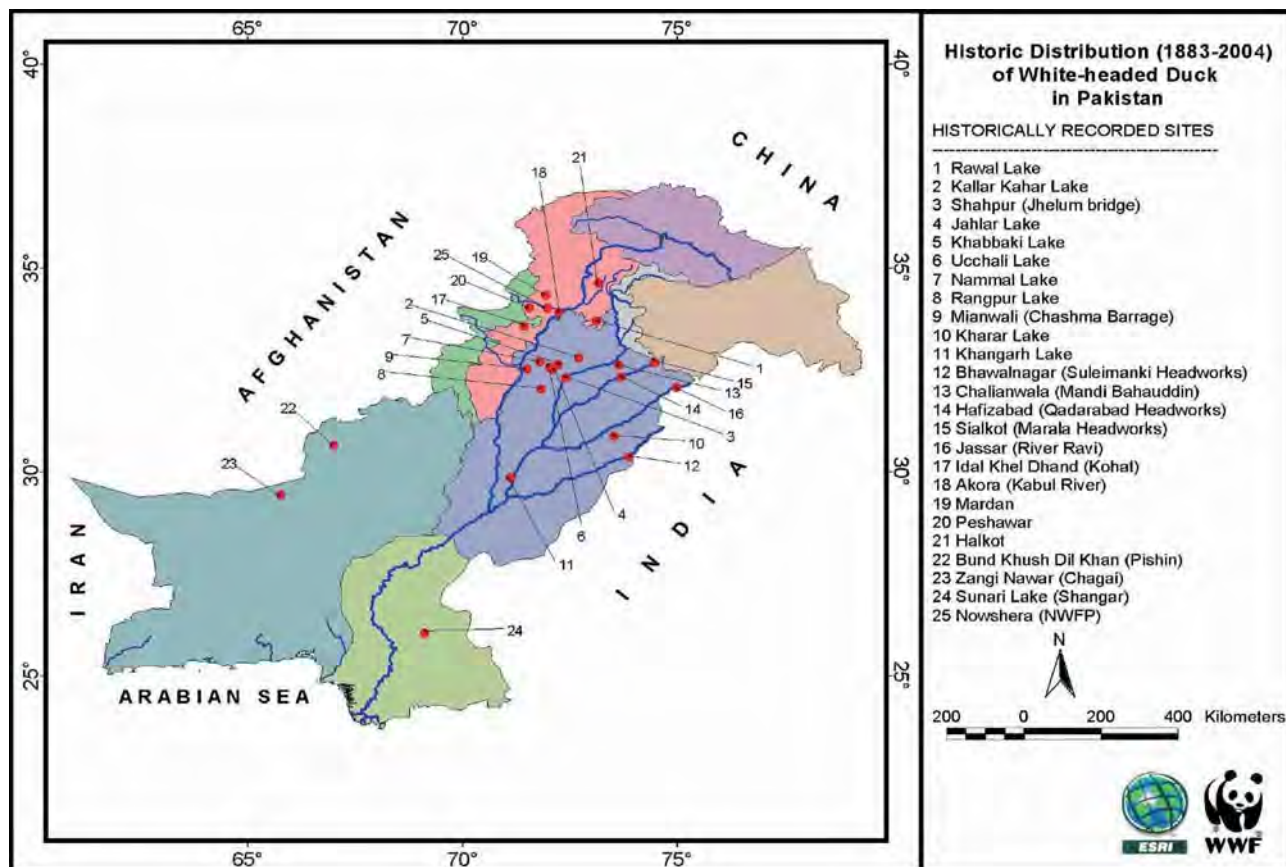

Fig. 1. Distribution of the White-headed Duck *Oxyura leucocephala* in Pakistan.

species, the results of which were published in a report. Surveys in Uzbekistan, Kazakhstan and Pakistan in 2003 and 2004 have provided new information on the important sites for the species. This paper provides an update on the status and conservation needs of the species.

## INTRODUCTION

The White-headed Duck *Oxyura leucocephala* is a globally threatened species, currently evaluated as Endangered in the IUCN Red List of Threatened Species (BirdLife International 2004). Its range and population size have decreased drastically since 1900, as a result of habitat destruction and hunting pressure (Green & Hughes 2001). The global population of the White-headed Duck was probably over 100 000 individuals in the early twentieth century, but had fallen to an estimated 19 000 birds in 1991 (Green & Hughes 1996). Since then, numbers have probably declined to as few as 8 000-13 000 individuals (Wetlands International 2002). This has aroused great concern for the conservation of this species.

With funding from the Convention on Conservation of Migratory Species of Wild Animals (CMS), Wetlands International carried out a comprehensive review of the status of the White-headed Duck in 12 Central Asian countries in 2002, and made a series of recommendations for its conservation. This

report focused on the status of the White-headed Duck in Afghanistan, China, India, Iran, Kazakhstan, Kyrgyzstan, Mongolia, Pakistan, Russia (east of the Ural Mountains), Tajikistan, Turkmenistan and Uzbekistan. The report was published in February 2003 (Li & Mundkur 2003). A review of the status of the species in the Central Asian countries of the former USSR was published in 2002 (Kreuzberg-Mukhina 2002).

This paper presents the latest information available on the species in Central and South Asia, based on these reports and additional observations in Pakistan, Kazakhstan, Mongolia and Uzbekistan in 2003 and 2004.

## STATUS OF THE WHITE-HEADED DUCK IN PAKISTAN

In Pakistan, the White-headed Duck has been widely recorded at more than 25 sites across four provinces, namely Punjab, Baluchistan, North-West Frontier Province (NWFP) and Sindh (Fig. 1). The numbers of White-headed Duck have dropped from 1 039 in 1968 and 733 in 1987 to only about 10 birds in January 2001. In January-February 2002, Abdul Aleem Chaudhry carried out a field survey in northern Pakistan (Chaudhry 2002); only five birds were observed during the survey in January (at Jahlar Lake), and this number had fallen to three in February. However,

**Table 1. Recent counts of the White-headed Duck *Oxyura leucocephala* and status of its wetland habitats in Pakistan.**

Site name	Last count of White-headed Duck	Status of wetlands in January-February 2002	Status of wetlands in January 2004	Threats to White-headed Ducks in Pakistan
Jahlar	8 individuals on 5 January 2004	Following light showers, there was some water in the lake. In the previous year, the lake had been completely dry.	The water storage capacity of the lake had been drastically reduced.	Drought. Habitat loss and modification. Hunting and disturbance. Introduction of fishes, e.g. Grass Carp and Tilapia.
Khabekki	5 individuals in January 2001	Due to a failure of the rains for the last few years, only about one eighth of the lake area was flooded. Very few waterbirds were seen.	Completely dry.	
Ucchali	19 individuals on 15 February 2004	Due to a failure of the rains, the water level was very low. Only a few waterbirds were observed on the lake.	The extent of water had decreased to only about 100 ha.	
Kharal	14 individuals in January 1990	The lake had been drained and was completely dry.		
Kallar Kahar	46 individuals in January 1984	The lake has been developed into a recreational resort, and because of disturbance, very few waterbirds now visit the lake.		
Nammal	3 individuals on 15 December 2003	No appreciable change in character except that the water level had dropped		
Rawal	7 individuals on 28 January 2003	A recreational resort was being developed	Increased disturbance from general public, boating etc.	

higher numbers were recorded in the next two seasons: 33 birds were recorded in January 2003, and 24 birds in January 2004 (Abdul Aleem Chaudhry pers. obs., February 2004). Loss of habitat due to development and drought has been the major threat to the White-headed Duck in Pakistan (Table 1).

#### POPULATION SIZE AND TRENDS OF NON-BREEDING/WINTERING BIRDS

The following summary of the population status of the White-headed Duck in South and Central Asia is based on Li & Mundkur (2003), but incorporates the latest information available from Pakistan and Uzbekistan (Table 2 and Fig. 2).

##### South Asian population

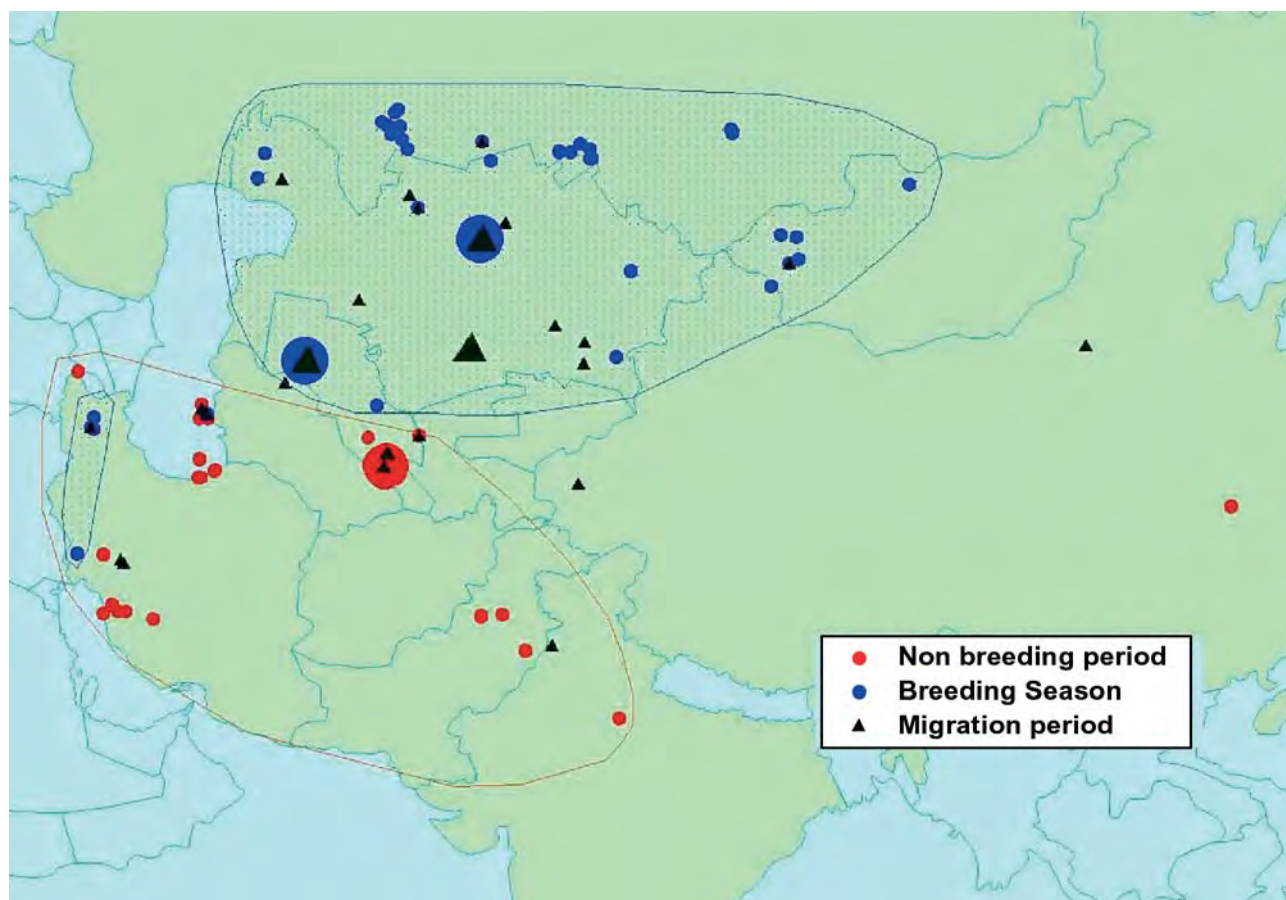

As noted above, the wintering (non-breeding) population in Pakistan decreased rapidly from 1 039 birds in 1968 to only about 10 birds in 2001 and 2002, 33 birds in January 2003, and 25 birds in January 2004. The species is rarely recorded in India, and the last record is of a single individual in January 1997 in Uttar Pradesh.

##### East Mediterranean & South-west Asia population

The numbers of birds recorded in Iran and Turkmenistan in January vary widely from year to year, with the total for the two countries reaching a peak of 1 300-1 500 birds.

In Uzbekistan, large numbers of White-headed Ducks were recorded for the first time in January 2000, when 1 137 birds were counted. Only 14 birds were counted in January 2002, but this low number should be treated with caution, as the count at Dengizkul Lake, where most of the White-headed Ducks were recorded in 2000, was incomplete because of poor access due to flooding. In January 2003, there was a very high count of 5 146 birds in Uzbekistan, mostly at Dengizkul Lake which in this year was being affected by natural drought and abstraction of water for agriculture. In January 2004, a total of 1 192 birds were recorded at several wetlands in Bukhara Province in Uzbekistan. It should be noted that in 2004 a significant amount of water that had been used for agricultural purposes was discharged into Dengizkul Lake. This changed the ecological conditions of the lake and led to a decrease in the numbers of wintering waterbirds including White-headed Ducks (Elena A. Kreuzberg-Mukhina pers. obs., March 2004). Observations have shown that there are no regular wintering sites for the White-headed Duck in Uzbekistan. Rather, it seems that the birds move from site to site depending on where conditions are favourable. Records of climatic conditions indicate that there has been a northward shift in the 0°C isotherm in January, and this is enabling birds to spend the non-breeding period further north than in previous years.

The numbers of White-headed Ducks in Turkey and Azerbaijan have fallen consistently over the past ten years. In

**Fig. 2.** Distribution of the White-headed Duck *Oxyura leucocephala* in Central and South Asia in 1990-2004.

**Notes:** Blue circles indicate breeding areas; red circles indicate wintering (non-breeding) areas; black triangles indicate staging areas during the migration periods. The large symbols indicate sites at which there have been counts of over 1 000 White-headed Ducks during the last five years.

Published sources of information are listed in Li & Mundkur 2003. Additional information provided by: Abdul Aleem Chaudhry (Pakistan), Alex Filatov (Uzbekistan), Andy Green (overall range), Bahtiyar Kurt (Turkey), Baz Hughes (overall range), Behrouz Behrouzi-Rad (Iran), Elena Kreuzberg-Mukhina (Uzbekistan), Evgeniya Lanovenko (Uzbekistan), Gradimir Gradev (Bulgaria), Hamid Amini (Iran), Hichem Azafzaf (Tunisia), José Torres (Spain), M. Zafar-ul Islam (India), Myrrhy Gauser (Turkmenistan), Paul Isenmann (Tunisia and Algeria), Rahat Jabeen (Pakistan), Sadegh Sadeghi Zadehan (Iran), Vladislav Vasilyev (Turkmenistan), Yavar Shahbazi (Iran), and Zulfiqar Ali (Pakistan).

**Note:** Most counts were undertaken in January. In some countries where coverage has been poor, data from November and December of the previous year and February have been included.

Turkey, numbers have fallen from 10 927 birds in January 1991 to about 1 000 birds in January 2000, 2001 and 2002, and in Azerbaijan, from 3 520 birds in January 1991 to 334 in January 2000. However, in the eastern Mediterranean, White-headed Duck numbers have apparently increased: 2 213 and 1 472 birds were recorded in Greece in January 1997 and 2000, respectively; 1 970 birds were recorded in Bulgaria in January 2001; and 520 birds were recorded in Romania in January 2001. This could suggest that the main wintering grounds of the White-headed Duck are shifting westwards.

During the period 1998 to 2002, the total number of White-headed Ducks recorded in January in the East Mediterranean & South-west Asia region was between 3 260 and 4 852. However, these data may give an incomplete picture of the wintering population in this region, as there was a lack of information from some countries in some years. In the 2003 review, Li & Mundkur (2003) therefore used the highest count of 4 852 birds (in January 2000) as the minimum estimate for the East Mediterranean & South-west Asia population, and gave the population estimate as around 5 000-10 000 birds. This estimate now needs to be revised in light of the new data from Uzbekistan, where 5 146 birds were recorded in January 2003.

#### UPDATE FROM MONGOLIA AND KAZAKHSTAN ON MIGRATION AND BREEDING POPULATIONS

According to Li & Mundkur (2003), the White-headed Duck breeds mainly in Kazakhstan, southern Russia, Uzbekistan and western Mongolia. Their report suggests that the Mongolian breeding population could be around 250 pairs and that in Kazakhstan, at least 300-500 pairs. Recent observations in Mongolia and Kazakhstan have provided further information on the size the breeding populations in these two countries. In Mongolia, 400 White-headed Ducks were observed in Khar Us Lake in July 2004 (Simba Chan pers. comm., September 2004). Belyalov & Kovshar (2004) provide information on the White-headed Duck in Kazakhstan in 2003. Highlights of their report include: a total of 1 021 adult birds with (uncounted) juveniles and chicks in the Tengiz-Korgalzhyn Lakes region in late August; 2 000 birds at Kyzylkol Lake, southern Kazakhstan, in September; and 162 birds at Sorbulak Lake in early April. Observations of birds at new sites include: a pair in Ustkamenogorsk region, eastern Kazakhstan, in June; 17 birds in Karaganda region, central Kazakhstan, in September; up to five birds at south Balchasch Lake (Lepsy River and Topar Lake) during May and June; and three to four birds at Sasykkol Lake, south-eastern Kazakhstan, from May to August.

## THREATS TO THE WHITE-HEADED DUCK

### Drought

The drought in Central Asia in 2000-2002 has greatly reduced the amount of wetland habitat for White-headed Ducks and other waterbirds. Many important sites for the White-headed Duck have dried out completely, or have had a much lower water level and greatly reduced water surface in some years. The long-term effects of drought on the viability of the White-headed Duck population are unknown but potentially serious.

### Habitat loss

The natural drought conditions have caused significant loss of habitat for the White-headed Duck. In addition, the unsustainable use of water resources for irrigation and the pollution of wetlands have further reduced the extent of suitable habitat. Water levels in the remaining wetlands of importance for the White-headed Duck have also been reduced.

### Hunting and disturbance

Although hunting of the White-headed Duck is banned in most countries, illegal hunting still occurs. Additionally, fishing, over-grazing and agricultural activities in and around lakes have both direct and indirect effects on the White-headed Duck.

## RECOMMENDATIONS

Li & Mundkur (2003) made six main recommendations for the conservation of the White-headed Duck in Central Asia, and these remain a priority.

- All countries need to undertake a review of their national policy and legislation to ensure adequate legal protection for the White-headed Duck and its enforcement. (National government agencies in the Range States).
- Sustainable management of water resources is needed to ensure adequate allocation of water to maintain the viability of wetland habitats used by the White-headed Duck. (National government agencies in the Range States).
- Site conservation measures, such as the establishment of an international network of sites of importance for migratory waterbirds including the White-headed Duck, need to be pursued. (Convention on Migratory Species and national government agencies in the Range States).
- A flyway-wide project should be developed for the conservation of the White-headed Duck and its wetland habitats through building and strengthening links between wetland managers and organizations involved in the conservation of the White-headed Duck across the region. (Convention on Migratory Species, national government agencies in the Range States, Wetlands International).
- A comprehensive population-monitoring programme should be developed to monitor the distribution and status of the White-headed Duck in the Central Asian region during the wintering, migratory and breeding seasons. (National government agencies in the Range States, site management authorities, NGOs).
- Research is urgently required to define the migration routes of the White-headed Duck and identify the population

boundaries. Population surveys at all historical sites and all potential sites for the species are an immediate concern. (Research institutes, universities, NGOs).

## ACKNOWLEDGEMENTS

We thank a number of experts who have kindly contributed valuable information to this study. They include: A.K. Yurlov, Alex Filatov, Alexander Yakovlev, Anatoli Ostachenko, Andrie Gavrilov, Andrew Grieve, Andy J. Green, Axel Braunlich, Bahtiyar Kurt, Batdelger Dashnamjilyn, Baz Hughes, Behrouz Behrouzirad, D. ### ABSTRACT

The south-east Caspian region of Turkmenistan is an important staging and wintering area for the globally threatened Lesser White-fronted Goose *Anser erythropus*. During the period 1975-2003, surveys carried out in late autumn and mid-winter recorded Lesser White-fronted Geese at a total of 14 sites. The numbers of geese fluctuated widely from a maximum of 1 850 individuals in November 1999 to none in several years. The most important sites were the Turkmenbashi, Balkan, Mikhailovskiy and Severo-Cheleken Bays in the central part of the Caspian coast of Turkmenistan, and the delta of the Atrek River in the southern part. Changes in the distribution and numbers of geese have occurred as a result of habitat degradation or alteration and other anthropogenic pressures, especially hunting. Various measures are proposed for the protection and management of the Lesser White-fronted Goose in Turkmenistan, and it is suggested that these measures could be used in the development of an international action plan for the conservation of the species in the Caspian region as a whole.

### INTRODUCTION

The basin of Caspian Sea is an important wintering area for the globally threatened Lesser White-fronted Goose *Anser erythropus*. However, the recent status and distribution of the species in the region, particularly in the south-east Caspian, have not been described in the literature. Information concerning the wintering populations of Lesser White-fronted Geese in the Caspian Sea basin has been lacking for a number of years (Morozov & Syroechkovskiy 2002). Furthermore, no attempts have been made to develop special measures for the conservation and management of the species in the Caspian region, in spite of the fact that the species is included in the national Red Data Books of the Caspian states. This paper provides a summary of recent information on the distribution and numerical abundance of the Lesser White-fronted Goose in the south-east Caspian region of Turkmenistan, and suggests a number of measures that should be taken for the protection and management of the population.

### METHODS

This paper is based on surveys carried out by V.I. Vasiliev in the south-eastern part of the Caspian Sea between 1980 and 2003, and also on data gathered by A.A. Karavaev in the lower basin of the Atrek River between 1975 and 1991 (Karavaev 1991). The surveys were undertaken by car, on foot, or in some years from a motor-launch, between October and March, usually twice a year – in the last ten days of November and first ten days of December, and in

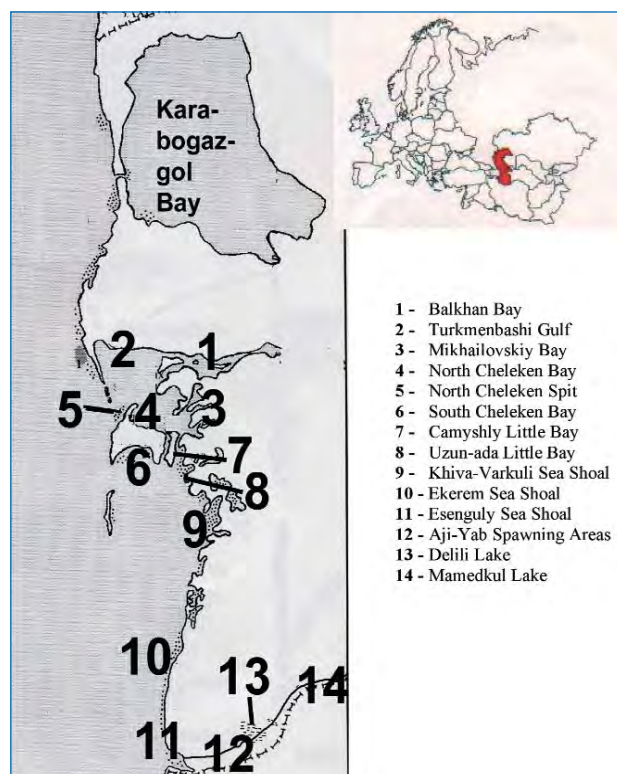

Fig. 1. Monitoring sites for the Lesser White-fronted Goose *Anser erythropus* in the south-east Caspian region of Turkmenistan.

the first ten days of January. These time periods coincided with the end of the autumn migration / start of the wintering period, and middle of the wintering period. Forty-six surveys were carried out on the Caspian seashore, and 54 surveys in the delta of the Atrek River. Waterfowl were recorded at a total of 36 wetlands, and Lesser White-fronted Geese were observed at 14 of these sites (Fig. 1). In total, 6 241 Lesser White-fronted Geese were recorded. Only 5 774 individuals have been included in the present analysis, as the remainder were birds counted during general avifaunal surveys and may not have been correctly identified.

### RESULTS

The Lesser White-fronted Goose did not occur annually at any of the sites under investigation. During the 29 years under review (1975-2003), the maximum number of birds counted was 1 850 individuals in November 1999; the minimum number (in years when at least some geese were located) was only two individuals in November 1982. There were no observations of the species in the years 1976-1978, 1986-1987 and 1992-1996.

**Table 1.** Counts of the Lesser White-fronted Goose *Anser erythropus* at monitoring sites in the south-east Caspian region of Turkmenistan. Monitoring sites are numbered as in Fig. 1.

Date	Monitoring sites													
	1	2	3	4	5	6	7	8	9	10	11	12	13	14

11-19.11.2000												144		18
14-21.01.2001												96		
21-30.11.2001	430		36									650	17	
08-19.01.2002		149		75								176		
27.11.2002	194													
06-23.01.2003	4						42	5	54		73	12	7	

However, the possibility that Lesser White-fronted Geese occurred at other wetlands along the south-east Caspian shore in these years cannot be excluded, as most of the wetlands possess habitat that is potentially suitable for the species during the migration seasons or wintering period.

The two most important factors influencing the distribution and population dynamics of the geese in Turkmenistan are changes in the hydrological regime of the wetlands and hunting pressure. The largest concentrations of Lesser White-fronted Geese were found in protected areas in Turkmenbashi (formerly Krasnovodskiy), Balkan, Mikhailovskiy and Severo-Cheleken Bays in the central part of the Caspian shore at the limit of the State Khazarskiy (formerly Krasnovodskiy) Strictly Protected Area (zapovednik) (Fig 1). Over the period under review, an average of 40% of all Lesser White-fronted Geese recorded in autumn in the south-east Caspian region were found in these areas, and an average of 53% of all those recorded in winter.

The Aji-Yab wetlands (Aji-Yab spawning areas) in the lower basin of the Atrek River were formerly almost as important as the wetlands on the central Turkmenistan coast, with the numbers of geese ranging from 16% to 38% of the total population. Unfortunately, these sites have recently lost their value for Lesser White-Fronted Geese and other waterfowl as a result of drainage.

Table 1 gives details of the numbers of Lesser White-fronted Geese recorded in late autumn and winter at the 14 monitoring sites in the south-east Caspian region. The fluctuations in numbers at wetlands in the central part of the Turkmenistan coast showed slightly different tendencies from those in the southern part (Atrek Delta). The numbers of geese were more or

less stable in the central part (470-600 individuals) and the southern part (maximum 667) during the autumn migration and early winter in 1999-2002. During the mid-winter period, the total number of geese usually falls: in 2002 the number in the central part decreased to 224 individuals, and in the southern part, to 176 individuals. The distribution of the species differed in some years. In January 1989 (in the middle of the wintering period), there were 759 Lesser White-fronted Geese in the lower Atrek Delta, and no birds in the central part. Similarly, in January 1991, there were 135 geese in the lower Atrek Delta and none in the central part. It should be noted that during the period 1975-1991, 84.4% of all Lesser White-fronted Goose observations in the Atrek Delta came from the period 1975-1983, and only 15.6% from the period 1984-1991 (Karavaev 1991).

The seasonal migrations of the Lesser White-fronted Goose in the south-east Caspian region produce two peaks: in autumn, in the first part of November, and in spring, in February, although the spring migration usually continues until March. The earliest date that Lesser White-fronted Geese have been observed in the lower part of the Atrek River is 25 October 1982, and the latest, 21 March 1983 (Karavaev 1991).

## DISCUSSION

The distribution and population dynamics of Lesser White-fronted Geese in the south-east Caspian region are characterized by fluctuations which are determined by habitat degradation or alteration and other anthropogenic pressures, chiefly hunting. A similar situation occurs on the breeding grounds where the goose populations face similar pressures (Morozov & Syroechkovskiy 2002).

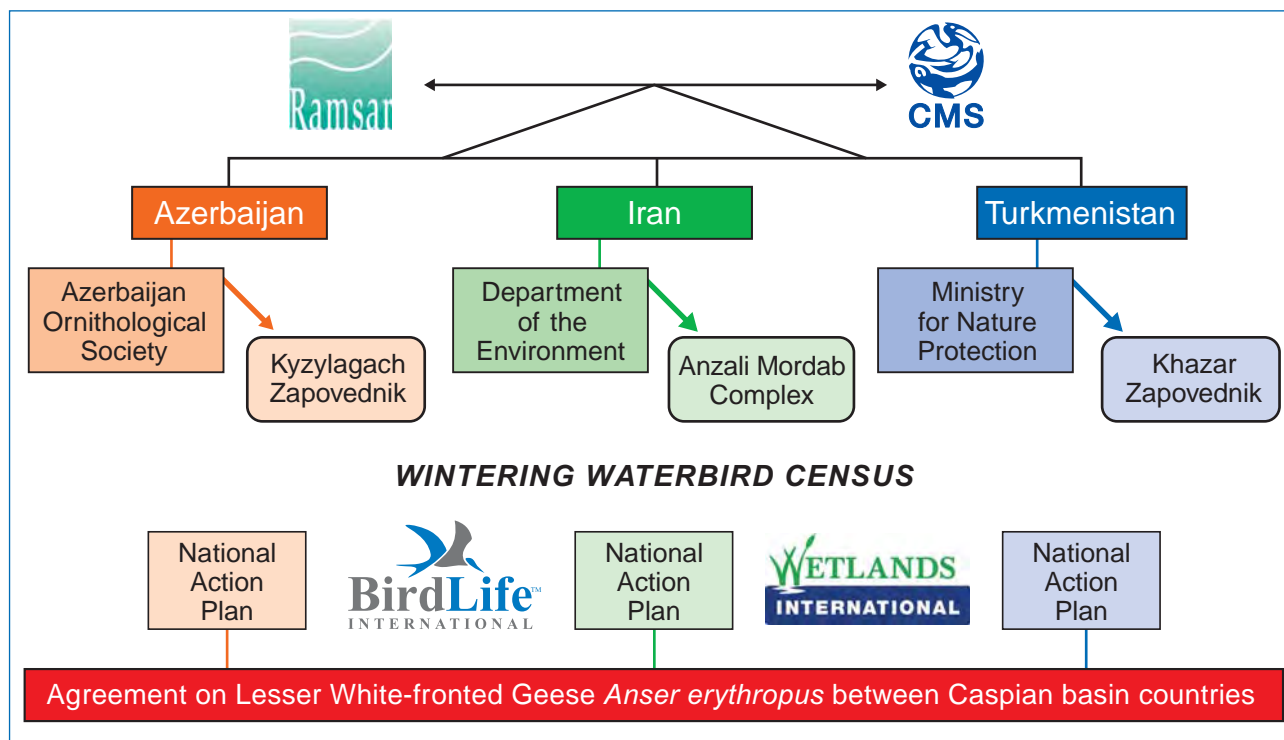

Fig. 2. Proposed model for integrated management of the Lesser White-fronted Goose *Anser erythropus* in the south Caspian region.

No strategy or action plan has yet been elaborated for the conservation of the species at regional level. In view of the present poor status of the Lesser White-fronted Goose in the region (e.g. erratic distribution, frequent movements between sites, low numbers and large fluctuations), we propose that the following measures be undertaken in Turkmenistan. These measures could be used in the future development of a strategy and action plan for the conservation of the species in the Caspian Sea region as a whole.

#### Improvement of national legislation, particularly hunting regulations

- Application of international instruments relevant to the conservation of wetlands and waterbirds, including the Ramsar Convention on Wetlands (Ramsar, 1971) and Framework Convention on the Protection of the Caspian Sea Marine Environment (Tehran, November 2003). Turkmenistan should ratify the Ramsar Convention and designate as its first Wetland of International Importance (Ramsar site) the wetlands in the State Khazarskiy Strictly Protected Area, which constitute one of the most important staging and wintering areas for the Lesser White-fronted Goose. These international instruments could be used for the protection of Lesser White-fronted Goose habitat.
- Revision of the National Hunting Regulations. The Lesser White-fronted Goose is included in the Turkmenistan Red Data Book (1995-1999), and hunting of the species is prohibited throughout Turkmenistan. However the species could easily be shot during the autumn-winter hunting season together with other grey geese (*Anser* spp.) because of the difficulties in identification and low level of hunters' awareness. The hunting of geese should be carefully controlled or prohibited in certain areas where the Lesser White-fronted Goose occurs in high numbers. Greater effort

should be made to control illegal hunting, and the penalties for hunting Lesser White-fronted Geese should be increased several fold.

#### Monitoring and conservation

- Continuation and expansion of the monitoring of Lesser White-fronted Geese during the migration and wintering periods in the south-east Caspian region, especially in Turkmenbashi, Balkhan, Mikhlailovski and Severo-Cheleken Bays, and in the Atrek Delta. The monitoring should include censuses of the population, mapping of habitat, and ringing.
- Preparation of a wetland inventory to document sites of known importance for the Lesser White-fronted Goose and to identify sites of potential importance.
- Establishment of a network of Important Bird Areas in the Caspian region, with the co-operation of BirdLife International. This network should aim to provide the optimal system of protected areas for the Lesser White-fronted Goose, and could help to raise the awareness of local communities.
- Elaboration of a National Action Plan for the conservation of the Lesser White-fronted Goose in Turkmenistan.

#### Education and awareness

- Raising awareness of the species' vulnerability. The Turkmenistan Society for Nature Protection should provide a programme of education in all settlements along the Caspian coast to raise awareness amongst local people, especially in Essenguly, Khazar, Turkmenbashi and Karabogaz.
- Providing education for hunters and raising their awareness through the Turkmenistan Society for Hunters and Fishermen, taking into account the recommendations of the Turkmenistan Ministry for Nature Protection.

- Drawing the attention of the central and local environmental organizations (government departments, NGOs and local societies) to the activities for raising awareness that are being undertaken within the framework of the UNDP-GEF Project on the sustainable use of the ecosystem in the State Khazarskiy Strictly Protected Area.
- Developing an action plan for the management of the principal habitats of the Lesser White-fronted Goose in the Turkmenistan sector of the Caspian Sea coast, to provide optimal management of protected areas as well as unprotected areas and hunting reserves.

We should like to stress that we are eager to co-operate in future investigations on the Lesser White-fronted Goose, not only in Turkmenistan, but also in Iran and Azerbaijan, with a

view to the elaboration of an integrated action plan for the international management of the migration routes, stopover sites and wintering areas of the Lesser White-fronted Goose in the south Caspian region. The main steps in the elaboration of such an action plan are shown in Fig. 2.

Mooij, J., Paulsch, A. & Scholze, W. 2006. Reintroduction of the Lesser White-fronted Goose *Anser erythropus* in Fennoscandia with the help of microlight aircraft. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 633-634.

The Lesser White-fronted Goose *Anser erythropus* is a monotypic species that formerly had a continuous distribution in the southern tundra between Lapland and Chukotka. Since the first population estimates of the 1950s, a drastic decrease in numbers was recorded from more than 100 000 to fewer than 27 000 birds in the 1990s. During the 1930s flocks of c. 50 000 Lesser Whitefronts were regularly recorded in the Western Palaearctic. During the 1950s the Western Palaearctic population was still estimated at more than 50 000 birds, but in the 1990s numbers recorded in this region during midwinter counts never exceeded 10 000 – 13 000.

Population numbers have decreased about 5% annually since the 1980's on most regularly monitored sites, and at present the wild Fennoscandian subpopulation is close to extinction. The reasons for this decline are changing conditions in stop-over and wintering sites, as well as hunting along migration routes in spite of the fact that hunting of the species is not permitted in most countries. The Lesser White-fronted Goose is included in Appendix 1 of the Bonn Convention, in Appendix II of the Bern Convention and in Annex I of the EC Directive on the Conservation of Wild birds. However, hunting of the quite similar looking Greater White-fronted Goose *Anser albifrons* causes high mortality of Lesser White-fronted Geese. Complete abandonment of hunting would be the best protection measure, but for at present this is not feasible.

The late Dr. Lambart von Essen started a re-introduction programme in Sweden in 1981. He avoided the main threats by creating a new safe migration route to safe wintering grounds using semi-domestic Barnacle Geese *Branta leucopsis* as foster parents for Lesser White-fronted goslings, which in this way learned to migrate to safe wintering grounds in Western Europe. With this programme von Essen showed that geese are imprinted on the area where they learned to fly and that young geese must be guided by their parents to the winter quarters. The Swedish re-introduction project founded the only expanding Lesser White-fronted Goose population worldwide. Today it consists of about 100-150 birds, all migrating to the Netherlands to winter. Although this project has been very successful, there are some genetic problems. Since 1991, a number of hybrids between Barnacle and Lesser-White fronted Geese were recorded in the range of the Swedish introduction scheme (Anderson & Larsson 2006).

The method of using microlight aircraft as foster parents was developed about a decade ago by Bill Lishman. Today it is an approved method used in Northern America, Europe and Asia, and already adopted for several endangered bird species, e.g. Whooping Crane *Grus americana*, Trumpeter Swan *Cygnus*

*buccinator*, Bald Ibis *Geronticus eremita* and Siberian Crane *Grus leucogeranus*.

Aktion Zwerggans and its Swedish and Finnish partners intend to re-introduce Lesser White-fronted Geese in Fennoscandia by means of the microlight method. Within a period of four years, it is planned to guide a total of about 400 genetically 'clean' Lesser White-fronted Geese from the former breeding areas in Fennoscandia along a western migratory route from Finnish Lapland via Sweden and Denmark to western Germany. In the selected wintering site wild Lesser White-fronts are observed wintering every year. Along the planned migratory route hunting of Greater White-fronted Geese is forbidden. A test flight in 1999 showed that the microlight method has high survival rates comparable to the Swedish Barnacle Goose method. Changing traditional migratory routes and wintering areas is not uncommon in wild goose species (for example Greater White-fronted Goose and Red-breasted Goose *Branta ruficollis* (Dereliev 2006) in the second half of the 20th century).

The microlight method seems to be very promising and, together with the Barnacle Geese foster parent method already used by the Swedish re-introduction project, will hopefully save the Fennoscandian Lesser White-fronted Geese from extinction. In addition, the re-introduction of young Lesser White-fronted Geese by microlight aircraft would exclude the risk of hybridisation with Barnacle Geese. Several conclusions may be drawn from this:

- In spite of all past measures, the local Fennoscandian subpopulation is decreasing by about 5% annually and will be halved in about 10 years. According to modern population genetics the critical size for small isolated populations is likely to be a few hundred individuals (Baker 2006). At present the population size is clearly below this level and the population has little chance to recover again without a strong input of new genetic material.
- Re-enforcement of the Fennoscandian subpopulation by 'genetic upgrading' through the re-introduction of Lesser White-fronted Geese from other breeding lines could help restore the viability of the population.
- The re-introduction of artificially bred Lesser White-fronted Geese of non-hybrid origin may be helpful in saving the Fennoscandian subpopulation from extinction.
- Re-introduced Lesser White-fronted Geese should be forced to adopt alternative migratory routes in a part of the range with low hunting pressure to reduce mortality rates.

- The Swedish method of re-introducing Lesser White-fronted Geese with the help of Barnacle Geese as foster parents is successful but carries a high risk of hybridisation between the two species. The re-introduction of young Lesser White-fronted Geese with the help of microlight aircraft has proved to be as successful as the Swedish method but excludes the risk of hybridisation.

Andersson, Å. & Larsson, T. 2006. Reintroduction of Lesser White-fronted Goose *Anser erythropus* in Swedish Lapland. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 635-636.

The Lesser White-fronted Goose *Anser erythropus* used to be a common breeding bird in the mountainous area of Swedish Lapland but by the late 1970s the Swedish, as well as the whole Fennoscandian, population had declined severely (Norderhaug & Norderhaug 1984, Lorentsen *et al.* 1999). Today, probably less than 5% of the original population remains in the region. The last known and fully verified breeding record of the original breeding population in Sweden is from 1989 (von Essen 1999), and in Finland breeding ceased during the 1990s, but a small population of about 30-45 pairs still breeds in Norway (Øien & Aarvak 2002). The main reasons for the decline are thought to have been hunting pressure and environmental changes in the southeastern wintering areas. In 1981 the Swedish Association for Hunting and Wildlife Management started to reintroduce the Lesser White-fronted Goose to a former breeding area in Swedish Lapland. The aim of this programme was to establish a new population which would migrate to safer and better wintering areas.

A captive stock of Lesser White-fronted Goose has been kept at Öster Malma Wildlife Management School in central Sweden where, just before fledging, young birds are reared and released in Swedish Lapland with Barnacle Geese *Branta leucopsis* as foster parents (von Essen 1996). The goslings are imprinted on the release area and are guided by their foster parents to winter quarters in The Netherlands. In spring, the immature Lesser

White-fronted Geese accompany the Barnacle Geese to central Sweden and then continue alone to the area in Lapland where they were released. All released goslings are individually ringed with leg rings and an observation network has been organized to study migration routes, return rate and breeding success.

During 1981 – 1999, a total of 301 goslings and 47 one-to-two year old geese were released in a well-known former breeding area in the mountainous area of Swedish Lapland. More than 47 breeding attempts have resulted in fledged young (Fig. 1). During the last five years at least 29 broods with a total of 83 immature birds have been recorded in early autumn. The size of the reintroduced population was estimated to be about 100 birds in autumn 2003.

The introduced Lesser White-fronted Geese use the area around Hudiksvall in central Sweden as a stopover site during both spring and autumn, with some geese also moulting there. The Hjälstaviken Ramsar site, in central Sweden, is used by some geese especially during autumn, but few families show up there. There is no other known regularly used autumn stopover site between Hudiksvall and the North Sea coast of Germany and the Netherlands, indicating that at least some geese make this journey as a non-stop flight. The established geese stay in coastal areas in The Netherlands during winter, where in recent years 60-80 birds have been regularly reported.

Genetic investigations on Lesser White-fronted Geese have confirmed that some of the birds in the Öster Malma stock were contaminated with genes from White-fronted Goose *Anser albifrons* (Tegelström *et al.* 2001). Pending the outcome of genetic studies, the release of birds in Lapland has been temporarily stopped and captive birds found to carry genes from White-fronted Goose have been destroyed. Efforts are now being made to recreate a breeding stock in captivity founded on wild young.

The project is run by the Swedish Association for Hunting and Wildlife Management in cooperation with the Swedish Environmental Protection Agency, WWF-Sweden and Sveriges Vildnad. It is also supported by The Swedish Wetland Fund, Alvin Fund and Göran Gustafsson Foundation.

Fox, A.D., Walsh, A.J., Norriss, D.W., Wilson, H.J., Stroud, D.A. & Francis, I.S. 2006. Twenty-five years of population monitoring – the rise and fall of the Greenland White-fronted Goose *Anser albifrons flavirostris*. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 637-639.

This paper describes changes in the populations of the White-fronted Goose during the past 25 years, discusses possible reasons for these and suggests courses of action required now.

The Greenland White-fronted Goose *Anser albifrons flavirostris* breeds in west Greenland and migrates through Iceland to winter exclusively in Britain and Ireland. It is the most morphologically and geographically distinct sub-species of the circumpolar White-fronted Goose *Anser albifrons* (Ely *et al.* 2005). The global population declined from 17 500-23 000 in the 1950s to 14 300-16 600 in the late 1970s (Ruttledge & Ogilvie 1979), when it was protected from hunting and many of the sites supporting internationally important concentrations were given statutory protection (Stroud 1992, 1993). Subsequently the population recovered, and at the major Irish wintering site at least, the expansion in numbers fitted that modelled on the assumption of completely additive mortality during the previous period of hunting (Fox 2003).

Under protection measures, and helped by a series of good breeding seasons, the Greenland White-fronted Goose increased from 17 000 in 1982/3 to 35 500 in 1998/9. However, in the subsequent years, numbers have fallen dramatically to less than 27 000 in 2001/2, a 25% decline in three years

**Fig. 1.** Total population estimates for the Greenland White-fronted Goose based on literature sources in the 1950s and late 1970s (upper and lower levels shown as lines), and based on total spring counts of all known haunts since winter 1982/1983 (filled squares). Note the value for 2001 is estimated because of the Foot and Mouth epidemic that year. Annual spring counts are shown for the two most important wintering resorts, Wexford Slobs (filled circles, southeast Ireland) and Islay (open circles, Inner Hebrides, Scotland).

**Fig. 2.** Trends in reproductive output amongst Greenland White-fronted Geese at Wexford (triangles) and Islay (squares) based on sampled age ratios of juvenile geese. Data are presented for the period prior to (open symbols) and post-protection from hunting on the wintering grounds (filled symbols). Broken horizontal line shows the long term overall average. The declines since protection are statistically significant at Wexford (solid regression model line), but not on Islay (dotted line).

(Fig. 1). Because the population is closed and the annual population census covers all known wintering resorts, the change cannot be the result of changes in immigration or emigration, and must result from changes in birth or death rates. Evidence from survival estimates based on resightings of collared individuals suggest no major changes since protection in 1982/3, a conclusion supported by the results of population modelling based on counts at the two major resorts, Islay (Inner Hebrides, Scotland) and Wexford (southeast Ireland, see Fox 2003). However, the proportion of young returning to winter at Islay and Wexford shows declining trends since protection (Fig. 2). Evidence from detailed observations of collared birds at Wexford shows that known aged birds have shown an increased delay in the age of first breeding, and that an increasingly small proportion (<5%) of all goslings surviving their first winter survive to ever breed at all (Fox 2003). The recent decline in numbers is due to the failure to replace annual losses that have not changed substantially over a period of decades, and may be explained by a sustained decline in reproductive output rather than a small increase in mortality, although the causes for this long-term decline remain unknown.

Declines in breeding success are ultimately due to extrinsic factors such as changes in nest predation rate or intrinsic factors to do with female body condition. There is no evidence for any change in nest predation rate in west Greenland, and it seems unlikely that such a change would occur synchronously throughout such an extended latitudinal range. Factors affecting the ability of females to attain breeding condition could potentially act on geese during their period on the wintering grounds, spring staging or breeding areas. Several potential factors could act at each point in the life cycle: (i) increases in local density, (ii) climate change and (iii) habitat change.

On the wintering grounds, analysis shows no consistent evidence for density dependent decreases in reproduction at the site level and no general evidence of effects of climate change. There is evidence that flocks wintering on intensively managed farmland have higher breeding success than those using bogland and semi-natural habitats, suggesting shifts from traditional habitats in the last 30 years have been associated with increased, not decreased, reproductive success (Fox *et al.* 2005).

On the spring staging areas and breeding areas, there is little evidence for climate or habitat change affecting breeding success (A.D. Fox *et al.* unpublished data). There are no obvious consistent effects of density dependence in breeding success detectable at the population level amongst Greenland White-fronted Geese (A.D. Fox *et al.* unpublished data). It therefore seems likely that some other factor, perhaps operating directly on the breeding grounds, may be responsible for the long-term decline in breeding success.

The population of Canada Geese *Branta canadensis interior* that breeds in northern Quebec and winters in the eastern United States has colonised west Greenland in the last 20 years, an expansion confirmed by satellite telemetry, ringing recoveries, resightings and DNA analysis (Fox *et al.* 1996, Kristiansen *et al.* 1999, Scribner *et al.* 2003). Studies of interactions between Canada Geese and Greenland White-fronted Geese on the summer areas show the behavioural dominance of Canada Geese, at least during the flightless moult, which results in local displacement of White-fronted Geese (Kristiansen & Jarrett 2002). Extensive aerial survey of the west Greenland breeding grounds showed that in spite of favouring the same geographical region, the two species were less likely to occur together than expected by chance, suggesting some segregation at large spatial scales (Malecki *et al.* 1999). However, more detailed studies and extensive surveys are required to determine whether this is the major factor involved in depressing breeding success in Greenland White-fronted Geese, and repeat aerial surveys of the breeding grounds will be carried out during the summer of 2005 to confirm changes in the local abundance and summer distribution of both species over the last six years.

In conclusion, while there are several explanations for the recent decline in Greenland White-fronted Goose productivity, the most likely would seem to be the interactions on the breeding areas with the increasing numbers of Canada Geese that are appearing in west Greenland from North America (Fox *et al.* 2006). However, we really require some detailed studies of the breeding biology of the two species in sympatry and allopatry before we can conclude cause and effect.

The Greenland White-fronted Goose has adapted to novel feeding opportunities presented by rapid changes in grassland management and modern agriculture in Iceland and on the

wintering areas, apparently enabling the population to adjust to the massive changes in the extent and quality of its natural peatland and wetland habitats that have occurred since 1940 (Fox *et al.* 2005). In addition, protection from hunting permitted its increase during the 1980s and 1990s. It is therefore somewhat ironic that changes in another hemisphere (agricultural improvement during the last century and hunting regulation since the 1990s in North America) have encouraged the expansion in numbers of another similar sized goose, *B. c. interior*, to the point where that population has colonised West Greenland. This extension of range may have now affected the reproductive success, and hence the population size, of another goose species wintering on the western fringe of Europe (Fox *et al.* 2006).

Canada Geese have become legal quarry in Greenland since spring 2004. Whilst there is no doubt that such exploitation may reduce their numbers locally, this will not solve the problem of declining reproductive success amongst Greenland White-fronted Geese. Care must also be taken to avoid increasing the kill of Whitefronts in West Greenland. The Greenland White-fronted Goose remains a quarry species in Greenland (where only a few hundred are thought killed each year because of their inaccessibility) and in Iceland, where the bag has shown a significant increase from 2 947 in 1996 to 3 685 in 2001 (data from the Icelandic Wildlife Management Institute). This increase, coincident with the decline in global population size, means that the Iceland hunting kill has risen from 8% to 12%, and now contributes a significant, and increasing, element of overall annual mortality. Whilst it is clear that the autumn hunt in Greenland and Iceland was sustainable during the period of population expansion of the 1980s and 1990s, the present level of kill cannot assist in returning the population to favourable conservation status. Furthermore, while the cessation of the autumn hunt cannot halt the current decline in the overall population, it is one tangible conservation action that will contribute to the slowing of the rate of decrease in numbers. In June 2006, the Icelandic government announced protection of Greenland White-fronted Geese, effective from autumn 2006. This is a most valuable contribution to the conservation of the population.

It is important that the management plan (Stroud 1992, 1993), drafted and agreed for this population in Wexford, Ireland in 1992 but never formally signed by the Range States (Ireland, United Kingdom, Iceland and Greenland), be reconvened and updated to establish research and monitoring priorities for action (Fox *et al.* 2006). Failing this, bilateral agreements between range states should be concluded. Actions must be targeted to secure the population for the future to ensure that the international investment in the protection of the population that occurred in the 1980s and 1990s was not in vain.

Glahder, C.M. & Walsh, A.J. 2006. Experimental disturbance of moulting Greenland White-fronted Geese *Anser albifrons flavirostris*. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 640.

Undisturbed wetlands are vital to waterfowl during their wing moult. In many Arctic goose populations, immature and non-breeding birds migrate to remote areas that contain both refuge lakes, safe from predators, and adequate food supplies for the moulting period. In West Greenland, even the most remote areas are today affected by many different human activities during summer. Moulting areas can be disturbed by mineral exploration (2.5–14.6% of ice-free land covered by licences in the 1990s), by hunters, their numbers increased 70% from 1994 to 2002, who now have the ability to reach most coastal areas in their motor-boats (20-fold increase since 1939), and by tourists (e.g. cruise liners have doubled over the last decade). In order to advise Greenland authorities, the aim of this study was to assess the behavioural and spatial response of moulting geese flocks to human intrusion.

Human disturbance was deliberately made to Greenland White-fronted Geese *Anser albifrons flavirostris* moulting on the Naternaq plain in central West Greenland. This Ramsar site holds about 10% of the total population of the Greenland White-fronted Goose (25–30 000). The study was carried out in July 1999 and 2000 in a 75 km<sup>2</sup> lowland tundra area dotted with lakes (68°18'N, 55°55'W). The hypothesis was that moulting geese would react to an intruding person in a similar way to their reaction to an attacking Arctic Fox *Alopex lagopus*: the geese would flee to a refuge lake and stay there until the intruder had disappeared, then normal behaviour would be resumed after a relatively short period. Prior to experimental disturbance, behaviour and distribution patterns of goose flocks were observed during one third of the moulting period (total c. 25 days). Goose flocks used lake systems of on average 4.4 lakes (SD=2.3, n=23) where distances between lakes were on average 52.9 m (SD=58.8, n=107). According to goose dropping counts, a strip no more than c. 20 m from lake shores was used for feeding and resting. There was a linear relationship between available feeding habitat and the number of moulting geese present at a lake ( $y = 5.96x - 3.56$ ,  $df = 147$ ,  $R^2 = 0.74$ ,  $P < 0.001$ ). This suggests that the food resource determines the number of moulting geese. The minimum feeding habitat that held geese was c. 2.3 ha. Furthermore, the distance from the nearest lake affected the presence of goose flocks: the shorter the distance the higher the likelihood of goose presence. A logistic regression model including feeding habitat and distance to nearest lake as variables, gave a highly significant description of the probability of a moulting goose flock to use a lake (Likelihood ratio  $G^2 = 37.89$ ,  $df = 2$ ,  $P < 0.0001$ ). From these analyses, it appears that the study area supports 70–75% of optimal goose numbers, indicating that few potential sites were vacant.

When a person disturbed the geese by walking straight towards a flock, it became alert at an average distance of 653 m

(SD=263, n=14) and fled at a significantly shorter distance of 448 m (SD=155, n=14). Fleeing flocks continued running and swimming for on average 26 minutes (SD=15, n=16) and traversed 1.1 km (SD=0.6, n=16). Moulting habitats from where geese were disturbed were either reoccupied (average period without moulting geese 3.2 days (SD=1.0, n=9)) or not reoccupied during the moulting period (average period 6.3 days (SD=3.4, n=7)). On average, the vacant period lasted for 4.6 days (SD=2.7, n=16) or about 20% of the moulting period. The observed disturbance reactions can impact the geese by (i) reducing their feeding ability because undisturbed habitats are likely to be occupied or not suitable, (ii) causing energy loss of a minimum of 5% of daily energy intake (one incident) due to prolonged running and swimming, and (iii) exposing them to Arctic Fox attacks during fleeing, returning and within inadequate habitats.

Simulations of a person traversing 10 randomly chosen transect lines (width 1 km) through the study area were made. On average 10.4% (SD=10) of all lakes in the study area holding geese were disturbed.

The disturbance effect of one intruding person was much more profound than hypothesised, since the period where geese were affected was measured in days and not in minutes or hours. About half of the moulting habitats stayed vacant for 10–15% of the moulting period, while remaining habitats where flocks were disturbed were unoccupied for the rest of the moulting period. Fleeing geese were not likely to find other adequate moulting habitats because a high proportion were already occupied.

The wetlands of Naternaq Ramsar site hold about 10% of the world population of Greenland White-fronted Goose *Anser albifrons flavirostris*. Photo: David Stroud.

## 5.2 Declining waterbirds: problems, processes and sites. Workshop Introduction

David A. Stroud

Joint Nature Conservation Committee, Monkstone House, City Road, Peterborough, PE1 1JY, UK. (email: DavidStroud@jncc.gov.uk)

Stroud, D.A. 2006. Declining waterbirds: problems, processes and sites. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 641-642.

The globally threatened Spoon-billed Sandpiper *Eurynorhynchus pygmeus* is in rapid decline for reasons that are not understood. The destruction and degradation of key sites on its East Asian flyway, especially in the Yellow Sea, will further impact on the species. Photo: Christoph Zöckler.

The status of many waterbird populations is poor, with major declines reported for many taxa, in many parts of the world as reported by many studies throughout this volume. Habitat loss and degradation remains the principle driver for these declines, although many other factors are significant, including the impact of over-exploitation as noted for geese by Syroechkovskiy in East Asia. For long-distant migrants, the ecological quality of major staging areas appears to be of key importance in sustaining populations. This has been noted especially for long-distance migrant waders (e.g. Barter, Syroechkovskiy and Stroud *et al.*).

The workshop reviewed the status of waterbirds and explored the processes underlying current observed declines. In particular, it considered issues at a number of 'mega-sites' which have been implicated as causes of declines of migrant waterbirds in those areas.

Whilst much conservation attention has been focused on the needs of migratory species — the subject of several international legal instruments concerning their conservation — a high proportion of globally or near threatened waterbird species are sedentary. Some of these species are much more poorly known and have a significantly worse conservation status than migrants. Evaluation

of their current status suggests these species should receive urgent priority conservation attention, especially in light of the absence of international structures (such as, for example, the Convention on Migratory Species) to promote their conservation.

Of particular conservation concern is the declining environmental status of several key staging areas (such as inter-tidal wetlands of the Yellow Sea described by Barter), which provide energetic spring-boards for long-distance migrants. The degradation of these areas compromises the status of many migrant waders and other waterbirds. The rapid collapse of populations, forced below threshold levels, has been predicted theoretically, and now appears to be occurring in a number of rapidly declining populations. Baker describes the genetic and ecological consequences of small population sizes in waders — issues of significance to other waterbird taxa also.

Conservation responses must urgently address causes of wetland loss and degradation, as well as enhancing monitoring and research so as better to inform appropriate conservation policies. National and international strategies and conservation instruments have scope to help, but need to be much more strategic in their implementation so as to address root causes.

The completion of the 33 km seawall at Saemangeum in South Korea will destroy 40 100 ha of tidal-flat and shallows - an estuarine system which on present knowledge is the most important wader site in the whole of the Yellow Sea, supporting internationally important numbers of at least 17 species of waders (including several globally threatened species). Photo: Mark Barter.

A range of actions are desirable:

- There is urgent need for more and better population monitoring. As a minimum, adequately funded national monitoring programmes are required. The International Waterbird Census co-ordinated by Wetlands International offers an effective framework within which such monitoring can be organised.
- Internationally co-ordinated programmes should be developed to assess waterbird productivity and survival. This information would aid in the development of more focussed and cost-effective conservation responses. Interpretation of

multiple information sources and especially spatial data is greatly helped by Geographic Information Systems.

- The application of IUCN Red-list criteria at subspecies/population level should be encouraged to highlight the conservation status of individual biogeographic populations. This information is especially valuable in the context of listings under various international treaties.
- Further comparative analyses, using existing data and information, of waterbird status in different regions and flyways should be undertaken.
- The status of waterbirds worldwide should continue to be reviewed with the aim of continuing to provide technical advice to international conventions and other organisations as to those populations which should receive major attention with respect to their conservation, monitoring and research.

World leaders at the World Summit on Sustainable Development, Johannesburg, in 2002, established a target of “a significant reduction in the current rate of loss of biological diversity” by 2010. The declines reported in from all over the world suggest that, for many groups of waterbirds, it will be extremely challenging to achieve these targets without major changes to economic processes and the attitudes of society.

World leaders noted that to achieve this target “will require the provision of new and additional financial and technical resources to developing countries”. It was noted also that at a minimum, significantly greater investment is urgently needed not only in developing countries, but also in developed nations. This is required to establish and maintain national monitoring schemes, as well as to understand the causes of population declines so that appropriate, targeted conservation responses may be made.

The rapid collapse of waterbird populations has been predicted theoretically and now appears to be occurring in a number of rapidly declining populations, including that of the Nearctic Red Knot *Calidris canutus rufa*. Photo: Rob Robinson.

## The conservation and population status of the world's waders at the turn of the millennium

Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 643-648.

### ABSTRACT

Using information from many sources, but especially data collated for the third edition of Wetlands International's *Waterbird Population Estimates*, we review the status of the world's waders in the late 1990s. There are widespread declines in most regions and biotopes caused principally by loss and degradation of wetland (and other) habitats. On different flyways, between 33% and 68% of populations are in decline, compared with only 0% to 29% increasing. Non-migratory, island species have especially poor status, with about half of all island waders being globally threatened with extinction. Of particular conservation concern is the declining environmental status of several key staging areas, which provide energetic 'spring-boards' for long-distance migrants. The degradation of these areas compromises the status of many migrant waders. The rapid collapse of populations, forced below threshold levels, has been predicted theoretically, and now appears to be occurring in a number of rapidly declining populations. Conservation responses must urgently address causes of wetland loss and degradation, as well as enhancing monitoring and research so as better to inform appropriate conservation policies. National and international strategies and conservation instruments have scope to help, but need to be much more strategic in their implementation so as to address root causes.

### INTRODUCTION

Other than in Antarctica, waders (or shorebirds) occur on nearly every shoreline of the world, as well as in many other biotopes. They are attractive birds, of economic and ecological importance, and accordingly in some parts of the world are well-studied. For some migratory waders, very large numbers occur at low densities over extensive breeding areas, but gather at much higher densities in the non-breeding season at a few localities, enabling their population status to be regularly assessed. They are thus amongst the better known groups of birds, and with their range of specialized feeding and migration ecologies, they are sensitive environmental indicators. Information on their international population status can accordingly be used to indicate the wider health of their environments: indeed, the task of ensuring the favourable conservation status of waders is inseparable from that of ensuring the conservation and wise use of their wetland and other habitats. Regrettably however, the loss and degradation of wetlands and other habitats continue apace all around the world (Millennium Ecosystem Assessment 2005), and are the underlying cause of the poor conservation status of so many species. Habitat changes have complex ecological, demographic and genetic consequences for waders.

In 2003, a conference of the International Wader Study Group (WSG) in Cádiz, Spain, brought together 132 specialists from 20 countries to review the population and conservation status of waders around the world. The global status of waders was assessed using the best available data, drawing on several major programmes that have compiled recent data, e.g. Dodman (in review 2002) and Thorup (2002), and summaries by Wetlands International (2002) and Zöckler *et al.* (2003). In particular, a major WSG review of the status of waders in Africa and Western Eurasia collated extensive new data (Stroud *et al.* 2004).

### RESULTS AND DISCUSSION

Following the taxonomy adopted by Wetlands International (2002), the scope of this review covers 511 populations of 214 species of waders in eleven families (Rostratulidae, Dromadidae, Haematopodidae, Ibidorhynchidae, Recurvirostridae, Burhinidae, Glareolidae, Charadriidae, Scolopacidae, Pedionomidae and Thinocoridae). Three of these species (and populations) are extinct; of the other 508 populations, trends are available for only 210.

Around the world, most populations of waders of known population trend are declining (Table 1) – a matter of international conservation concern. On different flyways, between 33% and 68% are in decline (overall 48%), compared with only 0-29% increasing (overall 16%): thus three times as many populations are in decline as are increasing. The reasons for these declines are diverse, although they are generally caused by habitat loss or degradation (Zöckler *et al.* 2003).

### Flyways in Western Eurasia and Africa

Comparisons between the three main wader flyway systems in Western Eurasia and Africa show that knowledge is better for populations using the largely coastal East Atlantic Flyway than for the other two: it has been possible to assess trends for 44 (93%) of East Atlantic Flyway populations, but for only 25 (76%) of the Black Sea/Mediterranean populations and for just 18 (35%) of West Asian/East African wader populations (Table 1; Stroud *et al.* 2004). Overall, the East Atlantic Flyway appears in the healthiest state: only a little over one-third (37%) of populations are decreasing. This is in contrast to the Black Sea/Mediterranean Flyway where, of populations with known trends, 65% are declining, and the West Asian/East African Flyway which has 53% of known populations in decline. Island populations – specifically those on the Canary and Cape Verde Islands, St. Helena and Madagascar – have a particularly poor conservation status and include most of the region's globally threatened species.

**Table 1.** Status of the world's waders at the turn of the millennium. Data summarized from Wetlands International (2002). Figures include both migratory and sedentary species and populations.

<sup>1</sup> Some species or populations may occur in more than one Ramsar region.

<sup>2</sup> Including extinct species.

<sup>3</sup> There is an urgent need to update formal IUCN Red-listings for Neotropical waders as a number of species are clearly of this status but are not currently categorised as such.

<sup>4</sup> Totals also included in Ramsar Regions; some populations occur on more than one of the flyways.

<sup>5</sup> Comparable information is not yet available for the following flyways: Pacific North America, Central North America, Mississippi, Atlantic North America – given the apparently major overlaps south of the breeding areas, data for these flyways are combined in the “North America/inter-continental” flyway category.

<sup>6</sup> Excludes Australian, New Zealand and associated island endemic populations.

<sup>7</sup> Australian, New Zealand and associated island endemic populations.

<sup>8</sup> Excludes New Zealand and associated island endemic populations.

Comparison with the status of 66 populations in the 1980s (Smit & Piersma 1989) indicates that more populations are in long-term decline (13) than are either stable (eight), or in long-term increase (four). Some populations are severely threatened and in decline, and extremely rapid population declines (>50% since the mid-1980s) have been recorded for four populations: the two populations of Sociable Lapwing *Vanellus gregarius*, the single population of Black-winged Pratincole *Glareola nordmanni*, and the western European breeding population of Black-tailed Godwit *Limosa limosa limosa*. None of Africa's globally threatened waders are increasing their small population sizes.

**Central and South Asian Flyway**

This is shortest of the world's wader flyways, lying entirely in the Northern Hemisphere. It is also one of the most poorly known, with a high proportion of its wader populations being unknown in either size or population trend (80% of populations; Davidson 2003a). Furthermore, nearly all existing estimates are over ten years old, meaning that contemporary knowledge of the waders in this part of the world is almost unknown. Nonetheless, the best available information indicates that about twice as many wader populations are declining as are increasing. There is an urgent need both to assess recent data for this flyway and to improve processes of basic data gathering and analysis.

There are five globally threatened waders in the flyway; the populations of four are in active decline, whilst the current status of the remaining species is unknown. A further six small populations

have unknown status, and at least one of the species concerned, the Long-billed Plover *Charadrius placidus*, clearly qualifies for IUCN Red-listing. The proposed establishment of a Central Asian Flyway Agreement under the Convention on the Conservation of Migratory Species of Wild Animals (CMS) is a welcome step forward towards better understanding and conservation of waders on this flyway, but the scale and range of issues indicate that it will need to be highly strategic in its operation to have positive impacts.

**East Asian and Australasian Flyway**

There are enormous human population pressures in this region which contains over a third of the world's human population as well as some of the world's fastest growing economies (Wilson 2003). This has major direct consequences for waders: over 80% of wetlands in east and south-east Asia are classified as threatened, with over half under serious threat. Of inter-tidal wetlands in South Korea, 43% have been destroyed by land-claim (with more underway), as also have 37% of inter-tidal wetlands on China's coastline (e.g. Barter 2002).

The East Asian/Australasian Flyway is the flyway with the highest number of wader populations and also the highest proportion of populations for which information on numbers and trends is lacking (85% of populations – see Table 1). For populations of known trend on this flyway, 82% are declining and only 9% increasing. The status of Australasian<sup>1</sup> endemic populations is better known (49% with unknown trend), and equal numbers (38%) are declining and increasing.

<sup>1</sup> Australia, New Zealand and its associated islands

Asia and Oceania between them hold 29 globally threatened and near threatened species – 69% of all such waders globally. Of the 12 globally threatened species on the East Asian/Australasian Flyway, one is possibly extinct, six are actively declining (including the Spoon-billed Sandpiper *Eurynorhynchus pygmeus*, which appears to be undergoing rapid population collapse; Tomkovich *et al.* 2002), and the status of the remaining five is unknown. None is recovering its status. The development of non-binding international mechanisms (APMWCS 2001) for conservation and monitoring is a welcome step forward, although there are huge challenges to secure the conservation of wetlands of global significance to waders so as to reverse current negative trends. This is especially so, given the intense socio-economic pressures within the region.

### Central Pacific Flyway

The region contains relatively few waders, but these are mostly small populations with poor conservation status (Gill *et al.* 2003), and there are more Critically Threatened and Endangered waders here than in any other part of the world. Excluding species endemic to New Zealand and its associated islands (which for the purposes of this paper are included in the East Asian/Australasian Flyway), 40% of populations are declining and none is increasing.

Whilst conservation actions have been taken for a few endemic species, the status of many other endemic and migratory species and populations is poorly known throughout this flyway. For endemic species, knowledge is better for species occurring in New Zealand and Australia than in the central and south Pacific (e.g. for species such as the Tuamotu Sandpiper *Prosobonia cancellata*).

Given the small population sizes and declines, there is an urgent need for greater conservation attention for endemic and especially migrant waders in the central Pacific. Limited conservation “capacity” of many Pacific island states and other nations’ overseas territories in the region is currently a significant constraint on reversing the unfavourable conservation status of many Pacific waders.

### North America (including inter-continental migrants)

Migrant waders use four main flyway systems in North America (Pacific, Central, Mississippi and Atlantic: Morrison 2003), with most migrants overwintering in Central and South America. There are six globally threatened and near threatened species: one of these, the Eskimo Curlew *Numenius borealis*, is probably extinct, and four of the five remaining tiny populations may still be in decline.

Population trend analyses have indicated extensive declines in wader populations in many parts of North America, especially in Atlantic areas of the USA and Canada (Morrison *et al.* 2001). Overall, 52% of populations using the North American flyways are in decline, and only 6% are increasing. These widespread declines, which include alarming examples such as the recent extremely rapid decline of the Red Knot *Calidris canutus rufa*, indicate that conservation concerns and actions around the world must be extended to include species that are not currently listed as “at risk”. Completion of Shorebird Conservation Plans in Canada (Donaldson *et al.* 2000) and the USA (Brown *et al.* 2001) are welcome national initiatives which have the potential to address the major issues, but it remains to be seen if they will be

adequately funded by governments. As yet, their implementation seems not to have led to improved population status of waders.

### South America (residents and intra-continental migrants)

None of the resident waders or intra-continental migrants in South America is currently recognized as globally threatened, and there are only four near threatened species. There is, however, an urgent need to update the IUCN Red List for South America to better reflect the current situation (González & Blanco 2003). South America also supports a significant number of endemic species and one endemic family of waders, the seedsnipes (Thinocoridae).

There is very poor knowledge of the population sizes and trends of South American waders, with this information lacking for 64% of all populations occurring only within South America (compared with only 31% of North American migrants). Of populations with known trend, 40% are declining and only 13% are increasing.

There is a major lack of funding for basic survey and population monitoring. This is especially the case for Neotropical migrant and resident waders, since international sources of funding are not readily available for monitoring, research and conservation.

## CONCLUSIONS

### The importance of staging sites for long-distance migrants

Long-distance migrant waders are highly dependent on the continued existence, in favourable conservation status, of a few key staging areas – the essential “stepping stones” to more northerly breeding areas. The importance of maintaining the ecological character of these vital places has been repeatedly stressed: what happens on staging areas such as the Wadden Sea in Europe, Delaware Bay in North America, the Yellow Sea in Asia and the Banc d’Arguin in Africa, seems to control much of the rest of the annual cycle – and survival – of these waders (e.g. Ens *et al.* 1990, Piersma 1994, van de Kam *et al.* 2004).

Declining food resources and reduced suitability of staging sites have major implications for the survival and reproduction of these migrants (Davidson 2003b). “Virtual habitat loss” can occur in these areas as a consequence of poor management arising from unsustainable exploitation of natural resources, disturbance and other local perturbations. This leads to damage to the ecological character of these wetlands with major consequences for their ability to continue to support waders.

### Loss of key staging areas

Major conservation issues currently face three internationally important coastal wetlands of critical importance to migratory waders:

- The completion of the 33 km seawall at Saemangeum in South Korea will destroy 40 100 ha of tidal-flat and shallows – an estuarine system which, on present knowledge, is the most important site for waders in the whole of the Yellow Sea, supporting internationally important numbers of at least 17 species of waders, including several globally threatened species. The Yellow Sea is itself by far the most important staging area on the East Asian/Australasian Flyway, hosting

**Table 2.** Conservation status of wader populations occurring on islands compared to continental land masses. Species status from BirdLife International (2000).

	Total no. of wader populations	Total no. of wader populations not Red Listed	Total no. of wader populations Red Listed	IUCN Red List Status					
				Extinct	Critical	Endangered	Vulnerable	Near Threatened	Data Deficient
Island populations	53	27	26	3	2	4	6	11	0
		51%	49%	6%	4%	8%	11%	21%	0.0%
Continental populations	458	425	33	0	3	2	9	18	1
		92.8%	7.2%	0.0%	0.7%	0.4%	2.0%	3.9%	0.2%

at least two million waders of 36 species during northward migration (Barter 2002). At least 25 000 people also depend economically on this wetland system, for fishing and shell-fishing.

- Delaware Bay is a critically important spring staging area in eastern North America. Over-exploitation by humans of food resources used by waders may now be affecting the ability of waders using this site to reach their Arctic breeding areas and to breed there successfully. This appears to be leading to drastic and rapid population declines in some species, especially the Red Knot *Calidris canutus rufa*.
- In the Dutch part of the international Wadden Sea, there is now compelling scientific evidence to indicate that unsustainable levels of industrial shell-fishing have led to redistribution of birds from the high quality feeding areas (e.g. Piersma & Koolhaas 1997, Piersma *et al.* 2001, van de Kam *et al.* 2004). Declines of the biogeographical populations of long-distance migrant waders most heavily dependent on the Wadden Sea have occurred and are continuing (Davidson 2003b). However, recent decisions in the European Court over the legality of the shell-fishery in relation to the nature conservation directives of the European Union mean that this over-exploitation has now ceased.
- The Banc d'Arguin National Park in Mauritania is a major wintering area for waders on the East Atlantic Flyway, yet fishing on an industrial scale by international fleets in the waters just outside the park is depleting fish resources and possibly impacting on the wider ecosystem.

### Agricultural intensification

Intensification of agriculture is a major driver of change to wetlands (Millennium Ecosystem Assessment 2005) and remains a major adverse factor affecting the status of waders not only in western Europe, with its long-established agricultural landscapes, but also in other regions such as eastern Europe and central Asia, where natural steppe landscapes have now been replaced by arable cultivation and other forms of agriculture. In North and South America, loss of natural habitats to agriculture is also of significant concern.

### Climate change

The ecological consequences of changing climate will be complex, but effects such as altered distributions already appear to be occurring (Rehfishch *et al.* 2004). Changed climate patterns, such as increased desertification of continental steppe regions, will exacerbate habitat loss and degradation.

### Status of short-distance, intra-continental migrants

Short-distance, intra-continental migrants have generally been afforded less attention than inter-continental migrants. In South America, Asia and Africa especially, there is a severe lack of information on intra-continental migrant waders (González & Blanco 2003, Stroud *et al.* 2004). For migrant waders which move long distances between rich and poor countries, there are several international mechanisms that fund research and conservation initiatives. However, for those species which move solely between southern, developing countries, there are few such international funding opportunities. This constrains essential monitoring and conservation activity.

### Status of non-migratory waders

Whilst much conservation attention has, correctly, been focused on the needs of migratory species – the subject of several international legal instruments concerning their conservation – about two-thirds (60%) of globally or near threatened wader species are sedentary. Some of these species are much more poorly known and have a significantly worse conservation status than migrants. Evaluation of their current status suggests that these species should receive urgent attention, especially in light of the absence of international structures to promote their conservation.

Many of the world's rarest and most threatened waders occur on islands (Table 2). About half of all island waders are globally threatened (compared to just 7% of populations occurring in continental areas), and these comprise a significant proportion of all globally threatened waders (Table 2). The conservation challenges faced by independent island nations and self-governing overseas territories of other nations are many, and there is often limited human capacity to address these. International organizations and conventions should assist these islands to develop appropriate conservation programmes as a matter of priority.

### Monitoring and research

There is urgent need for more and better population monitoring. As a minimum, adequately funded national monitoring programmes are required. The International Waterbird Census co-ordinated by Wetlands International offers an effective framework within which such monitoring can be organized. Monitoring might be most effectively undertaken through targeted enhancements focused on particular populations, especially those associated with certain geographic regions or habitats.

Characteristics of the population dynamics of waders, especially the larger species, are such that under certain circum-

stances, very rapid population “collapses” occur. Examples include the probably extinct Eskimo Curlew, the *rufa* population of Red Knot, and the globally threatened Slender-billed Curlew *Numenius tenuirostris*, Sociable Lapwing and Spoon-billed Sandpiper. For this reason, and on a precautionary basis, it is desirable that population monitoring systems at national and international levels are as responsive as possible. Formal alerting systems should accordingly be developed to warn of significant declines (e.g. Atkinson *et al.* 2006). Integrating population monitoring with demographic information should be developed to provide further “early-warning” systems.

In view of the extensive declines noted for many species of migratory waders, there is an urgent need to develop internationally co-ordinated research initiatives to uncover reasons for the declines, and also to understand why some populations are able to increase on flyways which have many populations in decline. Funding for such programmes should be a global priority.

### Genetic consequences for small populations

Genetic studies indicate not only that small populations are especially vulnerable to the accumulation of harmful genetic mutation (genetic drift), but also that “effective population sizes” are significantly smaller than “census population sizes” (Baker 2003, 2006). That is, not all individuals in a population contribute to the gene pool. Owing to the low genetic variability (homozygosity) of waders, there is particular concern as to the long-term genetic consequences of populations falling below 15 000 individuals (Baker 2006). A total of 140 wader populations, comprising 28% of the global total, are estimated to be smaller than this threshold. Special attention is needed for declining populations which are getting close to this threshold, since they may still have the capacity to recover.

### Further analyses to guide conservation actions

A range of actions are desirable:

- Internationally co-ordinated programmes should be developed to assess wader productivity and survival. This information would aid in the development of more focussed and cost-effective conservation responses to information from count programmes. Interpretation of multiple information sources and especially spatial data is greatly helped by Geographic Information Systems.
- The application of IUCN Red List criteria at subspecies/population level should be encouraged to highlight the conservation status of individual biogeographical populations. This information is especially valuable in the context of listings under various international treaties.
- Further comparative analyses, using existing data and information, of the status of waders in different regions and flyways should be undertaken.
- The status of waders world-wide should continue to be reviewed, with the aim of continuing to provide technical advice to international conventions and other organizations as to those populations which should receive major attention with respect to their conservation, monitoring and research.

World leaders at the World Summit on Sustainable Development, Johannesburg, in 2002 established a target of “a significant reduction in the current rate of loss of biological

diversity” by 2010. Before that, in 2001, European Union Heads of State at Göteborg adopted the more challenging target “that biodiversity decline should be halted with the aim of reaching this objective by 2010.” The declines reported in this paper from all over the world suggest that, for waders at least, it will be extremely challenging to achieve these targets.

World leaders noted that to achieve this target “will require the provision of new and additional financial and technical resources to developing countries”. We agree, and also note that at a minimum, significantly greater investment is urgently needed not only in developing countries, but also in developed nations. This is required to establish and maintain national monitoring schemes, as well as to understand the causes of population declines so that appropriate, targeted conservation responses can be made.

### ACKNOWLEDGEMENTS

Many individuals actively participated in the International Wader Study Group’s workshop on declining waders in Cádiz in September 2003, upon which this summary paper is based, and contributed to the preparation of the WSG’s analysis of the status of migratory wader populations in Africa and Western Eurasia. We thank them all.

## Long-term declines in Arctic goose populations in eastern Asia

Evgeny E. Syroechkovskiy, Jr.

Institute of Ecology and Evolution, RAS, Goose, Swan and Duck Study Group of Northern Eurasia, Leninskiy prospect 33, Moscow, 119071, Russia. (email: ees@gcnet.ru)

Syroechkovskiy, Jr., E.E. 2006. Long-term declines in Arctic goose populations in eastern Asia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 649-662.

### ABSTRACT

Originally, the wetlands of eastern Asia were probably comparable in size to those of the Western Palearctic and North America, and it is likely that as recently as 200-300 years ago, the size of the goose populations was similar. However, it is estimated that there are now only about half a million geese in eastern Asia, as compared with 4.5 million in the Western Palearctic and 17 million in North America. In recent decades, most goose populations in eastern Asia have undergone very rapid declines and several are now at critically low levels. Two notable exceptions are the populations of Greater White-fronted Goose *Anser albifrons* wintering in Japan and Korea, where successful conservation measures and improvements in feeding conditions for geese have led to recent increases. Available information indicates that the main threat to east Asian geese is the loss of habitat in the staging and wintering areas, especially in China, although hunting is also a problem in many areas. We summarize field surveys on the breeding grounds in northern Russia in 1991-2005, and focus on the declines in population and changes in distribution of four species: Greater White-fronted Goose, Bean Goose *A. fabalis*, Lesser White-fronted Goose *A. erythropus* and Brent Goose *Branta bernicla*. It is hoped that the results of these studies will help us to find better solutions for the conservation of the threatened goose populations of eastern Asia.

### INTRODUCTION

The poor status of the goose populations in eastern Asia has been mentioned by many local research workers as well as authors of wide-scale reviews (e.g. Andreev, 1997, Madsen *et al.* 1996, Mooij & Zöckler 2000, Syroechkovskiy 1997a, 2001, 2003). In this paper, we try to analyse population trends and major range changes in the geese of north-eastern Russia, which comprise the great majority of east Asian geese. Our analysis is focused on Arctic geese, which make up the majority of geese in Asia. It does not concern three species with a more southerly distribution: Greylag Goose *Anser anser*, Swan Goose *A. cygnoides* and Bar-headed Goose *A. indicus*. However, many authors who have looked at these species have reported similar trends to those in Arctic geese (e.g. Dugintsov 1996, Babenko & Poyarkov 1998, Poyarkov 2001, Kear 2005, Cao *et al.* 2006a, 2006b).

### MATERIALS AND METHODS

We have studied the dynamics of goose populations in the eastern regions of the Russian Arctic for 15 years. In this paper, the term "eastern Asia" is not used in a strict geographical sense, but is simply used to describe that part of eastern Asia inhabited by populations of "true geese" (the genera *Anser* and *Branta*). The region stretches across Russia east of the Yenisey River basin, and includes China, Japan and Korea. The boundary between Western and Eastern Palearctic populations of geese

Fig. 1. Goose population monitoring areas surveyed by the author and his team in the eastern Russian Arctic in 1991-2005. The years in which the areas were monitored are indicated.

Fig. 2. Key breeding areas and stopover sites for East Asian goose populations in Russia. The numbering of the sites follows Table 1.

varies between species. However, in this study, we have considered the Taimyr Peninsula as the western boundary of our study area. Here, the westernmost population of east Asian Bean Geese *Anser fabalis* reaches the western limits of its breeding

**Table 1.** Territories of key importance for goose populations in the Russian part of East Asia, 1. The sources used for compilation of the table are listed in References.

Area	Status of birds (breeding, moulting, migrating, wintering)	Protection status of the area	Key species of the Asian goose populations most numerous within the area 2, 3	Recent rate of importance of the area for Asian goose populations	Monitoring scope since 1995	Prevailing trends of goose species since 1995
1. Plains of the southern and eastern Taimyr	breeding, moulting	partly protected	Bean Goose	low	poor	increase <sup>5</sup>
2. Plain north of the Pronchischeva mountain range between the Anabar and Oleniok rivers	breeding, moulting	unprotected	White-fronted Goose	medium	poor	increase <sup>5</sup>

1 The territories important for the Asian goose populations wintering in North America are also included.

2 Snow Goose is excluded, since virtually all geese of this species occurring on the named areas belong to the American populations.

3 Black Brant and Emperor Goose numerous within the area are included. Most of the geese of these species belong to the American populations, though some birds may winter in Asia and belong to the threatened populations with extremely low numbers. All the areas important for the both species are included in the list of Important Goose Areas of Asia unless and until the precise pattern of distribution of the Asian populations of these species is determined.

4 Area is included in the Ramsar List.

5 Increase due to immigration of birds from the Western Palearctic goose populations.

range. This species penetrates farther west than any other east Asian goose (Kistchinskiy 1979). Our studies of east Asian goose populations were carried out between 1991 and 2005 in the region from Taimyr to Chukotka (Fig. 1).

For our analyses of population trends, we conducted a literature review, mostly of Russian sources including so-called “grey literature”, largely unavailable to English-speaking readers, and field studies to determine the present status of goose population and make comparisons with data from previous years. We used standard techniques in our field studies, as described in our earlier publications (e.g. Syroechkovskiy 1997a, 1999, Artyukhov & Syroechkovskiy 1999).

Our estimates of goose populations were based on data compiled by Wetlands International (Wetlands International 2002), local estimates from the Russian literature, and unpublished data received from our Russian, Japanese and Korean colleagues. The population estimates given here mostly correspond to our knowledge up to 2003, and have not been adjusted on the basis of data acquired in 2004-2006. As only rough estimates are given in publications from the beginning and middle of the twentieth century (and also in some later publications), and as counts were conducted using a variety of methods, we have often had to use qualitative methods of estimating goose numbers to determine population trends.

## RESULTS AND DISCUSSION

### Key areas for Arctic geese in eastern Russia

Recent knowledge of the main breeding grounds and migration routes of Anseriformes in Russia allows us to identify key breeding and staging areas for the goose populations. The great majority of these areas are either already included in lists of Important Bird Areas (IBAs) and wetlands of international importance, or will be in the near future (Krivenko 2000, unpublished data of RBCU, etc.).

The most important areas for east Asian geese are shown in Fig. 2. The list of sites (Table 1) includes the areas which are still important, as well as a number of sites that have lost some of their importance because of the drastic decline in goose populations in eastern Asia in recent decades (see below). Most of the latter areas are, however, still suitable for geese, and it is possible that they may regain their former importance if goose populations begin to increase again, as is now occurring in some regions of Kamchatka and Chukotka.

### Populations and trends of east Asian geese

The population estimates and trends for each of the populations of the six goose species considered are summarized in Table 2. The population differentiation of east Asian geese remains poorly studied. Based on current knowledge, we recognize 14 migratory populations of geese breeding in north-eastern Russia. Three of these (both populations of the Snow Goose *Anser (Chen) caerulescens* and the largest population of the Brent Goose *Branta bernicla*) winter exclusively in North America. Much the largest part of the wintering range of the Emperor Goose *Anser canagicus* is in Alaska. However, there are some data which suggest the existence of a separate “Asian” Emperor Goose population (Syroechkovskiy, in prep.). Recent studies have revealed a spring and autumn migration route running from the breeding and moulting grounds in southern Chukotka along the Korayk Mountains to the Kamchatka coast. There is also increasing evidence of the possible wintering of Emperor Geese

**Table 2.** Estimated numbers and trends of east Asian Arctic goose populations. Based on Andreev (1997), Gerasimov (1996), Kerbes *et al.* (1999), Li & Mundkur (2004), Lopez & Mundkur (1997), Madsen (1991), Madsen *et al.* (1999), Mooij *et al.* (1996), Perennou *et al.* (1994), Scott & Rose (1996), Tetsuro (1996), Wetlands International (2002), Yemelyanov (2000), unpublished data of JAWGP, GSDSG NE, V.V. Baraniuk and Yu.N. Gerasimov (pers. comm.).

Species	Subspecies/population	Numbers in mid-1980s	Numbers in 2000-2002	Population trends
<i>Anser fabalis</i>	<i>A. f. middendorffii</i> <sup>1</sup>	c. 140 000 <sup>2</sup>	70 000	Decreasing
	<i>A. f. serrirostris</i> (south Kamchatka – Japan)	6 000	6 000-7 000	Approximately stable, fluctuating
	<i>A. f. serrirostris</i> (excluding Kamchatka population)	c. 240 000 <sup>2</sup>	c. 60 000	Decreasing
	<i>A. f. rossicus</i> (Yenisey – China)	?	<10 000	Decreasing
<i>Anser albifrons</i>	Wintering in China	250 000 <sup>2</sup>	30 000-50 000	Decreasing
	Wintering in Korea	5 000-30 000	60 000- 110 000	Increasing
	Chukotka – Japan	20 000	75 000	Increasing
<i>Anser erythropus</i>	Eastern Russia – China <sup>3</sup>	c. 40 000	220 000	Decreasing
<i>A. caerulescens</i>	Two populations on Wrangel Island	80 000	105 000	First decreasing, now increasing slowly
<i>A. canagicus</i>	Total (summer estimates in Russia)	165 000 (5 000-10 000)	85 000 (25 000)	First decreasing, now increasing slowly
<i>Branta bernicla</i>	<i>B. b. nigricans</i> wintering in North America (summer estimates in Russia)	185 000 (?)	130 000 (40 000)	Decreasing then increasing
	<i>B. b. nigricans</i> wintering in China <sup>3</sup>	3 000-4 000	4 000-5 000	First decreasing, now stable
	<i>B. b. nigricans</i> wintering in Japan	700	1 000	First decreasing, now stable
<b>TOTAL</b>	<b>14+ populations</b>	<b>c. 925 000</b>	<b>490 000</b>	

<sup>1</sup> Current knowledge allows us to recognize at least three migratory populations of Taiga Bean Goose (subspecies *middendorffii*) in eastern Asia: an Okhotsk/Kamchatka-Japan population; a Yakutian-China population; and a Sayany-China population. There is likely more differentiation but further studies are needed. The Taiga Bean Goose is recorded in the Arctic but the main breeding areas are further south, and so this form has not been considered in detail here.

<sup>2</sup> Estimates based on a combination of data from direct counts and extrapolations and estimates based on a study of trends in various parts of the range.

<sup>3</sup> This most likely comprises several migratory populations.

along the Kronotsk coast (Yu.N. Gerasimov pers. comm.). The level of isolation of this population from the North American population has still to be determined. It is also possible that in the case of the Greater White-fronted Goose *Anser albifrons*, Lesser White-fronted Goose *A. erythropus* and Bean Goose, more detailed studies will allow further subdivision of populations, especially between birds wintering in China and those wintering in Korea. As can be seen from Table 2, the great majority of populations which are “pure Asian” have either declined dramatically and are still declining, or have stabilized at very low numbers, critical for their existence.

### Comparison with in goose populations in Western Eurasia and North America

To determine if such a decline in goose numbers was the general trend in Eurasia, we analysed data from Wetlands International on numbers and population trends of geese in Western Eurasia. In Fig. 3, the increases and decreases in goose populations in Western Eurasia since the mid-1980s are compared with those in Eastern Eurasia. It is obvious that negative population trends totally dominate in eastern Asia, while positive trends dominate in the goose populations wintering in Europe. Since the mid-1980s, the proportion of “European” geese in the total goose population in Russia has increased from 57% to 82% due to the increase in

most goose populations in Europe and simultaneous decrease in Asian populations (Syroechkovskiy 2001, 2003). In Fig. 4, we compare the total numbers of all goose species in three large regions of the Northern Hemisphere: Western Palearctic, Eastern Palearctic and North America. These three regions are very similar in size and have similar habitats suitable for migratory goose populations. It seems likely that long ago, and perhaps only 200-300 years ago, the total numbers of geese inhabiting these three regions were approximately similar. The current situation is alarming: the goose population of the Eastern Palearctic, numbering only about half a million birds, comprises little over 2% of the total goose numbers in the Northern Hemisphere. We suggest that this situation reflects the attitudes of the states in these three regions to the conservation of migratory birds and their habitats and the support they give to nature conservation. Most of the populations of even “common” geese in eastern Asia are now at such low numbers that they would immediately be given threatened status if they inhabited Europe or North America.

### Local population trends of geese in eastern Russia

We analysed data on local changes in goose numbers to assess regional variations in trends in goose populations in eastern Asia. This analysis was based on data from long-term population monitoring and the results of current studies, and was conducted

**Fig. 3.** Changes in numbers in the goose populations in a) western Russia, and b) eastern Russia in the last 20 years. Numbers in the mid-1980s are given as the “zero level”. The size of the columns show by how much the populations have increased or decreased since the mid-1980s. The names of the populations are represented by the first letters of the scientific names of the species/subspecies. Sources as in Table 2.

A group of 300 moulting Brent Geese *Branta bernicla*, caught in the delta of the Nishnyaya Taymyr river, Eastern Taimyr, July 1990, on the first Dutch-Russian-German-UK Siberian expedition. This expedition was the start of a long term research programme on the ecology and migration of Brent Geese and arctic waders between the Russian Federation and the Netherlands. Annually since 1990, Russian-Dutch expeditions to Taimyr have taken place with a changing number of participants from other countries. Photo: Gerard Boere.

**Fig. 4.** Comparison of the size of the goose populations in the Eastern Palearctic, Western Palearctic and North America (Nearctic).

for the two most abundant species with vast ranges in eastern Asia: the Greater White-fronted Goose (Fig. 5) and eastern Tundra Bean Goose *A. f. serrirostris* (Fig. 6). Publications by research workers in the early and mid-twentieth century rarely contain detailed count data, but still give a good enough idea of the relative abundance of geese in certain study areas. When it was not possible to compare quantitative data, we used qualitative comparisons of relative abundance.

It is possible to evaluate whether the estimates of trends shown in Figs 5 & 6 are representative by comparing them to Fig. 2, which depicts key IBAs, the most important sites for

**Fig. 5.** Local population trends of the Greater White-fronted Goose *Anser albifrons* as monitored in eastern Russia during the last 40 years. Trends: upward pointing arrow – increasing trend; downward pointing arrow – declining trend; oval – relatively stable numbers. Methods of estimating trends: 1 – comparison of counts; 2 – results of counts combined with estimates from experts; 3 – combination of data from various sources, including qualitative and numerical data and information from local residents. The shaded area (4) shows the range of the increasing Russian-Japanese population. Sources as listed in References, with additional information from N.D. Poyarkov and Yu.V. Shibaev (pers. comm.).

**Fig. 6.** Local population trends of the Tundra Bean Goose *Anser fabalis* *serrirostris* and *A. f. rossicus* monitored in eastern Russia during the last 40 years. Legend as in Fig. 5. Sources as listed in References, with additional information from N.D. Poyarkov and Yu.V. Shibaev (pers. comm.).

geese in eastern Asia. It is clear that population trends have been estimated mainly in the most important areas for geese, and so in general we can conclude that the data are quite representative for the entire flyways.

#### Population differentiation and trends in Asian geese Greater White-fronted Goose

In this study, we have not considered subspecific differentiation, which has been discussed by Mooij & Zöckler (2000). Here we consider only the differentiation of Asian populations of the Greater White-fronted Goose, which are poorly known. There is an assumption that considerable mixing between populations ("pan-mixia") can occur in Asia, as it does in the Western Palearctic populations of this species (Mooij *et al.* 1996). It is possible that mixing occurs to some extent between the populations wintering in China and Korea, as their migration routes partly overlap. However, data from satellite transmitters (M. Kurechi pers. comm.) and a colour-marking programme in Chukotka in 2001-2005 have revealed the existence of a quite separate Chukotka-Japan population of White-fronted Geese. Of 120 birds marked by our team in southern Chukotka in the last five years, 25% were recorded on wintering grounds in Japan or on the way there. No birds were recorded in Korea, where more and more attention has been given to geese in recent years, nor were any birds recorded in other parts of the species' range.

Over a considerable part of Russian east Asia, the trends in White-fronted Goose populations have been negative throughout recent decades (Figs. 5, 7 & 8). A comparative analysis of the changes in numbers on the wintering grounds in China and Korea is of interest. In China, where the Greater White-fronted Goose was abundant in the past and possibly the most numerous of the geese, the population has been steadily declining and now probably comprises no more than 30 000 birds concentrated in the Yangtze valley (Cao *et al.* 2006a, 2006b). At the same time, in Korea the numbers of this species have been increasing. Counts

in the late 1980s (Perennou *et al.* 1994) revealed less than 5 000 birds in Korea. It is likely that this was a considerable underestimate, but the total wintering population of the species in Korea was clearly small. The official mid-winter (January) counts in Korea in 1997-2001 gave estimates of 10 000-61 000 birds (Li & Mundkur 2004). However, according to Korean goose researchers (Lee Ki-Sub pers. comm.), the true number of this species in Korea since 2000 has exceeded 100 000 birds; e.g. 108 000 were counted in early winter concentrations in South Korea in November 2002 (Han *et al.* 2003). It was presumed that most of these birds would have been missed by the January counts because they disperse widely over agricultural land when the water bodies in the demilitarized zone freeze over.

In any event, there has been considerable growth in the Greater White-fronted Goose population in the Korean wintering grounds during the last decade. This is undoubtedly related to the favourable conditions that have existed for geese in Korea in recent years. The hunting of geese has been totally banned since the 1980s, and many areas of inter-tidal mudflat and salt marsh on the west coast have been turned into rice fields and have become ideal wintering grounds for geese (Lee Hoonsoo pers. comm.). These changes have not only favoured geese but also some ducks and, in particular, have contributed to the large increase in numbers of Baikal Teal *Anas formosa*. The big increase in the wintering population of Greater White-fronted Geese in Korea might be partly due to natural population growth, and partly to immigration from the wintering areas in China, where numbers have been declining in recent decades. This can only be clarified by undertaking co-ordinated international counts and large-scale colour-marking of geese in the region.

The warmer winters, as a result of global climate change, may be contributing to the establishment of a more stable over-wintering population of geese in Korea, which is located at the northern climatic limit of potential goose wintering range in eastern Asia.

Analysis of local trends in north-eastern Russia (Fig. 5) reveals that in the greater part of this region (in Yakutia), a steady decrease in the numbers of Greater White-fronted Geese has been recorded almost everywhere. This is consistent with the negative trends in the wintering areas in China which have been linked with the breeding areas in Yakutia by ringing recoveries (data from Bird Ringing Centre of Russia). The situation is different in Kamchatka and Chukotka. Here, the observations of a research group supervised by N.N. Gerasimov and Yu.N. Gerasimov and our expeditions since 2000 have revealed considerable growth in the goose populations, especially in areas adjacent to the Pacific coast. This is obviously a reflection of the increase in numbers of geese on the wintering grounds in Japan in the 1980s and 1990s (Kurechi 2005, M. Kurechi pers. comm.), and later also in Korea. An analysis of the population dynamics of Greater White-fronted Geese in the region of the Anadyr Estuary has revealed that during the period from the early 1990s until 2003, there was a gradual replacement of birds wintering mainly in China (Kondratyev 1993) by birds wintering in Japan (E.E. Syroechkovskiy and A.I. Artyukhov, unpubl. data). We also observed an increase in numbers and range expansion in the Greater White-fronted Goose populations in southern and eastern Chukotka Peninsula in 2000-2004 (Fig. 5), compared with the situation in the 1960s, 1970s and 1980s

**Fig. 7.** Decrease in numbers of geese (individuals  $\text{km}^{-2}$ ) counted during aerial surveys on the breeding grounds in northern Yakutia between 1960 and 1990. Locations (from west to east): 1 – Lena Delta; 2 – Yana-Indigirka Lowland; 3 – Kolyma-Alazeya Lowland. Based on Yegorov (1965), Degtyarev (1994) and A.V. Andreev (unpublished data).

**Fig. 8.** Population (number of individuals) decline on migration stopovers of Bean and White-fronted Geese at southern Siberia and Russian Far-East from 1950s onwards.

Based on (Dymin, 1986; Gerassimov, 1988; Dugintsov, 1996; Andreev, 1997; Antonov, 2000; Yemeliyanov, 2000; Rozenfeld, Smirenskiy, 2001)

- 1 Zeya Lowland (middle Amur, south-west of city of Blagovestchensk) numbers of both Bean and White-fronted Geese
- 2 Khakassiya (Southern Central Siberia) – Bean Goose numbers
- 3 Zeya Lowland – Bean Goose numbers only
- 4 Apkhara Lowland (central Amur, east of Bureya River mouth); Khinganskiy Zapovednik -Bean and White-fronted Geese
- 5 Penzhina (north western Kamchatka peninsula) – mainly Bean Goose including some White-fronted Geese

(e.g. Portenko 1972, Tomkovich & Sorokin 1983). These observations are confirmed by local people in the settlements of Novoye Chaplino, Sireniki, Yanrakynnot, Lorino and Lavrentiya, and reindeer herders visiting the basins of the Yoniveem, Igelveem, Chegitun, Kurupka, Erguveem and Seutakan rivers and the Konnerginskaya tundra. In the last decade, Greater White-

fronted Geese have become much commoner in these areas than they were in the 1980s. We suggest that this increase is related to the occurrence in these areas of geese from the favourable wintering grounds in Japan and Korea. These birds are probably now partly replacing birds from the Chinese wintering population which were formerly common here.

From the results of our aerial survey in 2002, we conclude that the present breeding range of the Greater White-fronted Geese wintering in Korea and Japan includes the Koryak Mountains, Anadyr Bay coasts, Kanchalaksaya, Uelkalskaya and Konnerginskaya tundras, Amguema River basin, north and west coasts of the Tenkyrgynpilken Estuary (up to Smidt Cape), and most of the Chukotka Peninsula except perhaps for the north coast of Koluchin Bay and Neshkansky tundra. The exact distribution of birds from different populations in the Chukotka area has still to be determined.

The current status of the Greater White-fronted Goose in the middle reaches of the Anadyr River also has to be clarified. The Chinese wintering population of Greater White-fronted Geese inhabited this area about 30 years ago and then almost completely disappeared (Krechmar 1986, Krechmar *et al.* 1991, A.V. Krechmar pers. comm.). It is possible that the area is now inhabited by birds from the Japanese and Korean wintering populations.

The supposition that there is exchange between the Chukotkan and Alaskan populations of Greater White-fronted Goose seems to us poorly justified and based on a misinterpretation of observations of goose migration in the vicinity of Arakamchechen Island. Our observations in 2004 and an analysis of information derived from questioning local people in Providenskiy District of Chukotka do not confirm this supposition.

The local people living in the lower reaches of the Anabar River in extreme north-western Yakutia reported an increase in the Greater White-fronted Goose population at the end of the twentieth century. According to them, since the early 1990s most Greater White-fronted Geese arriving on the lower reaches of Anabar River in spring arrive from the west, from the direction of Taimyr, while the traditional arrival from the south has almost ceased. At Ystankh-Khocho village in the summer of 1997, we observed Greater White-fronted Geese migrating from the west towards the Lena River delta, on their way to the moulting sites. It is possible, therefore, that a considerable proportion of the Greater White-fronted Geese from the western Yakutian tundra, and particularly those from the moulting sites north of the Pronchishcheva Mountains, belong to the Western Palearctic populations.

The observations discussed above suggest that a process of territorial re-distribution is occurring between migratory populations of Greater White-fronted Geese in eastern Asia. Vast areas of tundra in Yakutia and Chukotka, where the numbers of geese have drastically declined due to the shrinkage of the wintering grounds in China, are gradually being occupied by birds penetrating into the area from other, more successful populations in Taimyr and Koraykia. Thus, large shifts in goose populations are occurring in eastern Asia as a result of anthropogenic factors.

### Bean Goose

It is commonly accepted that only one subspecies of Tundra Bean Goose *A. f. serrirostris* inhabits eastern Asia (Alphéraky 1905, Stepanyan 2003, Delacour 1954, Mooij & Zöckler 1999, and others). Whether or not the subspecies *A. f. rossicus* can be

subdivided into separate migratory populations remains unclear. Most global reviews, including the most recent (Kear 2005), indicate that *A. f. rossicus* migrates only to Europe, and consider it as belonging wholly to the Western Palearctic. However, most Russian research workers (e.g. Ptushenko 1952, Kistchinskiy 1979, Mel'nikov 2001), including those who have made a thorough study of the morphology and taxonomy of the species (Yemelyanov 2000), have shown that most Bean Geese from Taimyr, although belonging to the subspecies *rossicus*, migrate southwards along the Yenisey River valley and its tributaries at least as far as Lake Baikal. China is the only region where birds passing through this area might spend the winter. This suggests that both *serrirostris* and *rossicus* share wintering grounds in China. We are not aware of any thorough taxonomic study of Bean Goose subspecies wintering in China, but such a study could solve the puzzle as to whether or not there are separate migratory populations of *rossicus*.

Population differentiation in east Asian Bean Geese is not clearly understood. Our present knowledge allows us to identify at least four migratory populations (Table 2), although in reality there are probably more. In recent decades, Asian Tundra Bean Geese have experienced huge anthropogenic pressures. In the mid-twentieth century, they were among the most abundant and widespread geese in eastern Asia. In the past, the east Asian populations of Bean Geese extended across the whole of Taimyr, for almost a thousand kilometres from east to west, whereas the westernmost of the east Asian populations of Greater White-fronted Geese probably penetrated only as far west as eastern Taimyr. Bean Geese also differ from Greater White-fronted Geese in having a migration route along the Yenisey. Birds follow this route in spring from the wintering grounds in China to central Siberia as far as the edges of the West Siberian Plain and Gydan Peninsula (Syroechkovskiy 1965, Kistchinskiy 1979, Rogacheva 1992).

In the mid-twentieth century, Bean Geese were abundant everywhere in the tundra areas of Taimyr, Yakutia, Chukotka and Kamchatka (Ptushenko 1952, Vorobyev 1963, Uspenskiy *et al.* 1962, Yegorov 1965, Portenko 1972, Rogacheva 1992). At that time, according to our estimates, Asian Bean Goose populations exceeded one million birds. However, many researchers recorded a steady decline in Bean Goose populations in the 1960s, 1970s and 1980s: in the breeding areas in Taimyr, the lower Lena River and eastern tundra in Yakutia (Kokorev 1989, Rogacheva 1992, V.I. Pozdnyakov pers. comm.), and along the migration routes in the middle reaches of the Amur River, Kamchatka and other regions in the Russian Far East, as well as along the Yenisey migration route (Rogacheva 1992, Yemelyanov 2000, Savchenko *et al.* 2003) (Figs. 6 & 8). Our studies conducted at key wetlands in northern Yakutia and Chukotka in 1994-2004 revealed a further decline in numbers. The breeding range has now become highly fragmented. Formerly a common species, the species now inhabits only small patches of suitable habitat, often situated tens or even hundreds of kilometres apart (Syroechkovskiy 1997). In our annual three-month surveys of geese in the lower reaches of the Anabar, Olenek Yana and Indigirka rivers in 1996-1999, we were able to find a total of fewer than ten nests of this species and only a few moulting sites, with fewer than 1 000 birds.

Despite the relatively favourable conditions on the wintering grounds in Japan in recent years, there has been no sustained

growth in the southern Kamchatka-Japan Bean Goose population, as there has in the Greater White-fronted Goose population. This Bean Goose population began to increase in 1980, but never became abundant and is now probably declining again (Yu.N. Gerasimov pers. comm.). The number of Bean Geese wintering in Korea is low, and if the rate of decline is the same as that in China, the population will be close to extinction within the next decade.

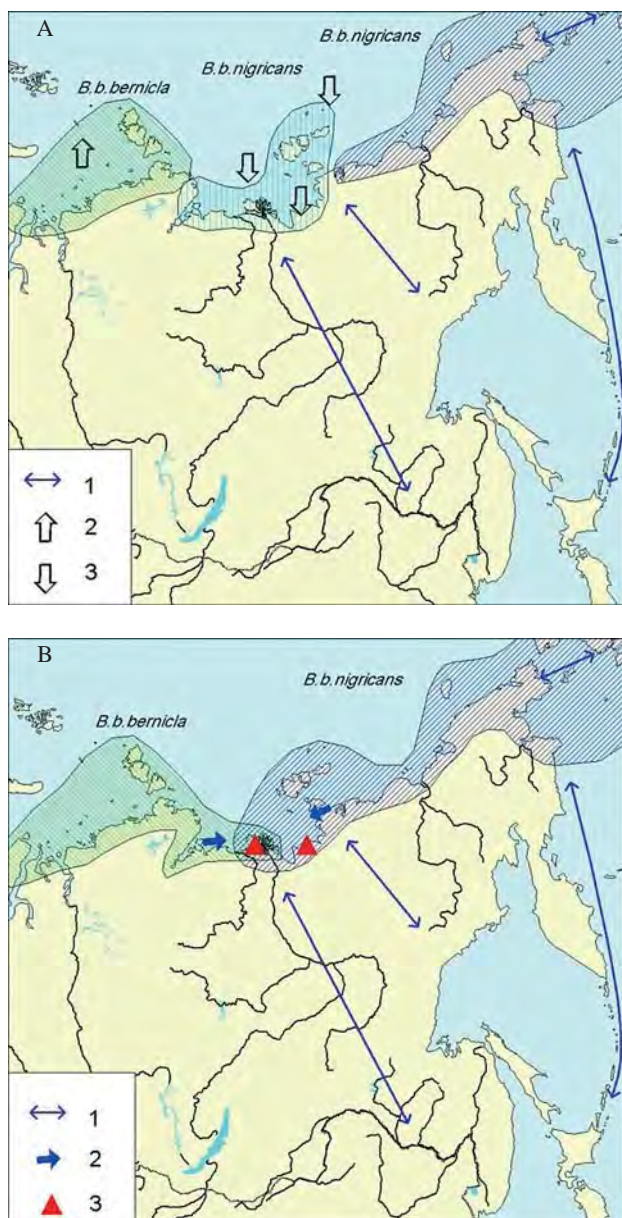

The only area where positive trends have been recorded in an Asian population of Bean Goose in recent years is in the extreme west, in the vast bogs and flood-lands in the upper and middle reaches of the Nizhnyaya Baikha River, in the middle reaches of the Enisey River. According to staff of Turukhansk Hunting Inspectorate, the Taiga Bean Goose had become rare in this area after a long-term decline in the numbers of migrating and breeding birds, but in the early 1990s, this trend was reversed as a result of a considerable increase in the numbers of geese arriving from the south-west. In the late 1990s, staff of the Hunting Inspectorate in Ust-Eniseysk District of Taimyr Autonomous Region also recorded an increase in the numbers of Bean Geese arriving in spring from the direction of the West Siberian Plain. Thus, it would seem that the process of population replacement in Asia, as described for Greater White-fronted Geese, has only just begun for Bean Geese.

The overall status of Bean Geese in eastern Asia is depressing. We suggest that the remaining populations of the Tundra Bean Goose represent only about 10-15% of the total numbers in eastern Asia about a century ago. It is obvious that the hunting of all subspecies of Bean Geese should be banned immediately throughout their ranges in eastern Russia, and the strictest measures should be taken to protect the species' staging and wintering sites.

#### Lesser White-fronted Goose

Information on population trends in Lesser White-fronted Geese, which is easily mistaken for Greater White-fronted Geese, is even scarcer than for the other species of geese in eastern Asia. A review of the population decline and range fragmentation in this species has recently been published elsewhere (Morozov & Syroechkovskiy 2002). Little is known about population differentiation in this species, although it most likely exists. It is difficult to believe that the birds following a migration route along the Angara River in central Siberia belong to the same migratory population as those passing through Kamchatka. Scattered observations of this species on passage (Portenko 1972, Rogacheva 1992, Dugintsov 1996, Yu.N. Gerasimov pers. comm., pers. obs) suggest the existence of at least three migration routes: Central Siberian (Angarian), Amur-Yakutian and Far Eastern. The latter may have two branches: Kamchatka-Chukotian and Okhotsk-Kolymian. There is an urgent need for studies with the help of satellite transmitters to resolve this. It is possible that there have been some shifts in the wintering populations similar to those that are now occurring in the Greater White-fronted Goose, as the only known wintering area for the Asian populations of the Lesser White-fronted Goose is at Dongting Lake in China. The Asian populations of this species are in a critical state, with total numbers now less than 20 000 birds (Cao *et al.* 2006a, 2006b). Population trends have been found to be negative wherever they have been investigated during the last 20 years (Morozov & Syroechkovskiy 2002).

**Fig 9.** Re-distribution of three populations of Black Brant in Yakutian tundra in the second half of 20th century.

A) Middle 20th century.

- 3 – records of decreasing trends in the breeding grounds

B) End of 20th century.

- 1 – migration routes
- 2 – directions of expansion of populations replacing decreasing Asian population of Black Brant
- 3 – possible areas of remaining breeding of Asian population of Black Brant

### Brent Goose

The population dynamics and changes in range of the Asian populations of the Brent Goose (subspecies *nigricans*, often known as Black Brant) in Russia have been studied in some detail (Syroechkovskiy 1995, 1997b, 1999, Syroechkovskiy *et al.* 1998, etc.). Declines in the populations of Brent Geese throughout the

Russian Arctic in the second half of the twentieth century resulted in fragmentation of the breeding range. Only scattered colonies of this species have survived. In the 1960s and 1970s, the total number of Brent Geese in the Russian Arctic was in the region of 20 000–30 000 birds. Since the 1970s, the North American population of *nigricans* and the population of the nominate subspecies in Western Eurasia have been increasing, but this has not happened in the Asian populations of *nigricans*. As a result of the drastic population decline (Fig. 9), the areas formerly inhabited by the Asian populations of *nigricans* have been gradually occupied by birds of the nominate subspecies invading from the west and North American birds coming in from the direction of Chukotka. These conclusions have been confirmed by ringing recoveries and direct observations.

The Asian populations of *nigricans* are very small, poorly studied and close to extinction. The wintering sites in China are poorly known, and the breeding areas, which are thought to be on the lower Lena and Yana rivers, have not been surveyed. In view of the high anthropogenic pressures and speed of development in the Chinese coastal areas where Brent Geese winter (Barter 2002), we surmise that these populations will soon be extinct unless urgent measures are taken to safeguard them. To some extent, the breeding populations might be maintained by immigration of birds from the North American population. Ringing recoveries from Japan suggest that this may already be occurring (T. Ikeuchi pers. comm., V.I. Pozdnyakov pers. comm., data of the Bird Ringing Centre of Russia). The migration system of Brent Geese wintering in Japan and observed on migration along coastal Kamchatka still remains unclear. It is probable that there is a loop migration, with birds crossing the Asian mainland in spring (Pozdnyakov & Germogenov 1988, Syroechkovskiy 1999) and returning via the Pacific coast in autumn, with a major stopover at the Malamvayam Estuary in Kamchatka (Gerasimov & Gerasimov 1999, Syroechkovskiy 1999). However, these suppositions need thorough verification, preferably with the help of satellite transmitters.

### CONCLUSIONS

Various authors have described the poor conditions for goose populations, large-scale poaching and loss of suitable wetland habitat in China (Degtyarev 1995, Goroshko 2000, Barter 2002, Cao *et al.* 2006a), but no special studies of these problems are known to us. Although some positive steps have been taken to mitigate the impacts of development on wetlands and waterbirds (Anonymous 2002), much remains to be done to improve the situation for east Asian geese. A detailed analysis of the situation should be the subject of a separate study and publication.

Our main conclusions regarding the trends in east Asian goose populations are as follows:

- The majority of east Asian goose populations are in long-term decline, in contrast to most populations of geese in the Western Palearctic and North America.
- There are only about half a million geese left in the whole of eastern Asia. This huge area is inhabited by less than 2.5% of the geese in the Northern Hemisphere.
- Although all countries in eastern Asia with populations of geese have contributed to their decline in numbers due to habitat change and excessive hunting, the critical bottlenecks for the goose populations are the staging and

wintering areas in China. Further studies and awareness campaigns are urgently required there.

- Some east Asian goose populations have reached critically low levels below 20 000 birds (Lesser White-fronted Goose, the two Asian Brent Goose populations); most of the other, formerly abundant populations have recently fallen below 100 000 birds and are in urgent need of conservation measures throughout their flyways.
- Both the Greater White-fronted Goose and the Bean Goose are still hunted in the Asian part of Russia, despite their declining trends and low numbers. The Russian Far East should impose a temporary (but long-term) ban on goose hunting, most importantly in spring, but in many areas also in autumn. Special rights could be given to indigenous minorities, and the hunting law should be strictly enforced throughout eastern Russia.
- Shifts in breeding range have been reported in the eastern and western parts of our study area. Fragmented breeding areas abandoned by the declining Asian populations of Greater White-fronted Goose and Bean Goose are being occupied by birds from the increasing populations in neighbouring flyways, which have more secure wintering areas in Western Europe, Japan and North America.
- Thirty years of conservation efforts for the Greater White-fronted Goose and Bean Goose in Japan have had positive results, resulting in the stabilization and increase in numbers of several populations, and setting an excellent example recognized by the international conservation community. The experience gained in Japan in the conservation of geese and especially habitat restoration could be widely used in other parts of Asia, especially in China.
- The rapid increase in the Greater White-fronted Goose population in Japan, which followed rather simple habitat conservation and restoration efforts, shows the high adaptive potential of geese. It has demonstrated the potential for future reestablishment of goose populations in Asia, even in highly industrialized developed countries, especially in association with “goose friendly” rice-production technologies which result in very low levels of conflict with farming interests and increasing numbers of geese.
- The increase in numbers of geese wintering in South Korea should be subject to further study and documentation. South Korea could be the second “growing point” for goose populations in eastern Asia after Japan.

## ACKNOWLEDGEMENTS

Firstly, I would like to thank the Japanese Association for Wild Geese Protection, and especially President Masyuki Kurechi and Yoshihiko Miyabayashi, for their constant help, both by assisting us financially and by providing information and advice at all stages in our work, through the implementation of the Asia-Pacific Migratory Waterbird Conservation Strategy. I also thank the Administrations at all levels in Chukotka and Yakutia for supporting our surveys, and the friendly people of the Arctic villages who helped us enormously in our field work. Our work received financial support from many sources, especially the Russian Academy of Sciences, Toyota Foundation, Kei Dan Ren Science Foundation, Santory Whisky Foundation, CIC Migratory Bird Commission, Arctic Ecology and Anthropology Research Centre (Moscow), U.S. Fish & Wildlife Service,

Foundation for Support of Domestic Science (Russia) and Dr Werner Trense. Volunteers from eight countries have contributed greatly to our field surveys: C. Schenk, P. Palmer, J. O'Sullivan, M. Trobits, M. Boegehausen, T. Kuppel, G. Eihorn, J. Lugert, R. Probst, M. Pavlichev, A. Braunlich, H. Karhu, J. MacCalum, C. Kelly, T. Jakkonen, T. Noach, V. Nilssen, M. Lieser, M. Stensmyr and A. Tree. Field data were collected with the help of many colleagues, and I would especially like to mention E.G. Lappo, C. Zöckler, P.S. Tomkovich, S.V. Volkov and A.I. Artiukhov for their major contributions to the surveys of Arctic waterfowl during our expeditions. Comments from Yu.N. Gerasimov, K. Livin, N. Poyarkov, A. Kondratyev, E. Lappo and anonymous reviewers have improved the text.

Barter, M.A. 2006. The Yellow Sea – a vitally important staging region for migratory shorebirds. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 663–667.

### ABSTRACT

Surveys conducted during the last 11 years show that the extensive inter-tidal areas and near-coastal wetlands of the Yellow Sea are the most important staging region for migratory shorebirds in the East Asian-Australasian Flyway. Thirty-six species have so far been found to occur in internationally important numbers at one or more sites in the Yellow Sea; two of the species are classified as globally-threatened, whilst another two are near-threatened. Twenty-seven sites have been identified as supporting at least one species in internationally important numbers. The rapid growth of the human populations and economies of China and South Korea is causing serious loss and degradation of coastal habitats. Achieving effective conservation of migratory shorebirds and their wetland habitats around the Yellow Sea coastline will be particularly challenging due to the high dependence of the local communities on inter-tidal resources. The exceptional importance of the Yellow Sea biodiversity, both on a global scale and as a shared resource for the three littoral countries, makes it highly desirable that conservation activity be implemented at eco-region level.

### INTRODUCTION

The East Asian-Australasian Flyway, one of eight shorebird flyways around the world, stretches from Siberia and Alaska southwards through east and south-east Asia to Australia and New Zealand, and supports over seven million shorebirds of which some five million are migratory (Bamford *et al.* 2005).

The shorebirds of the East Asian-Australasian Flyway face the challenge of sharing it with more than one-third of the world's human population, many of whom live in countries that have some of the fastest developing economies in the world. The resulting economic and social pressures are posing major threats to wetlands, with more than 80% of the significant wetlands in east and south-east Asia being classified as threatened in some way; 51% of these are under serious threat (Scott & Poole 1989).

Much has been learnt about the breeding and non-breeding portions of shorebirds' lives within the flyway. However, relatively little is known of the migration strategies of the individual species – a deficiency which is particularly serious, given that the key wetlands used during migration in east and south-east Asia are the most threatened in the flyway (Melville 1997). This need for greatly improved information on important shorebird staging sites has led to extensive survey and counting activity over the last 20 years, particularly along the coastline of the Yellow Sea.

### THE YELLOW SEA AND SHOREBIRD STUDIES

The Yellow Sea is a semi-enclosed shallow sea, with extensive inter-tidal areas, located between the Korean Peninsula in the east and China to the west (Fig. 1). The Chinese coastline consists of extensive stretches of tidal flats separated by the

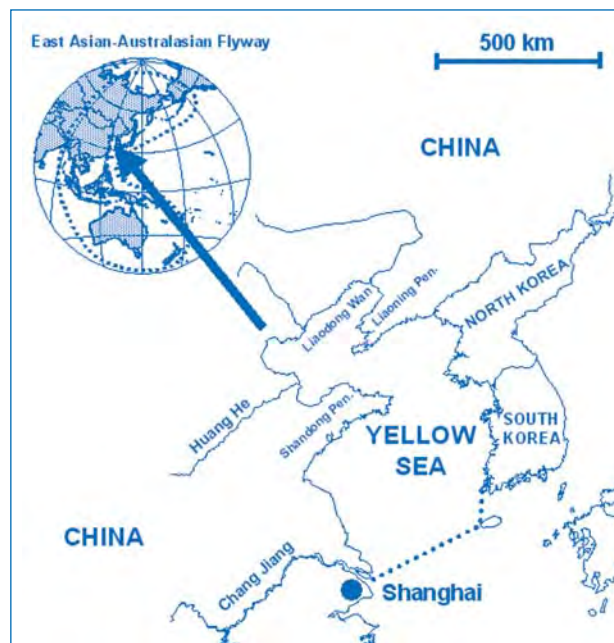

Fig. 1. The Yellow Sea: location, national boundaries, constituent parts and major rivers.

rocky regions of the Shantung and Liaoning Peninsulas and north-west Liaodong Wan, whilst the west coast of South Korea consists of large tidal flats which are contained in broad estuaries in the north and surround islands in the south-west. The total area of inter-tidal flats in the Yellow Sea, including the south coast of South Korea, is about 20 000 sq. km. The tidal ranges of the central west coast of the Korean Peninsula are amongst the highest in the world.

Since 1996, Wetlands International – China has been carrying out surveys during the northward migration period for shorebirds around the Yellow Sea coastline of China. In South Korea, staff of the Avian Laboratory, Ministry of Environment, have been conducting intensive counts of important sites in the Yellow Sea on both northward and southward migration since 1993. Non-governmental organizations in South Korea have also made a major contribution in recent years. Unfortunately, very little information is available from North Korea. The data collected up to 2000 have been analysed and published in the monograph *Shorebirds of the Yellow Sea – importance, threats and conservation status* (Barter 2002) and form the basis for this paper.

### SURVEY RESULTS

#### Species present in internationally important concentrations

A total of 36 shorebird species has so far been found to occur in internationally important numbers at one or more sites in the

**Table 1.** Species ranked according to the number of sites at which they occur in internationally important numbers.

Species	Number of sites of international importance				
	Total	Northward migration	Southward migration	Non-breeding season	Breeding season
Kentish Plover <i>Charadrius alexandrinus</i>	21	11	16	4	2

Yellow Sea (Table 1). This number represents 60% of the migratory shorebird species in the East Asian-Australasian Flyway.

Table 2 provides a summary of the estimated numbers of birds using the Chinese and South Korean portions of the Yellow Sea during northward migration for those species for which sufficient count data are available (see Barter 2002 for an explanation of how these estimates were made). An estimate is also given of the proportion of the flyway breeding populations being supported at this time of the year. The use of proportions of breeding populations is the most appropriate way to measure of the Yellow Sea's importance, as this does not include the often significant numbers of non-migrating immature birds remaining on the non-breeding grounds further south.

The great importance of the Yellow Sea for shorebirds during northward migration is demonstrated by the fact that it supports 30% or more of the flyway breeding populations of 18 species; for six of these species, the region supports almost the

entire flyway breeding population.

The Yellow Sea is particularly important for four species of special conservation concern: the Endangered Spotted Greenshank *Tringa guttifer* and Vulnerable Spoon-billed Sandpiper *Eurynorhynchus pygmeus*, and the Near-Threatened Far Eastern Curlew *Numenius madagascariensis* and Asian Dowitcher *Limnodromus semipalmatus*. All four of these are endemic to the East Asian-Australasian Flyway. It is highly likely that the great majority of the Spotted Greenshank and Spoon-billed Sandpiper populations use the Yellow Sea during both northward and southward migrations. More than 90% of the estimated breeding population of the Far Eastern Curlew migrate through the Yellow Sea on northward migration, and 50% of the Asian Dowitchers.

In total, it is estimated that a minimum of 2 000 000 shorebirds use the wetlands around the Yellow Sea during northward migration, i.e. approximately 40% of the estimated flyway popu-

**Table 2.** Proportion of the breeding populations of shorebirds supported by the Yellow Sea during northward migration.

Species	Population estimate	% breeding of population
Great Knot	290 000	>90

South Korean sites: 1 Ganghwa Do; 2 Yong Jeong Do; 3 Daebu Do; 4 Namyang Man; 5 Hongwon Ri; 6 Asan Man; 7 Seosan Reclaimed Area; 8 Geum Gang Hagu; 9 Mangyeung Gang Hagu; 10 Dongjin Gang Hagu; 11 Paeksu Tidal Flat; 12 Hampyeong Man; 13 Meian Gun Tidal Flat; 14 Aphae Do; 15 Suncheon Man; 16 Nakdong Gang Hagu.

lation of migratory shorebirds. Perhaps 1 000 000 shorebirds pass through the region on southward migration.

### Internationally important sites

Twenty-seven internationally important sites have been identified around the Yellow Sea coastline (Fig. 2). Ten of these sites are located in China, one in North Korea and 16 in South Korea. Six of the ten Chinese sites, the North Korean site and a small part of one of the 16 South Korean sites are within protected areas. A summary of information on the numbers of internationally important species and highest seasonal counts at each site is presented in Table 3.

The sites exhibit a great diversity in the number of species of shorebirds that they support in internationally important numbers. Half of the sites carry at least five species in internationally numbers, whilst six support 15 or more species. At five sites, the highest counts of shorebirds have exceeded 100 000 on northward migration, whilst one site supports almost 250 000 shorebirds on southward migration. Some sites support a high proportion of the flyway population of one or more species; those sites holding >5%, >10% and >20% of the estimated flyway populations are listed in Table 4. These sites have very important conservation significance.

Six extremely important regions within the Yellow Sea have been identified:

- central and northern Jiangsu coast (Yancheng NNR and Dongsha);
- Bohai Wan (Huang He NNR, Tianjin Municipality and Shi Jiu Tuot);
- northern Liaodong Wan (Shuangtaizihekou NNR and Linghekou);
- Yalu Jiang NNR;
- Namyang and Asan Mans;
- the Mangyeung and Dongjin estuaries.

Each of these regions supports peak numbers well in excess of 100 000 shorebirds on northward migration, whilst the Jiangsu coast holds more than 250 000 on southward migration and is also the most important area within the Yellow Sea during the non-breeding season.

### Threats

The rapid growth of the human populations and economies of China and South Korea is causing serious loss and degradation of coastal habitats. Approximately 37% of the inter-tidal areas existing in the Chinese portion of the Yellow Sea in 1950 and 43% of those in the South Korean part in 1917 have been reclaimed to date. China has plans to reclaim a further 45% of its current mudflats and South Korea an additional 34%. The two largest rivers flowing into the Yellow Sea, the Huang He (Yellow River) and Chang Jiang (Yangtze River), are undergoing significant changes that will greatly reduce the input of sediments, and it is predicted that future loss of inter-tidal areas will occur at an increasing rate due to the combined effects of reclamation and reduced accretion. The declining river flows and high levels of pollution are leading to reduced benthic productivity and thus a decline in food supplies for shorebirds. Human disturbance, by affecting feeding and roosting birds, and competition, through unsustainable harvesting of benthic fauna, may also have a serious impact on shorebirds.

**Table 3.** Sites in the Yellow Sea ranked according to the number of species of shorebirds occurring in internationally important numbers and the highest seasonal counts (see Fig. 2 for site locations).

Site	No. of species occurring in internationally important numbers	Highest count		
		Northward migration	Southward migration	Non-breeding season
Yancheng NNR	23	111 285	82 530	27 181

Hongwon Ri	1	-	-	-
Mundok MBWR	1	-	-	-

Key: NNR = National Nature Reserve; PNR = Provincial Nature Reserve; MBWR = Migratory Bird Wetland Reserve.

The adverse effects of the various threats being encountered by shorebirds in the Yellow Sea are most significant during northward migration, when shorebirds are not only preparing for their final long flight into the breeding grounds, but also gaining additional reserves to sustain them during the period immediately after arrival, when feeding conditions may be poor but territories have to be fought for and eggs laid.

Of particular concern is the ongoing reclamation of the Mangyeung and Dongjin estuaries as part of the 401 sq. km Saemangeum Reclamation Project. These estuaries are the most important sites in South Korea during both northward and southward migration, in terms of both maximum counts and numbers of species occurring in internationally important concentrations. During the northward migration period, the two estuaries jointly carry 30% of the Great Knot *Calidris tenuirostris* breeding population. The estuaries also support the most significant concentrations within the Yellow Sea of the endangered Spotted Greenshank and vulnerable Spoon-billed Sandpiper during southward migration. Between them, the two estuaries support the highest recorded concentrations in the Yellow Sea during northward migration of three species, and during southward migration of seven.

## CONSERVATION STATUS OF SHOREBIRDS IN THE YELLOW SEA

The widespread and ongoing reclamation of inter-tidal areas, excessive pollution levels and high levels of human disturbance indicate very clearly that migratory shorebirds are already encountering serious problems in the Yellow Sea. These difficulties can be expected to increase. Thus, the conservation status of shorebirds is poor and is likely to decline further. Effective conservation of migratory shorebirds and their wetland habitats is a challenging task at any time, but it is particularly difficult around the Yellow Sea coastline, where development activities are generally undertaken with little regard for environmental consequences.

The traditional approach to nature conservation, i.e. the creation of a network of protected areas with severe limitations being placed on human activities, is inappropriate in the Yellow Sea due to the very extensive nature of the inter-tidal areas in the region and the high dependence of the local communities on the inter-tidal resources. Even nature reserves in China have large human populations, e.g. 90 000 people live within the Yancheng National Nature Reserve.

**Table 4.** Sites supporting >20%, >10% and >5% of an estimated shorebird flyway population during northward migration, southward migration or the non-breeding season.

Sites	>20%	>10%	>5%
Chongming Dao PNR			Kentish Plover (NM)
Dong Sha			Asian Dowitcher (SM)
Yancheng NNR		Spotted Redshank (SM) Marsh Sandpiper (NM) Sanderling (NM) Little Ringed Plover (SM)	Spotted Redshank (NM) Marsh Sandpiper (SM) Sanderling (NB) Dunlin (NM) Kentish Plover (SM)

Mangyeung Gang Hagu		Great Knot (NM) Kentish Plover (SM)	Black-tailed Godwit (SM) Spotted Greenshank (SM) Dunlin (NM) Lesser Sandplover (NM, SM)
Dongjin Gang Hagu		Great Knot (NM)	Spotted Greenshank (SM) Kentish Plover (SM) Lesser Sandplover (NM, SM)

NM = northward migration; SM = southward migration; NB = non-breeding season.

Successful conservation activity will depend on the adoption of suitable national policies and plans for the appropriate use of inter-tidal and sub-coastal areas. These will need to be harmonized across the three littoral countries. Local community support will be an essential factor in creating the necessary political environment for the development and successful implementation of these policies and plans.

## Population declines and the risk of extinction in waders: genetic and ecological consequences of small population size

Allan J. Baker

Department of Natural History, Royal Ontario Museum, and Department of Zoology, University of Toronto, Toronto, Ontario, Canada.

Baker, A.J. 2006. Population declines and the risk of extinction in waders: genetic and ecological consequences of small population size. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 668-671.

### ABSTRACT

World-wide population declines in waders are of great concern because many species have not yet recovered from loss of genetic variation caused by population bottlenecks in the late Pleistocene. Therefore genetically effective population sizes are much smaller than census population sizes. Genetic drift can be more important than selection in determining the fate of new mutations in small populations, in which case populations are expected to accumulate deleterious mutations. The fixation of such deleterious alleles is expected to reduce reproductive success of a species and lead to extinction unless new beneficial mutations are fixed by selection and help restore part of the lost fitness. Critical effective size could be as small as a few hundred individuals, above which a population will persist without extinction due to genetic load. However, this requires an approximately 10-fold higher census population size because of the variance in breeding success and fluctuations in numbers in different generations. In populations such as the Red Knot *Calidris canutus rufa* which is currently undergoing a drastic decline in numbers due to bad ecological conditions, the risk of extinction is exacerbated. This paper reviews genetic and ecological evidence of why the population is declining, and argues that an increasing number of species may be in the same risk category.

### INTRODUCTION

Wader species and their constitutive populations are of international conservation concern, following a recent review of population trends around the world (International Wader Study Group 2003, Stroud *et al.* 2006). For those species in which population trends were reported, three times as many are in decline as are expanding. Forty-two of 214 species (19.6%) listed by the International Wader Study Group were assessed as either Globally Threatened or Near Threatened. Although this number includes some species that are already thought to be extinct, it is a strong indication that the loss of biodiversity in this charismatic group of birds is accelerating. The causes of this increasing risk of extinction in waders are poorly understood, and raise important issues in conservation management

generally, as well as specific questions about how to halt global declines and engage in population restoration.

While the loss of wetlands and destruction of associated food supplies is likely implicated in most population declines, it is often not appreciated fully that the risk of extinction involves both genetic and ecological consequences of small population size. The purpose of this paper is to bring to the attention of wader biologists some recent theoretical work on the genetic risks of extinction of small populations (Whitlock 2000), and to emphasize that ecological and genetic risks operate in different time frames. However, both need to be considered in the restoration of small populations if we are to try to give them a future in other millennia.

### LOW GENETIC VARIATION IN WADERS

Assays of genetic variation in waders have uncovered the rather surprising fact that many species and populations are genetically impoverished, relative to other groups of birds such as passerines. This was first reported by Baker & Strauch (1988) using protein electrophoresis (see Table 1). Low genetic variability is evident not only in small populations of threatened endemics such as the African Black Oystercatcher *Haematopus moquini* and Mountain Plover *Charadrius montanus*, but also in migratory species with much larger population sizes (e.g. Purple Sandpiper *Calidris maritima* and Willet *Catoptrophorus semipalmatus*). The latter implies that at some time in their recent past, Purple Sandpipers and Willets were reduced to small ancestral populations, thereby losing genetic variation, and have expanded subsequently to larger populations. Not enough time has elapsed since the populations expanded for many mutations to accumulate in the genomes of these species and restore the genetic variation expected in equilibrium populations.

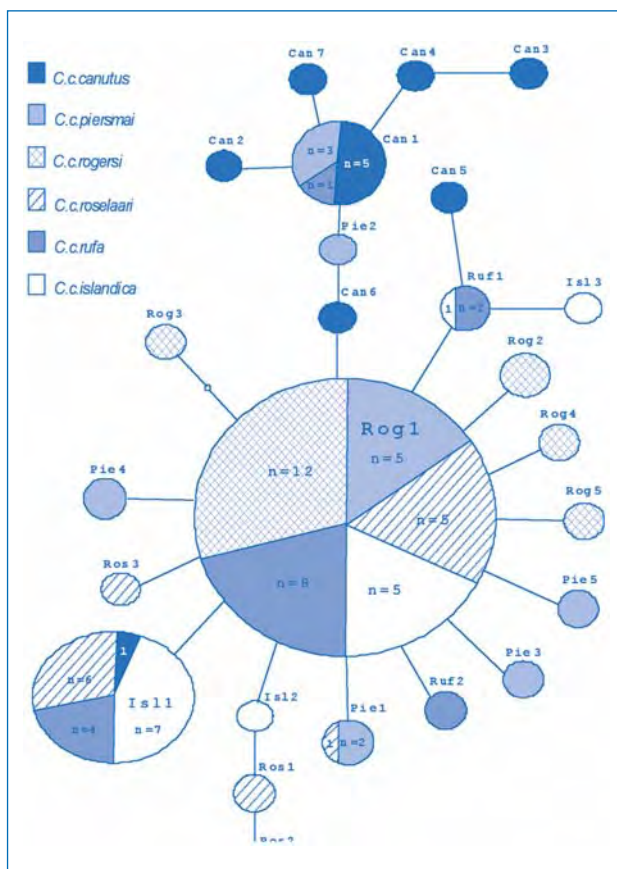

### HISTORICAL DEMOGRAPHY AND GENETIC BOTTLENECKS

One source of loss of genetic variation in wader populations dates back to previous episodes of population declines in the last glacial maximum (LGM) about 22 000 years ago in the Northern

**Table 1.** Estimates of genetic variability at 30 loci of some wader species based on protein electrophoresis.

Species	N	No. alleles/locus	% Polymorphic loci	Average heterozygosity
African Black Oystercatcher <i>Haematopus moquini</i>	13	1.1	8.3	0.019
Grey Plover <i>Pluvialis squatarola</i>	13	1.1	7.5	0.011

Willet <i>Catoptrophorus semipalmatus</i>	23	1.1	5.0	0.002
Passerine average				0.053

**Fig. 1.** Minimum spanning network connecting 91 haplotypes found in 657 bp of the mitochondrial DNA control region in globally distributed populations of the Red Knot *Calidris canutus*. The star-like pattern is created because most haplotypes differ by one mutation from the common haplotypes. From Buehler & Baker (2005).

Hemisphere, or possibly earlier glacial maxima in the Pleistocene. Especially for migratory waders breeding in the high Arctic tundra, such as the Red Knot *Calidris canutus*, the genetic footprint of a small population that survived the LGM is readily apparent in the very limited variation in mitochondrial DNA sequences of the six subspecies (Baker *et al.* 1994). Only 25 haplotypes were found in 675 bp sequences of the control region, the fastest evolving part of the mtDNA molecule. Furthermore, the 91 individuals that were sequenced were sampled over the global range of the species (Buehler & Baker 2005). The minimum spanning network has the pattern expected under a demographic contraction and population bottleneck in the LGM: a few ancestral common haplotypes that survived the bottleneck, and most of the remainder arising by mutations of one or a few bases subsequently as the population expanded (Fig. 1).

Such a star-like phylogeny is typical of small populations of recently bottlenecked species. Although such a pattern can also be generated by selection acting on linked genes in the nucleus, this is unlikely in Red Knots because (1) the same star-like pattern has been found in other species of waders suggesting a general demographic contraction in response to harsh Pleistocene environmental conditions, and (2) a similarly low level has been found in nuclear loci (Table 1) and in genomic scans of Red Knots using amplified fragment length polymorphisms (AFLP, Table 2). The scans also show that waders such as the Red Knot and Dunlin *Calidris alpina* have less genetic

variation at hundreds of nuclear loci than a range of other bird species. The lowest value was recorded in the Red Knot (all subspecies included), even though a larger number of loci (836) were scanned than in passerine taxa.

### POPULATION PERSISTENCE AND THE GENETIC RISK OF EXTINCTION IN SMALL POPULATIONS

In a seminal paper, Whitlock (2000) assessed the genetic risk of extinction in small populations in which he not only considered the fixation of deleterious alleles that thereby affect the fitness of all individuals, but also factored in the fixation of beneficial mutations that can reduce this genetic load. Beneficial alleles are more likely to be lost and deleterious alleles are more likely to be fixed in small populations because random genetic drift is more important relative to selection. Thus small populations have a high probability of extinction because of the inexorable decline in fitness.

However, Whitlock showed that there is a critical threshold size ( $N_e$ ,  $crit$ ) above which populations are expected to persist indefinitely because the loss of fitness from the fixation of deleterious alleles is countered by the fixation of beneficial alleles. This critical effective size in populations varies according to a number of factors. First, if the rate of beneficial mutation is large relative to the rate of deleterious mutation, the loss of fitness will be restored in smaller populations than would be the case if the rates were reversed. Second, when the mean effects of mutation are high, the importance of genetic drift of nearly neutral alleles is decreased, and thus critical effective size is lower. Third, if beneficial mutations are likely to be more frequent or have a larger effect in compensating for a previous decline in fitness, then  $N_e$ ,  $crit$  will be lower. Fourth, a high ratio of effective population size (and hence the number of breeding adults) to census population size will decrease the critical threshold size for population persistence. Finally, sexual selection could also lower this threshold by removing deleterious alleles, as alleles that decrease productivity are also likely to reduce mating success (Whitlock 2000).

Due to uncertainty and lack of empirical estimates of these parameters, the critical effective size can only be approximated, but is thought to be in the range of hundreds of individuals. However, the ratio of effective population size to census population size in waders (Buehler & Baker 2005) is typically about 0.1, as it is in other wildlife (Frankham 1995). Therefore, as Whitlock (2000) pointed out, census population size for population persistence in the longer term needs to be at least 10 times larger than the critical effective size, typically in the thousands.

### POPULATION PERSISTENCE AND THE ECOLOGICAL RISK OF EXTINCTION IN SMALL POPULATIONS

Ecological and demographic factors such as breeding failure and low recruitment rates, low adult annual survival and worsening environmental conditions present much more immediate risks of extinction than genetic factors (Lande 1998). This is because ecological pressures can operate on a much shorter time frame of a few generations in long-lived organisms such as waders, whereas genetic problems accumulate slowly through time. In the *rufa* population of Red Knots, for example, the immediate threats are more likely to be ecological. Late arrival at Delaware Bay in spring and inadequate refuelling at this last stopover before migrating to the Arctic breeding grounds have resulted in

**Table 2.** Genomic diversity in bird taxa estimated with amplified fragment polymorphisms (AFLP).

Species	No. amplified loci	No. polymorphic loci	% polymorphic loci
House Finch <i>Carpodacus mexicanus</i>	363	223	61.4
Chiffchaff <i>Phylloscopus collybita</i>	251	141	56.2
Bluethroat <i>Luscinia svecica</i>	232	81	34.9
Willow Flycatcher <i>Empidonax traillii</i>	708	197	27.8
Dunlin <i>Calidris alpina</i>	900	203	22.6
Red Knot <i>Calidris canutus</i>	836	129	15.4
Average	585.4	150.2	31.4

decreased annual survival of adults and low recruitment rates in the period 2000-2001 (Baker *et al.* 2004). The further loss of 13 000 birds from the over-wintering population in Tierra del Fuego, as recorded by an aerial census in February 2005, considerably increases the risk of extinction of this population. In the short period of five years, the population has declined from about 53 532 to 17 653.

The large-scale losses of birds could, in part, be a lag effect of inadequate refuelling at stopover sites, increased risk of breeding in unpredictable climatic conditions in the Arctic due to global climate change, and increased susceptibility to pathogens and parasites. In small populations, the latter can be associated with the loss of adaptive variation and the accumulation and fixation of deleterious mutations which reduce fitness. We therefore expect such populations to be more prone to large mortalities in unfavourable ecological circumstances such as annual food failures, increased incidence of pathogens, and pollution. The joint effects of environmental stochasticity and genetic processes could increase the risk of extinction even further, as appears to be the case in the Red Knot. Not only have refuelling problems and late arrival at stopover sites been implicated in the severe decline in the Tierra del Fuego population, but also spring migrants passing through Lagoa do Piexe in southern Brazil in 1997 were observed dying in small flocks after foraging on ocean beaches. The cause of this mortality could not be determined, but was possibly due to a viral pathogen.

The interaction of genetic and ecological risk factors was the basis for the “parasite” hypothesis of wader migration which predicted that long-distance migrants such as the Red Knot have to winter in low-parasite marine environments (Piersma 1997), because they trade-off increased energy expenditure for immune system suppression. This in turn was also predicated on the observation that many species of waders are genetically impoverished as a result of population bottlenecks in the late Pleistocene (Baker & Strauch 1988, Baker *et al.* 1994), and thus have reduced levels of adaptive variation. The salient point about species that have survived a prolonged bottleneck (as in the millennial duration of glacial maxima) is that a population must exist at a much larger size for a very long time to recover from the negative effects on fitness suffered when the population was small (Whitlock 2000).

Migratory waders are vulnerable not only because of their life history characteristics and specialized ecologies, but also because of the genetic erosion of adaptive genetic variation from small population size in the past (Piersma & Baker 1999). We should thus not be surprised that so many migrant waders are declining world-wide and many species will be in the same risk

Dunlin *Calidris alpina* surface-tension feeding. Dunlins have lower genetic diversity than many other bird species. Photo: Rob Robinson.

category, and must be cognizant that restoration of their populations probably depends on managing for larger census population sizes than implied in the old 50 : 500 rule of thumb. This rule suggests that an effective population size of 50 breeding adults may be adequate in avoiding inbreeding depression, whereas an effective size of about 500 is required to prevent the loss of genetic variation in quantitative traits with high heritability (Harris *et al.* 1987, Simberloff 1988). This rule implies a census population size of about 5 000 adults for minimum viable population size, but if the ratio of beneficial to deleterious mutations is low, then it is wise to manage for at least double this population size to increase the chances of long-term persistence.

Although critical threshold size for population persistence has large uncertainties associated with it, larger census populations are good insurance in mitigating ecological and genetic risk factors. Finally, it is better to act earlier in declaring species or populations threatened or endangered. Rather than waiting until numbers have dwindled to hundreds or a few thousands, population restoration has to be attempted much sooner when the population is correspondingly bigger. Not only will this decrease adverse genetic effects, but it will also increase the prospects for a demographic expansion and reduce the risk of extinction.

Lake Durankulak on the Bulgarian Black Sea coast is one of the major wintering areas for Red-breasted Geese *Branta ruficollis*. The species has only ever been recorded from 115 sites worldwide and of these 70% qualify for Ramsar designation. The long-term viability of this species will depend on the conservation of these ecologically linked sites. Photo: Sergey Dereliev.

Flyway-level conservation requires attention to site networks, not just individual sites. Such wide-scale consideration (sometimes at continental scales) provides a practical challenge to planners and managers. Among other problems and constraints are limited resources, patchy data, restricted opportunities for new designations of protected sites, and the wide distributions of migratory species in space and time. Especially in response to the latter, with the advent of climate-mediated distributional shifts, approaches to the creation of site-networks are required that have a dynamic quality: with processes that allow regular assessment of effectiveness – and adaptation to ‘fine-tune’ effectiveness.

The symposium reviewed and discussed different approaches to: identifying key sites; building a coherent ecological network; linking site networks with the Convention on Biological Diversity’s ‘ecosystem approach’; recognition and

practical conservation of site networks. Examples of national (or wider) networks were reviewed from the UK (Baker & Stroud), the Western Hemisphere Shorebird Reserve Network (Duncan), as well as in the context of the specific needs of individual species such as for Lesser White-fronted *Anser erythropus* and Red-breasted Geese *Branta ruficollis* (Dereliev), Greater Flamingo *Phoenicopterus ruber* (Bechet *et al.*), as well as for Siberian Crane *Grus leucogeranus* (Prentice *et al.*).

Pritchard stressed that the objectives of a site network must foster a synergy of the functions and values of its parts. The objectives (and strategies) of key site networks should have a sound scientific basis, so that it can be a credible statutory objective and a yardstick for measuring success. Pritchard challenged the workshop to be more specific about the ecological meaning that underpins our network concepts, including as related to site network coherence within existing legal frameworks.

## Towards coherence in site networks

### ABSTRACT

When does a collection of sites become a network? And when does a network become coherent? Network administrators are often vague in defining the purposes and targets for individual networks. As a result, “coherence” often means little more than “a network that includes all my sites”. Objectives of a site network must foster a synergy of the functions and values of its parts. The objectives (and strategies) of key site networks are explored to give the concept a more scientific basis, so that it can be a credible statutory objective and a yardstick for measuring success. Issues include: cost-effectiveness (geographical concentration); risk reduction (geographical spread); “capture”; “completion”; representativity; and viability. These objectives have implications for the way statutory site frameworks are operated, and the policy choices to be made. This paper challenges us to be more specific about the ecological meaning that underpins our network concepts, and also briefly comments on site network coherence within existing legal frameworks.

### INTRODUCTION

When we talk about site networks, we need to be clear about the objectives we have in mind. Those objectives also need to be ecologically meaningful at the network scale. Historically, much emphasis has been put on criteria for choosing sites. This generates a list of sites, but it does not necessarily follow that the list will have functions at the level of a network. In recent years, more emphasis has been put on management and on objectives for individual sites. This might help to secure the integrity of the individual sites, but again it does not necessarily contribute to coherence of the network. So what is this “coherence”? When does a collection of sites become a network? And when does a network become coherent?

### DISCUSSION

#### Network-level objectives

To make a list of sites into a network, probably the minimum element required is a defined common purpose to which all the sites contribute. Network administrators face the question of whether their collection of sites is designed to provide scientific reference points, to serve as flagship cases to rally the conservation cause, to be used as demonstration sites for management techniques, to preserve the values that made each site qualify for designation, to restore more “natural” conditions, or something else. These questions get one as far as being able to say why any particular sites belong to a common collection. It is very important to relate sites to some context like this, but that in itself will not produce network coherence.

So perhaps coherence is an issue to do with the relationships between sites, and the properties of the “glue” which holds them together in some kind of unity. That is unlikely, because these things relate merely to the mechanism producing coherence.

The coherence itself resides instead in the resulting state of what the dictionary definition calls “being well held together”. It is an expression of what the totality represents.

One can be slightly more strategic by adding a thought such as “if we wish to add more sites to the network, what scheme of priorities are we working to?” But even doing this does not necessarily involve defining an end-objective or target state for the network as a whole. Rather, what is really required is to define an objective which is concerned with the network in total having more functions and values than simply the sum of its parts. This, moreover, will be different in each case: it is not something which is possessed in a general way, automatically, by any plurality of sites.

If the common purpose is, for example, “sites holding examples of a rare species” or “the best quality examples of an ecosystem”, then even if the strategy which has been adopted is a reactive site-by-site one, it is implicit that there is a job being done by the system, as well as the job being done by any one site within it. So in the first example referred to, this would be the function of making a specified contribution to the fate of the species, or in the second example, the function of representing within the network a sample of a value-set which extends outside the network. Alternatively, the system might be aiming at objectives such as making a contribution to sustaining an economic resource, or increasing overall capacity to support a particular species or habitat.

Once this has been resolved and an objective for the system has been defined, coherence also involves a second somewhat harder question. Threshold issues need to be addressed which assist in deciding when there are enough of the right kind of sites in the system to accomplish the end objective. Some examples of the objectives of site networks are examined below.

#### Risk reduction/cost-effectiveness objectives

One goal for a site network may be to provide a sustainable representation of the range of distribution of the species or habitats at stake, as an expression of ecological character, biological diversity or population dynamics. Two potentially competing objectives towards achieving this goal are risk reduction and cost-effectiveness.

In order to minimize vulnerability and risk, a strategy of selecting sites so that the variety of values at stake is spread throughout the largest possible number of sites (geographical spread) may be appropriate. A strategy such as this is an insurance against the total loss of a resource being caused by localized impacts such as fire, flooding, disease or inappropriate land-use decisions. This kind of strategy also helps the chances of recovery from such events by offering a spread of gene-pools for potential re-colonization. In addition, site networks might need to include some “spare” resources for emergencies, such as sheltered refuges for birds in unusually severe weather. Spreading sites across several geopolitical jurisdictions may also

help, to guard against the effects of political support for conservation fluctuating from time to time and from place to place.

If an objective of minimizing the cost per unit benefit is adopted, the opposite kind of strategy (geographical concentration) might be produced, because this would suggest that the maximum variety and abundance of values should be concentrated in the smallest possible number of sites. This could also maximize complementarity, i.e. each site being as different from the others as possible.

A social question which potentially affects the number and distribution of sites within a network is whether to have an objective of maximizing accessibility of sites to people. This might be important if the aims of the system include considerations such as human enjoyment of natural areas for bird-watching, or provision of amenity “greenspace”.

### “Capture” and “completion” objectives

These spreading or concentrating approaches do not necessarily say anything in themselves about the composition of the sites that make up the network. To address this, one would require an approach to site selection based upon an objective something to the effect of maximizing the diversity of what is covered by the network. This is what could be thought of as a “capture objective”, defining what the system aims to capture and hold within it. However, objectives to “maximize” something do not help to quantify the target end-state, unless it is genuinely intended that the system will cover 100% of whatever is of interest. Hence, while they could be called capture objectives, they could not normally be thought of as “completion objectives”.

Completion objectives go further, by addressing the issue of how to know when to stop, i.e. when the network is coherent in the sense of containing enough sites of the right type. If this can be defined, then one can also search for sites to fill gaps in coverage. Two main strategies for completion objectives are representativity and viability. These are probably the main areas of benefit involved in moving from a single site to a site network.

### Representativity strategy

Representativity is a strategy for including enough sites or types of site within the network to demonstrate the range of functions, values and attributes at stake, and to enable a contribution to be made to the conservation of each of these. This is not just a matter of presenting samples: it has the crucial additional element of sufficiency.

Examples of “representation” objectives might be those targeting:

- the “best manifestations” of whatever is valued;
- the typical or reference type examples of whatever is valued;
- examples which demonstrate a particular aspect of knowledge or understanding;
- the cases least affected by human influence;
- sufficient cases to represent the full range of variety;

- a “basic minimum” of the heritage to pass on to future generations; and
- examples from each spatial subdivision of the geographical scope of the network.

### Viability strategy

Viability is a strategy for including in the network a sustainable minimum of something, such as a self-sustaining population, so that it can be conserved within the sites, perhaps on a basis of assuming a scenario where the aspect of value is lost from everywhere outside the network. Network concepts as such, as distinct from the question of simply having a large total area, come into their own especially in respect of the multiple site requirements of migratory or otherwise mobile taxa. This is a question of designing a network to include all the different geographical, climatic and other factors which play different roles at different times, and combine together to support the population.

Some networks may have an objective of including sites which play a “critical” role in relation to viability. This may include seasonal, climatic or biophysical “bottlenecks” of some kind in the life cycle or population cycle of a species.

### Site network coherence within existing legal frameworks

The coherence of site networks already features in one or two legal regimes. The Strategic Framework for Ramsar sites under the Convention on Wetlands contains a reference to network coherence, in that case at national level.

Under the European Union’s Habitats Directive, if a project which is likely to damage a designated site nevertheless meets various public interest tests and has to be approved, there is a requirement for habitat compensation which has to serve an aim of protecting the overall coherence of the designated site network. It can be seen that this could translate into an idea of using maintenance of network coherence as one criterion for judging the adequacy of mitigation and compensation measures, more generally.

One assumption being made here is that overall network coherence can be preserved even if there are changes in the individual constituent sites. The concept therefore admits some interchangeability among the ingredients which go to make it up. The corollary, though, is that an impact on any one part of the system has to be considered in terms of its implications for the whole system.

### CONCLUSION

In conclusion, it seems clear that a coherent network cannot simply be thought of as “a network that includes all the sites I want it to include”! This paper has explored a few ways of giving the concept a more scientific and functional basis. This is an area that should be developed further in future, so that coherence can be a credible statutory objective and a yardstick for measuring success.

## Establishment of a UK network of Special Protection Areas for waterbirds: the SPA review and future directions

Helen Baker & David A. Stroud

Joint Nature Conservation Committee, Monkstone House, City Road, Peterborough, PE1 1JY, UK.  
(email: Helen.Baker@jncc.gov.uk)

Baker, H. & Stroud, D.A. 2006. Establishment of a UK network of Special Protection Areas for waterbirds: the SPA review and future directions. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 675-679.

### ABSTRACT

Special Protection Areas (SPAs) are sites designated under the European Union Directive on the Conservation of Wild Birds (79/409/EEC). The first analyses of the SPA network in the UK were published in the early 1990s. These reviews approached network creation on the individual merits of each site. Another network review was published in 2001, following agreement of formal UK SPA selection guidelines. The 2001 review was significantly different in its species-based approach; protection requirements of each species were assessed and a *suite* of SPAs selected accordingly. The national *network* comprises the aggregated SPA suites for 103 species or biogeographical populations, with 242 sites designated. The UK is of international importance for its waterbird populations and high proportions of many populations occur within the SPA network. Sites of importance for assemblages of over 20 000 non-breeding waterbirds are also included. The 2001 review highlighted gaps in the network, especially in the marine environment, which are now being addressed. National standards in monitoring SPA condition have been implemented, with each site assessed every six years. This will aid management of individual SPAs, and will allow regular assessment of the effectiveness of the national network in contributing to species conservation.

### INTRODUCTION

Special Protection Areas (SPAs) are strictly protected sites designated in accordance with the European Union (EU) Directive on the Conservation of Wild Birds (79/409/EEC; the “Birds Directive”). SPAs are designated for rare and vulnerable species within the EU (listed in Annex I of the Directive), and also for other regularly occurring migratory species. SPAs, together with Sites of Community Importance (SCI; identified under the EU Directive on the Conservation of Natural Habitats and of Wild Fauna and Flora - 92/43/EEC; “the Habitats Directive”), form the Natura 2000 network, which is intended to be a coherent ecological network. Designation of an area as a Natura 2000 site provides a high level of habitat protection, with explicit procedures and strict tests to be followed in relation to proposed developments affecting the site. SPA management is focused on the requirements of the species for which the site has been selected (“qualifying species”); potential impacts of activities that might negatively affect the site are assessed against effects on these birds.

Despite the intention that SPAs will contribute to a coherent European ecological network of protected sites, there are no detailed guidelines or criteria agreed at the EU level for selecting SPAs. The Directive provides broad guidance stating that the most suitable territories in number and size shall be classified

and that these should ensure survival and reproduction within the species’ area of distribution. In addition, for migratory species, SPA provision should take into account breeding, moulting and wintering areas and staging posts along the migration route, paying particular attention to protection of internationally important wetlands. The specific mention of internationally important wetlands is an implicit reference to the Convention on Wetlands (Ramsar, 1971) and an indication that the Ramsar site selection criteria should guide selection of SPAs for migratory waterbirds (Temple-Lang 1982).

Since the Birds Directive came into force, legal cases have influenced development of SPA selection approaches. Of greatest significance was Case C-3/96 *Commission v Netherlands* [1998] ECR I-3031, which established that in the absence of a scientific evaluation published by a government, the European Court of Justice could assess Member State SPA provision against BirdLife International’s Important Bird Area (IBA) network (Grimmett & Jones 1989). The IBA identification process uses specific criteria for selecting sites, but there has been no formal adoption of these criteria as a common standard for selecting SPAs at either UK or European Union scales. The IBA process makes no reference to network coherence, and no IBA suites for species are identified, although its stated aim is to provide a network of sites that are of importance for the long-term viability of those populations amenable to site-based conservation across their biogeographical range. BirdLife International considers the IBA network to be the minimum essential to ensure the survival of these species (Heath & Evans 2000).

The means of achieving the SPA components of a coherent ecological network of Natura 2000 sites are therefore not clear. The Habitats Directive states that the designation of habitats, either alone or in order to support species, should be proportional to their occurrence. However, the Directive provides no guidance on what proportions would be adequate to contribute to a coherent ecological network. During moderation of national SCI lists, arbitrary levels of biogeographical representation were used to prioritize further network development (EU Habitats Committee 1997). When the proposed SCIs within a region supported more than 60% of a habitat or species, the consideration of more sites was of low priority. This level was chosen as it is likely to ensure that in most cases the objectives of the Habitats Directive would be met. However, the selection of SCIs is guided by more specific criteria than the Birds Directive provides for SPAs, and no similar target has been established for assessing the European SPA network.

In this paper, we describe the approach in the UK to establishing a network of SPAs, and the UK SPA selection guidelines. We also explore what the network provides specifically for

### Box 1. The UK Special Protection Area Selection Guidelines (JNCC 1999).

Application of the guidelines involves two stages. Stage 1 is intended to identify areas that are likely to qualify for SPA status. These areas are then considered further, using one or more of the judgements in Stage 2 to select the most suitable areas in number and size for SPA classification.

#### Stage 1

1. An area is used regularly by 1% or more of the Great Britain (or in Northern Ireland, the all-Ireland) population of a species listed in Annex I of the Birds Directive (79/409/EEC as amended) in any season.
2. An area is used regularly by 1% or more of the biogeographical population of a regularly occurring migratory species (other than those listed in Annex I) in any season.
3. An area is used regularly by over 20 000 waterfowl (waterfowl as defined by the Ramsar Convention) or 20 000 seabirds in any season.
4. An area which meets the requirements of one or more of the Stage 2 guidelines in any season, where the application of Stage 1 guidelines 1, 2 or 3 for a species does not identify an adequate suite of most suitable sites for the conservation of that species.

#### Stage 2

1. **Population size and density**  
Areas holding or supporting more birds than others and/or holding or supporting birds at higher concentrations are favoured for selection.
2. **Species range**  
Areas selected for a given species provide as wide a geographic coverage across the species' range as possible.
3. **Breeding success**  
Areas of higher breeding success than others are favoured for selection.
4. **History of occupancy**  
Areas known to have a longer history of occupation or use by the relevant species are favoured for selection.
5. **Multi-species areas**  
Areas holding or supporting the larger number of qualifying species under Article 4 of the Directive are favoured for selection.
6. **Naturalness**  
Areas comprising natural or semi-natural habitats are favoured for selection over those which do not.
7. **Severe weather refuges**  
Areas used at least once a decade by significant proportions of the biogeographical population of a species in periods of severe weather in any season, and which are vital to the survival of a viable population, are favoured for selection.

waterbirds. Finally, we provide a brief overview of monitoring and the future development of the UK SPA network.

### DEVELOPMENT OF THE UK SPA NETWORK

The UK began its programme of SPA designation in 1982. In order to assess progress, a full analysis of the SPA network in

Britain was carried out and published in 1990, with site details published in 1992 (Stroud *et al.* 1990, Pritchard *et al.* 1992). SPAs in Northern Ireland were evaluated, adopting an approach similar to that used in Great Britain, on an All-Ireland basis in the early 1990s (Way *et al.* 1993). These reviews approached the task of defining a network of sites from an assessment of "best" sites on their own individual merits, rather than an assessment of the national, or international, needs of the species for which the network was being established. This type of approach was based on that for IBAs and the identification of potential Ramsar sites through its series of directories of wetlands of international importance (e.g. Carp 1980). The UK had designated 33 SPAs at the time of completion of the 1990 review, but critically the review identified a further 190 areas that should be considered for designation. A further list identified other areas where more data were required before further assessment of status could be made.

In 1994, the UK government requested that the Joint Nature Conservation Committee (JNCC) co-ordinate another review of the network and provide guidance on site selection. This resulted in the publication of formal UK SPA selection guidelines (JNCC 1999; Box 1) and a full review of terrestrial SPAs (Stroud *et al.* 2001).

The 2001 review was significantly different from previous reviews in that it approached site selection from a species perspective; site protection needs of both Annex I species occurring in the UK and other regularly occurring migratory species were assessed. Integral was the application of the UK SPA selection guidelines through a clearly defined decision-making process (Stroud *et al.* 2001). SPAs were not selected for Annex I or migratory species that are widely dispersed (and therefore deemed unsuitable for site-based conservation measures), but at least one SPA was selected for each of 103 species or biogeographical populations. The review assessed the protection requirements of each species or population in detail, and for each of these, derived a *suite* of SPAs accordingly. The overall UK *network* of SPAs is derived from the combination of all 103 suites for species or populations.

### THE UK SPA SELECTION GUIDELINES

The formal UK SPA selection guidelines (JNCC 1999) rely very much on the international precedence set by both the contemporary Ramsar Criteria and IBA Criteria, whilst taking into consideration the requirements of the Birds Directive and the desire for a more species-led approach. The UK SPA selection guidelines are not criteria – the application process is a two stage process, and it allows a degree of ecological assessment to inform the selection of the "most suitable" sites (see Box 1). Hence, the SPA suite for a particular species may not necessarily comprise all nationally or internationally important areas for that species, but may contain sites with fewer birds that have been added, for example, to improve coverage of a species' distribution.

### THE UK SPA NETWORK

The UK SPA network currently comprises 242 designated SPAs, and extends to more than 1 470 300 ha – about 6% of the UK's land surface. It includes suites of SPAs for 103 species or biogeographical populations, and incorporates 115 Ramsar sites.

The UK is of major international importance for several groups of birds. These include: breeding seabirds; wintering and

**Fig. 1.** The proportions of international populations of non-breeding waterbirds within the UK SPA network in relation to their occurrence in the UK (from Stroud *et al.* 2001). Solid line: linear relationship for Annex I species;  $y = 0.8743x - 0.0261$ ;  $R^2 = 0.9353$ . Broken line: linear relationship for non-Annex I migratory species;  $y = 0.6018x + 0.0044$ ;  $R^2 = 0.7029$ .

passage waterbirds; birds of Britain's distinctive uplands; and birds of Caledonian pinewoods. A high proportion (in some cases all) of the national and international populations of such species are contained within the UK SPA network. The habitat protection provided for these birds is a major contribution to their international conservation. Those species of greatest conservation concern in the context of the Birds Directive tend to have the highest proportions of their populations within the UK SPA network, as do those that have the smallest geographical ranges, and those where the UK holds a high proportion of international numbers (Fig. 1). Such figures allow an assessment of whether a network of sites is achieving its conservation aims in terms of providing a sufficient extent and geographical range of habitats for any given species.

The UK is of outstanding international importance for its waterbird populations, a consequence of its mild winter climate and strategic location on migratory flyways. In the mid-1990s, the SPA network supported an average of over 2 186 000 non-breeding waterbirds, approximately 40% of all waterbirds present in the UK in mid-winter. Fifty-seven sites of importance for assemblages of over 20 000 non-breeding waterbirds have been selected. In addition, a further 62 SPAs support internationally and/or nationally important numbers of waterbirds.

The performance of the UK SPA network for non-breeding waterbirds has been assessed and shown to be good (Jackson *et al.* 2004), but can be demonstrated more generally by a brief review of a few examples. Many species have high representation in the UK SPA network, with sites meeting most of the species' needs. For example, the network supports over 60% of the British breeding population of Black-throated Divers *Gavia arctica*, with sites providing nesting, roosting and feeding requirements during the breeding period. A number of waders

are well represented in the non-breeding season, such as the Bar-tailed Godwit *Limosa lapponica*, Dunlin *Calidris alpina alpina*, Red Knot *Calidris canutus* and Grey Plover *Pluvialis squatarola* for which the UK SPA network supports 70-90% of the British populations. In the case of the Annex I listed Bar-tailed Godwit, the network supports around 40% of the *lapponica* subspecies. For these species, SPAs include both feeding and roosting habitats, and so meet the birds' ecological needs during migration and in winter.

SPA provision in the UK for the Icelandic population of the Pink-footed Goose *Anser brachyrhynchus* is a good example of how a network of protected sites can make a significant contribution to the conservation of a species' population. This non-Annex I migratory population winters almost exclusively in the UK and is highly aggregated: 24 SPAs have been selected for it, supporting approximately 80% of UK numbers and 70% of the biogeographical population. Birds have been shown to use these SPAs as a true network, taking advantage of the different sites within the suite as they make seasonal movements to alternative feeding areas (Mitchell & Hearn 2004). The level of representation of the species in the UK network can be considered to be adequate, and the need for additional sites, given the current quality of habitats in the network and behaviour of the population, to be unnecessary. Hence, in this respect the network meets the requirements of Article 4 of the Birds Directive. However, these figures could be considered to be misleading in the sense that the focus of site protection for the species is primarily to provide safe roosting areas; the suite contains very little foraging habitat, which for this species is primarily intensively managed farmland. The designation of SPAs to include such habitat may not be appropriate, given that the species has been highly adaptable to changes in agriculture over the last 40 years and has

derived significant benefit from this (Mitchell & Hearn 2004, Fox *et al.* 2005). To achieve a coherent ecological network for this species, a complementary approach to SPA designation of some form of wider landscape management that would ensure the perpetuation of suitable foraging areas, and access to them, may be more effective. Defining disturbance-free feeding zones around the sites within the network, and possibly also corridors (in the form of daytime resting places), could be beneficial in such a landscape approach. However, there is no defined mechanism for this kind of approach within the Birds Directive, although Article 3 could be interpreted as seeking the establishment of protected areas with a less strict level of protection than Natura 2000 sites. Other mechanisms may also be available to ensure that feeding areas have some degree of protection, such as agri-environmental provisions. For such species, including many other Anatidae, it may be that agri-environmental policies should aim to define a certain overall *extent* of feeding habitat within a defined distance of major roosts without being overly concerned about specific feeding locations. However, further assessment of the protection requirements of foraging habitats for those species using arable crops is required.

Not all species are as well represented within the UK SPA network, for a number of reasons. For example, less than 5% of British Mallards *Anas platyrhynchos* occur within the SPA network (representing less than 1% of the biogeographical population) due to the species being more widely dispersed during the non-breeding period. The contribution that protected sites can make to the conservation of dispersed species will be small, and wider countryside measures become of primary, but complementary, importance. The concept of a coherent ecological network for the conservation of such species must be developed at landscape-scale.

Overall, the terrestrial component of the UK SPA network is considered by the UK government to be substantially complete and the representation of each species within the network to be, in the majority of cases, at a sufficient level to meet the objectives of Article 4 of the Birds Directive. However, as no quantitative targets are set by the Birds Directive and few studies of conservation strategies for birds have been made that define optimal levels of site protection, there is no contemporary guidance on acceptable levels of population representation in the network. There have been previous attempts to define target ranges for species representation in a network of protected sites (e.g. Stroud *et al.* 1990, based on Bezzel 1980), but the final ranges produced remain arbitrary. Nevertheless, this kind of approach, which uses variables such as range occupancy, abundance, trends and international responsibility to highlight levels of high, moderate and low provision, seems intuitively useful. Furthermore, setting levels of population representation to assist in selecting networks of protected sites has been shown to be an effective approach (Jackson *et al.* 2004). Further refinement of a target-setting approach for population representation, based on testing of outcomes, would perhaps provide a simple and meaningful way to guide the definition of national and international networks.

Utilizing the standard Natura 2000 data submitted by Member States to the European Commission (available from the European Topic Centre on Biological Diversity), it is possible to begin to develop an understanding of how the overall European SPA network contributes to the conservation of populations. For example, there have been at least 235 SPAs designated for

Bewick's Swan *Cygnus columbianus bewickii* throughout the EU15. Numbers peak in eastern European sites in autumn and spring, as birds migrate through the Baltic countries, and in western European sites, in winter. The UK has designated 15 SPAs for this population, and these support over 95% of British numbers and around 30% of the biogeographical population. However, it is difficult to assess the degree to which the EU15 SPA network provides support for this population from the standard data alone. The development of meaningful evaluation techniques, at population level, of the Natura 2000 network is essential, but to ensure that this network meets its objectives, the component national networks need to be of a sufficient standard. However, national action must be placed within the context of the full range of the species, especially for migratory species. Clearer approaches to target setting for national networks and guidance on achieving a coherent European ecological network is essential if SPA provision is to be a truly effective conservation tool at pan-European level. The long-term performance of the network will ultimately be assessed by the conservation status of the populations concerned.

## THE FUTURE DEVELOPMENT AND MONITORING OF THE UK SPA NETWORK

The 2001 UK SPA review highlighted cases where current data are inadequate to allow the selection of SPAs for certain species or at certain times of the year. These include sites for gulls and raptors in winter, and for mixed populations of passage waders. In addition, the review had a terrestrial focus, and a separate review process has been initiated for birds in the marine environment.

The UK government established a post-review scientific consultative group in 2001 (UK SPA and Ramsar Scientific Working Group – see <http://www.jncc.gov.uk/page-1770> for more information) to advise it on the development of the SPA network, its monitoring and management. This group includes representatives from the government, non-governmental conservation organizations, and land and marine industrial sectors. One of the group's work areas is to review the importance of cropped habitats as feeding areas (for species such as the Pink-footed Goose) and evaluate possible approaches to the conservation and management of these areas in the context of the Birds Directive. Another area of work is to develop further a target-setting approach for population representation that may aid in further assessment and development of the SPA network.

The establishment of a network of SPAs must be accompanied by effective monitoring and management. EU Member States are obligated to avoid both the deterioration of habitats within SPAs and significant disturbance to the birds using these sites.

Monitoring protocols for SPAs, termed "Common Standards Monitoring", have been developed in the UK: all qualifying species will be monitored on each SPA at least once every six years (JNCC 2004). The aim is to provide an "alerts" type system which warns of unfavourable changes in the condition of the qualifying bird features, the causes of which can then be further explored and site management modified if appropriate (see Austin *et al.* 2006). Standardized monitoring of birds is already in place for many sites, with national schemes, such as the BTO/WWT/RSPB/JNCC Wetland Bird Survey for waterbirds, providing regular counts of birds, and in some cases trends, in many SPAs. Such schemes are heavily reliant on the

considerable efforts of volunteer bird-watchers, and both major non-governmental conservation organizations and the government have aided the development of such monitoring capacity. However, some sites are infrequently monitored, especially those in remote areas, and for these, the Common Standards Monitoring approach (JNCC 2004) will provide a valuable opportunity to enhance the collection of information and use this to better focus the conservation management of individual SPAs. It will also allow periodic assessment, at national network scale, of the continuing effectiveness of SPAs in contributing to the conservation of certain bird populations.

## CONCLUSIONS

The UK Special Protection Area network comprises 242 designated sites, with suites of sites for each of 103 bird species or populations, and extends to about 6% of the UK's land area (Stroud *et al.* 2001). A species-based approach to building the network has allowed the selection of sites that not only support large numbers of birds, but are also sufficient to maintain species' ranges within the UK. Although substantially complete in the terrestrial environment, the network remains in development and SPA provision for birds in the marine environment is the current priority for such development. The key challenge remains understanding when the network is sufficient to meet the conservation needs of a species in the context of the species' ecology and other complementary measures. We believe that a species-based approach is intuitively the best way to build a coherent network, but recognize that setting targets is conceptually and scientifically difficult to do and that sufficiency is likely always to be measured in terms of scientific judgement; this should not detract from striving to create effective protected site networks.

Cranswick, P.A., Denny, M.J.H., Hearn, R.D., Mitchell, C.R., Robinson, J.A., Rowell, H.E., Ward, R.M. & Worden, J. 2006. Waterbird Review Series: site inventories for swan and goose populations in Britain and Ireland. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 680-681.

Great Britain is of major importance for many populations of swans and geese, supporting during winter five entire or near-entire biogeographical populations, and a significant proportion of a further six (Table 1). A long-history of wildfowl (Anatidae) monitoring in Britain, particularly by The Wildfowl & Wetlands Trust (WWT) and supported by the Joint Nature Conservation Committee (JNCC) and its predecessor organisations, has developed into a programme of targeted surveys for these populations. Detailed information on the numbers and trends of these species at their key haunts is vital to the conservation and management of these populations at site, national and international levels. The need for national inventories is widely recognised by international conservation agreements and single species management plans; for example, the UK implementation plan for the African-Eurasian Waterbird Agreement specifically identifies the need for waterbird inventories to underpin habitat conservation. The Waterbird Review Series provides a comprehensive tool for conservation practitioners and decision makers, whether working at international level or as site managers.

The Waterbird Review Series brings together up to four decades of data and knowledge from the long-term monitoring programmes of swan and migratory goose populations that winter in Britain and Ireland. In each review, introductory sections describe abundance, distribution and ecology, particularly in Britain and Ireland but also throughout the population's range. Central to each review is a detailed inventory of impor-

tant sites. Population numbers and trends are presented (e.g. Fig. 1) along with a summary of site protection status, habitats and site usage by the population. Information is provided for all sites of international and national importance in the late 1990s, but also for sites of former importance where numbers have since declined. An overview of historical importance is provided at a regional level. The reviews demonstrate the value of long-term monitoring programmes, particularly in being able to highlight the dynamic distributions of many of these species, their expansion into new areas, their declines in others and, in some cases, apparent switching between favoured roost sites at a local scale.

Fig. 1. Bewick's Swans at the Ouse Washes: peak counts (bars) and British index (line) 1960/61-1999/2000

**Table 1.** Native swan and goose populations occurring in Britain: 'Estimate' is the number of birds in Britain except for East Canadian High Arctic Light-bellied Brent Geese, where the estimate is for birds in Ireland.

Species/sub-species	Population/race	Estimate	% of flyway population
Mute Swan <i>Cygnus olor</i>	Britain	37 500	100
Whooper Swan <i>Cygnus cygnus</i>	Iceland	5 720	27
Bewick's Swan <i>Cygnus columbarius bewickii</i>	NE Europe	8 070	28
Taiga Bean Goose <i>Anser f. fabalis</i>	<i>fabalis</i>	400	<1
Tundra Bean Goose <i>Anser fabalis rossicus</i>	<i>rossicus</i>	100	<1
Pink-footed Goose <i>Anser brachyrhynchus</i>	Greenland/ Iceland	241 000	100
Greenland White-fronted Goose <i>Anser albifrons flavirostris</i>	<i>flavirostris</i>	20 900	77
European White-fronted Goose <i>Anser a. albifrons</i>	Baltic/North Sea	5 790	<1
Greylag Goose <i>Anser anser</i>	Iceland	81 900	100
Barnacle Goose <i>Branta leucopsis</i>	E Greenland	45 000	83
Barnacle Goose <i>Branta leucopsis</i>	Svalbard	22 000	100
Dark-bellied Brent Goose <i>Branta b. bernicla</i>	W Siberia	98 100	46
Light-bellied Brent Goose <i>Branta bernicla hrota</i>	Svalbard/N Greenland	2 900	58
Light-bellied Brent Goose <i>Branta bernicla hrota</i>	East Canadian High Arctic	20 000	100

These reviews have highlighted the need for continued and enhanced monitoring, particularly of demographic variables such as productivity and survival, in order to track changes more closely, particularly at a site level, and to understand the processes driving changes at a population level. Although the reviews focus upon wetland sites, many swan and goose species also use semi-natural and agricultural habitats, but systematic information on the use of these areas is lacking for most sites. This remains a priority area for future surveys in order to relate feeding areas to roost sites, to understand the changing distributions of these species, and to enable effective conservation and management. The Waterbird Review Series is available on WWT's web site: <http://www.wwt.org.uk/monitoring/waterbirdreviews/>.

## ACKNOWLEDGEMENTS

The largest thank you is to the many thousands of counters, mostly volunteers, who have contributed the vast amount of data upon which these reviews are based. Without such skilled and dedicated people, these reviews would not have been possible.

Many people, too numerous to mention here, contributed towards the production of the Waterbird Review Series, but special thanks go to Helen Baker, David Boertmann, Hugh Boyd, Allan & Lyndesay Brown, Preben Clausen, Kendrew Colhoun, Gudmundur A Gudmundsson, Paul Marshall, Graham McElwaine, Oscar Merne, Eileen Rees, Chris Spray and David Stroud. The Waterbird Review Series was funded under the WWT/JNCC Partnership.

In winter, the UK supports the entire Svalbard population of Barnacle Goose *Branta leucopsis* and over 80% of the east Greenland population. The conservation and appropriate management of their key sites is critical to the long-term viability of these populations. Photo: Paul Marshall.

## The Western Hemisphere Shorebird Reserve Network (WHSRN)

Charles D. Duncan

Manomet Center for Conservation Sciences, 76 Emery Street, Portland, Maine 04102, USA. (email: [cduncan@manomet.org](mailto:cduncan@manomet.org))

Duncan, C.D. 2006. The Western Hemisphere Shorebird Reserve Network (WHSRN). *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 682-686.

### ABSTRACT

The Western Hemisphere Shorebird Reserve Network (WHSRN) is a voluntary coalition of people and communities linked through association with sites that host biologically important numbers of shorebirds. WHSRN's mission is to protect shorebird species through a network of key sites in the Americas. The focus is on site-based actions, particularly actions that can best be accomplished through a network of partners acting in concert. The Network was started in 1985 and now includes 60 sites in eight countries, with some 250 partner organizations, representing approximately eight million ha. Sites qualify at one of three levels: "hemispheric" (used by over 500 000 shorebirds per year, or at least 30% of a flyway population), "international" (over 100 000 per year, or at least 10%) or "regional" (over 20 000 per year, or at least 5%). In all cases, a site's landowners must agree to its inclusion in the Network before it can be accepted. Recent data indicating rapid declines in the populations of many shorebird species suggest that many additional sites need to be protected and included within the Network. Targeted conservation actions for species undergoing steep declines, having small populations, or otherwise at risk, are urgently needed. WHSRN has recently completed a thorough review of its mission, conservation vision, and strategy, including goals and objectives, for 2004-2008. With these has come a new organizational structure of nested geographic councils. The Network's Office continues to be a program of the Manomet Center for Conservation Sciences. Tasks ahead for the Network and a summary of lessons learned since the Network's founding are presented.

### HISTORY

The Western Hemisphere Shorebird Reserve Network (WHSRN) is one of the oldest flyway-scale conservation organizations. It traces its origin to a proposal by Guy Morrison of the Canadian Wildlife Service (CWS) for an international "series of protected areas linking key sites" for shorebirds throughout their range, made in 1982 at an International Waterfowl and Wetlands Research Bureau (IWRB) symposium (Morrison *et al.* 1995). The original concept, for totally protected "sister parks," was intimately connected with the CWS atlas work being carried out by Morrison and Ken Ross to quantify the use of the South American "wintering" grounds by shorebirds breeding in Canada, as well as with work of the International Shorebird Surveys operated out of Manomet Observatory (now Manomet Center for Conservation Sciences, and hereafter simply "Manomet"). The idea was developed with Morrison and other researchers by J.P. Myers, first at the Philadelphia Academy of Natural Sciences and then at the National Audubon Society.

Myers and Pete McLain (of the New Jersey Department of Fish, Game and Wildlife, USA) presented the idea to the International Association of Fish and Wildlife Agencies (IAFWA) in 1985. IAFWA adopted the plan and pledged to

collaborate with the World Wildlife Fund-US (WWF) in advancing the network, by then formally named WHSRN (Myers *et al.* 1987). This was a key step because it brought the concept to the attention of a wide variety of wildlife managers across North America and served as justification for work on shorebirds (Morrison *in litt.* 2004). Other organizations, including Audubon, CWS, and Manomet, soon joined with IAFWA and WWF.

WHSRN was the first hemispheric system of linked reserves to protect important shorebird habitats. Fittingly for a Network concerned about protection of stopover and staging areas, hemispherically important Delaware Bay, USA, was the first site accepted into the Network. The site was nominated by the governors of the states of New Jersey and Delaware; it was declared in November 1985, and dedicated at a ceremony on 21 May 1986.

From the first, WHSRN's governance has consistently been through a voluntary, representative Council. The first Council meeting included representatives from the U.S. Fish and Wildlife Service (USFWS), CWS, the Suriname Forest Service, Manomet, the University of Córdoba, Argentina, and IAFWA. Many of these have been key institutional partners and leaders throughout WHSRN's history. Many other organizations have also made important contributions, especially at the regional level, both in recruiting and supporting site nominations and in expanded shorebird conservation actions. WHSRN's Office, under a variety of names, has been variously housed over the years at the following organizations and locations: Wildlife Habitat Canada (Ottawa); Buenos Aires, Argentina; National Audubon Society (New York City, USA); and Manomet (Massachusetts, USA).

### Site criteria

Sites qualify for inclusion in WHSRN in one of the following three categories:

- Regional significance: at least 20 000 shorebirds per year, or at least 5% of a flyway population for a species;
- International significance: over 100 000 shorebirds per year, or at least 10% of a flyway population; or
- Hemispheric significance: over 500 000 shorebirds per year, or at least 30% of a flyway population.

To qualify, sites must also have the explicit agreement of the landowner(s) and their commitment to:

- make shorebird conservation a priority at the site;
- protect and manage habitat for shorebirds; and
- update the Network at least annually of any changes in the site's status or contact information.

While many sites represent discrete sections of beach or coastline, others, such as Delaware Bay, comprise much larger land-

scapes. The only requirement concerning the scale of a site is that the number of landowners be such that the Network can communicate with them all and that all have agreed to be enrolled. A complete listing of current sites is available at Manomet's web-site.

Despite the Network's activities to date, the populations of many shorebird species continue to decline. The United States Shorebird Conservation Plan (USSCP) has shown that 22 of North America's shorebird taxa are in significant decline (Brown *et al.* 2001), and the International Wader Study Group has concluded that 48% of the world's shorebirds with known population trends are declining, while only 16% are increasing (International Wader Study Group 2003, Stroud *et al.* 2006). Analysis of migration data from eastern North America shows that nine species are declining and none is increasing. Most severely among these, the American Golden Plover *Pluvialis dominica* was found to be declining at a rate of 7.2% annually (Bart *et al.* 2004).

## THE NEW STRATEGY

As a result of these and other realities, a thorough re-examination of the Network's purpose and structure was initiated in May 2003. This strategic planning process sought to ensure that the Network adapted to changes since its creation, and to craft a strategy for the ensuing five years aimed at halting and even reversing the negative population trends. The review began as a series of discussions among many individuals who have been close to WHSRN and to shorebird conservation over a number of years. A day-long session, held at the VIIth Neotropical Ornithological Congress in Puyehue, Chile, in October 2003 and attended by 43 participants from 14 nations, was of inestimable value in creating the draft plan. The draft was then made available for review on the Internet. Comments received were considered before the preparation of the final version by WHSRN staff. The final document, available in English and Spanish at Manomet's web-site, outlines WHSRN's mission, vision, goals, and operating strategy in the context of the current state of shorebird conservation, including that for individual species, as well as conservation programs that may have overlapping goals. The Strategic Plan for 2004-2008 was adopted by the WHSRN Council in April 2004.

## Mission and guiding principles

WHSRN's mission, as refined during the creation of the Strategic Plan, is the conservation of shorebird species and their habitats across the Americas through a network of key sites. Two critical words in this mission statement are "network" and "sites." WHSRN seeks to accomplish shorebird conservation by engaging in actions collaboratively, actions that no one site could undertake on its own, but where a collection of sites – a network – can achieve results. Similarly, WHSRN emphasizes activities that are site-based rather than trying to be involved in all aspects of shorebird conservation.

WHSRN has five guiding principles:

- Site designation and conservation action are based on the best available scientific and other information.
- Site-based conservation is the centerpiece for accomplishing WHSRN's mission within the larger ecological context of each site.
- Traditional and local ecological knowledge and cultural practices are recognized, valued and respected.

- Integration and collaboration at local, national and international scales both within the Network and with other conservation groups and programs enhance WHSRN's capacity to achieve its vision.
- Communication and voluntary partnerships are key to an effective network and achieving common conservation goals.

## Strategy

Many species of shorebirds are highly migratory and often highly concentrated at a small number of places. Their vast breeding grounds and the remote areas where they spend their non-breeding season both face severe threats. The underpinning of WHSRN's conservation strategy is two-fold. First, shorebird conservation requires site-based action at a grand, indeed, hemispheric, scale. Second, the power of WHSRN is the power of co-operation: to accomplish goals as an alliance of partners which could not be achieved by the sum of the separate efforts of these people and organizations. Thus, the goals and objectives developed in the Strategic Plan were selected for being site-based and best accomplished through a network of partners acting in concert.

These two criteria also define what WHSRN is not. WHSRN's role is not to be the be-all and end-all of shorebird conservation. It is not, for instance, a designer of monitoring schemes, nor primarily a group lobbying for increased funding or legislative changes. Instead, WHSRN seeks opportunities where its own efforts can support other groups that do such work, including the several national shorebird conservation plan councils. Similarly, there are many times when the goals of these groups and councils can best be accomplished through WHSRN's network of sites. Thus, collaboration and communication among all members of the conservation community is a requisite for all of WHSRN's efforts.

## Goals and objectives

WHSRN's new Strategic Plan established four major goals for 2004-2008, as follows:

- A. Conservation Planning: Ensure that the Network's conservation actions are the effective and appropriate application of the best available information.
- B. Conservation Action: Implement shorebird conservation action at Network sites throughout the Americas.
- C. Shorebird Conservation Communities: Create and maintain informed, involved, empowered and interconnected human communities at Network sites.
- D. Strengthening the Network: Become the strongest network of sites possible to meet the challenges and threats to shorebirds.

Within each goal, specific objectives with measurable outcomes have been defined. These objectives form the basis of the Network's activities over the coming five years. The activities will be the responsibility of the several governing bodies and implementing groups, described below.

## Related programs

WHSRN, of course, is not the only conservation program that focuses its attention on sites. The 1971 Ramsar Convention on Wetlands predates WHSRN significantly and has a global reach.

Several “Important Bird Area” (IBA) programs have also been created to identify sites and lend support for conservation, with that of BirdLife International having the greatest geographic coverage. The East Asian-Australasian Shorebird Site Network, started in 1996, applies WHSRN’s approach to its own geographic area. While these programs have their own sets of criteria, they are, broadly speaking, entirely compatible with WHSRN’s approach. In fact, it will be the rare exception when a WHSRN site would not also qualify as a Ramsar site or as an IBA. (One unlikely case might be where a WHSRN site supports large numbers of shorebirds of several species, but where no one species reaches the IBA criterion). In recognition of the complementarity of missions and approaches, senior staff members from these programs have been invited to serve on the WHSRN Hemispheric Council. Within the Western Hemisphere, Ramsar, BirdLife, and WHSRN have begun to cooperate more closely in the identification, designation, and conservation-planning of new sites.

### Organizational structure

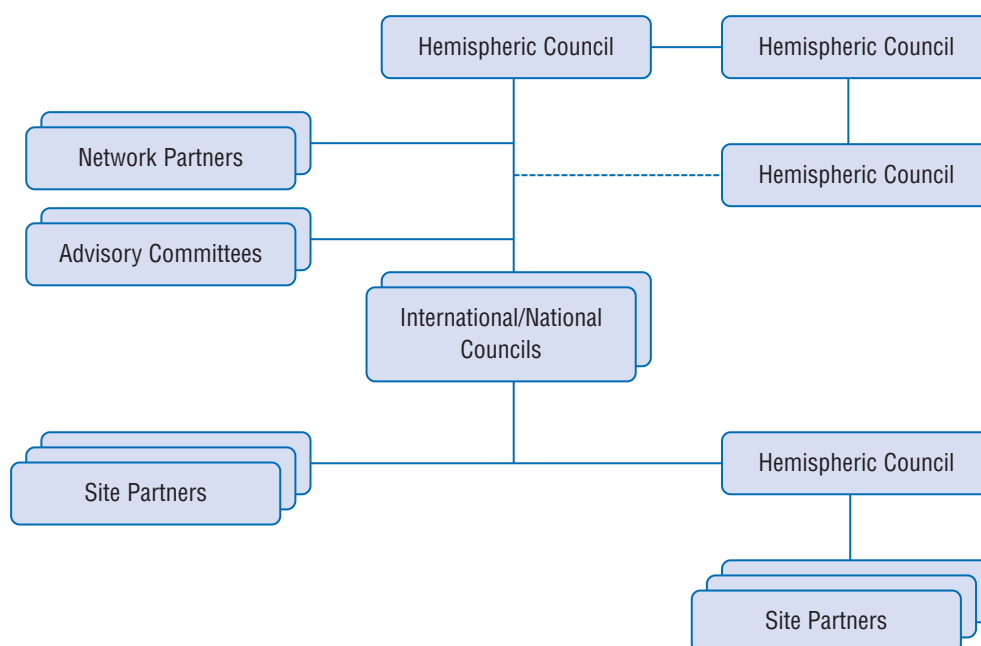

While the sites are the backbone of WHSRN, three groups are critical for the implementation of the five-year strategy, as well as longer-term plans. These are: Site Partners, the people on the ground at each WHSRN site; Network Partners, the organizations that support the Site Partners and the Network overall; and the Advisory Committees. In this last category is the Scientific Advisory Committee, providing scientific support to both Members and Partners.

Leadership of WHSRN is implemented at several scales. The WHSRN Hemispheric Council is the body responsible for the strategic direction of the Network and matters affecting the WHSRN program as a whole. The Hemispheric Council works closely with Manomet, the anchoring institution. National Councils design and implement pertinent activities that contribute to the achievement of the Network’s mission. Communication among the several components and levels of WHSRN’s structure is a shared responsibility of all participants. The new Network structure, schematized in Fig. 1, is designed specifically to serve the conservation needs of the Site Partners and to de-centralize other activities, such as identification and enrollment of new sites.

The WHSRN Office provides executive staff and services to the Network’s Members, Partners, governing Councils, and the Scientific Advisory Committee, for the implementation of the Strategic Plan and work programs. The staff is employed by Manomet, and supervised with input from the Hemispheric Council.

### Funding

Funding for specific projects continues to be obtained from grants and contracts with a variety of funding bodies including Manomet, as it has since WHSRN’s creation. The new strategy, however, contemplates that members of the Hemispheric Council will also have responsibility for ensuring that funds are available for WHSRN activities.

**Fig. 1.** The structure adopted by WHSRN to implement its 2004-2008 Strategic Plan.

### Notes:

1. International and National Councils are involved when the Site Partners and/or Network Partners within a nation or group of nations choose to create them.
2. Some Site Partners may work directly with an International Council (lower left branch), others with their respective National Councils (lower right).
3. National Councils for large and active nations may work directly with the Hemispheric Council. They may also choose to be affiliated with an International Council.
4. The WHSRN Office is a program of, and supervised by, Manomet, with input from the Hemispheric Council. It serves to support all elements of the Network.

## THE FUTURE

### Tasks ahead

The Western Hemisphere Shorebird Reserve Network has grown in an organic way with sites added where there has been a convergence of shorebird usage, willing owners, and an awareness of the Network's existence. The resulting distribution of sites has been heavily biased toward North America, with only nine of the 60 current sites in South America and only one in Central America. The present goal is to add sites based on their importance to shorebirds, rather than on geopolitical or cultural convenience.

The declines observed in some species are severe, and action is urgently required. The American Golden Plover *Pluvialis dominica*, for instance, is declining at 7.2% annually in eastern North America (Bart *et al.* 2004). WHSRN will emphasize protecting key sites as well as catalyzing site-based conservation action for species such as the American Golden Plover with small, declining, or threatened populations.

The Network's Office, working with the Hemispheric Council and the newly forming national councils, will take a pro-active approach to recruiting sites, particularly those that qualify as being of "international" or "hemispheric" importance. For many species, especially poorly known resident species and austral migrants, identifying these will involve the creation of working groups to establish species priorities and refine knowledge of their distribution throughout the annual cycle.

Management of WHSRN sites for shorebirds can benefit from application of a uniform analysis of the key threats and the sources of the threats that each site faces, followed by the design of conservation strategies to abate the threats. Evaluation measures permitting monitoring of progress toward threat reduction and achieving population goals must be determined *a priori*. Particularly important is the identification of multi-site and multi-scale threats that the Network may be able to address more efficiently than can managers of individual sites.

For those species already known to be of highest conservation concern based on prioritization schemes such as that of the USSCP (Brown *et al.* 2001) or BirdLife International (see website), WHSRN is working urgently with site partners. Examples include a tri-national project for the New World race of Red Knot *Calidris canutus rufa* in the USA, Argentina and Chile, and another to protect and manage wintering habitat for the Buff-breasted Sandpiper *Tryngites subruficollis* in Brazil, Uruguay and Argentina. Where species-specific working groups already exist, WHSRN will collaborate and seek to ensure that the geographic scope of their work covers the entirety of the species' range. Where such groups are lacking, WHSRN will seek to catalyze their formation and their functioning with the goal of rapid identification of an initial set of priority sites for conservation action and inclusion in WHSRN.

Many communities involved with WHSRN sites have expressed the need for educational and outreach material, and the Network has responded wherever feasible. WHSRN will continue to provide these information products, and indeed, seeks to refine them through analysis of the needs of target audiences, be they school groups, local or regional governments, park guards or people engaged in the eco-tourism industry.

### Lessons learned

Over the course of WHSRN's almost 20 years of existence, it has become evident that strong networks for flyway-scale

conservation have a variety of requisites. First among these, perhaps self-evidently, is the need for strong partnerships. An immediate corollary is a high degree of trust, and this must be consciously and actively built and maintained. International networks, by definition, involve people with distinct cultural, historical and, frequently, linguistic backgrounds. Every effort must be made to acknowledge these differences so that they do not impede progress toward the shared goals of the several partners. Typically this will mean that correspondence and other network documents, including web pages, should be translated into the appropriate languages.

Because flyway-scale conservation is inherently complex, and because the relationships of trust just described are not quickly built, it is imperative that rapid turn-over of staff be avoided. Generally this requires, at minimum, a stable base of core funding. Donors frequently like to give to "projects" where their contributions are felt to have immediate conservation impact. It is equally important to guarantee that stable structures and staffing be in place throughout the system to achieve the changes they seek to effect.

Building local capacity to protect and manage habitat at network sites is another crucial element. The designation of a site by an international network carries weight beyond what may be given to local efforts. Nonetheless, building lasting support in the host communities, adapting to changing conditions, and monitoring the effectiveness of conservation action is best done by people intimately familiar with the local situation. Progress toward the network's goals at the site will be greatly advanced if there is a mechanism to provide the training and other resources needed to people based there.

Accomplishing results at the level of biogeographical populations for highly migratory species such as shorebirds turns an old dictum on its head. To succeed globally, we need to think - and act - locally. If our goal is protecting global populations and even reversing declines, we must craft strategies that work at local levels. Frequently, well-designed measures of success that are applicable at the local level for monitoring progress toward the larger goal have been lacking. One reads proposals all too often that include "number of posters printed," or "number of meetings with local officials" among the standards by which it is proposed that the project can be evaluated. A needed conceptual advance is a way for locally applied projects to measure their progress and their contribution to population-level targets.

A collaborative network is only as effective as its communication tools. In this regard, current networks have tools that were inconceivable when WHSRN was started in 1985. Electronic mail and the now ubiquitous web-sites have facilitated communication on an unprecedented scale, and at a virtually instantaneous pace. Digital photography and spatially explicit tools such as geographic information systems affect the content of communications. The ways that ideas are presented affect how the ideas are conceptualized. There is no reason to imagine that such technological change in communication is ending, or even slowing down. Conservation networks need to plan, and budget, for rapid adoption of appropriate new communications technologies if they are to keep pace with the acceleration of threats to the species they hope to protect.

A crucial advance for shorebird conservation in the Western Hemisphere was the creation of national shorebird conservation plans in the USA (Brown *et al.* 2001) and Canada (Donaldson *et*

al. 2000). Prior to the creation of these plans, information on the sizes and trends of shorebird populations was fragmented and disorganized. The compilation of the best available knowledge in the plans allowed species to be ranked according to the degree of conservation concern, clearly indicating those that need the most immediate action by WHSRN and its partners. These compilations and syntheses need to be maintained and updated where already begun, and need to be expanded geographically to the entirety of the Western Hemisphere. WHSRN places a high priority on supporting and expanding the continuation of these scientific collaborations, as indicated under its “best available information” goal. Indeed, transparent, shared access to scientifically-sound conservation planning information is essential to the effective use of scarce conservation dollars.

Anahuac National Wildlife Refuge, Texas, was named a WHSRN site because of the high numbers of Whimbrels *Numenius phaeopus* that use it each April and May (> 2 000). These are presumed to be mostly or entirely of the *hudsonicus* subspecies and therefore >10% of the estimated biogeographic population of 18,000 for that subspecies. Photo: Paul Marshall.

## Conservation of waterbirds and wintering areas through Important Bird Areas in India

**M. Zafar-ul Islam**

Bombay Natural History Society, Hornbill House, Shaheed Bhagat Singh Road, Mumbai – 400 023, India.  
(email: zafar\_bnhs@rediffmail.com or zafarul@gmail.com)

Islam, M.Z. 2006. Conservation of waterbirds and wintering areas through Important Bird Areas in India. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 687.

India is among the top ten nations of the world for high levels of biodiversity. Its immense biological diversity represents about 7% of the world's flora and 6.5% of its fauna. It embraces 10 biogeographical zones and 26 biotic provinces (Rodgers *et al.* 2000). There are 614 amphibians and reptiles, 1 300 birds and 350 species of mammals in India. Among the larger animals, 173 mammals, 78 birds (BirdLife International 2001), and 15 reptile species are considered endangered. This large range of species inhabit the country's various habitats, from its crowded and colourful corals reefs to icy, alpine grasslands. However, there is very little information on the biology of the vast majority of these, many of which have not yet been named. Their value as sources of genes, food, medicine, or as essential parts of ecological systems, has been little assessed.

Wetlands in India include marshes, swamps, flood-plains, bogs, peatlands, shallow ponds, littoral zones of larger water bodies, tidal marshes etc., and are hugely diverse. But whether they are ponds, marshes, coral reefs, peatlands, lakes or mangroves, they all share one fundamental feature: the complex interaction of their basic components - soil, water, animals and plants. This feature fulfils many functions and provides many products that have sustained humans over the centuries. In India, wetlands are distributed in all the biogeographic regions and exhibit significant ecological diversity, primarily because of the variability of climate conditions and the changing topography. They provide a multitude of ecosystem services - including water purification; regulation of flow; fisheries; habitats for plants, animals and micro-organisms; opportunities for recreation and tourism; and so forth. Their hydrological processes buffer against such extremes as droughts and flooding. Many wetlands have been converted for agriculture, industry and settlements, some have been affected by industrial effluents, sewage, household waste and sedimentation due to degradation of catchments.

Indian wetlands support spectacular concentrations of wetland-dependent wildlife, such as the million or more shore-birds visiting Point Calimere Wildlife Sanctuary (Tamil Nadu), Chilika Lake (Orissa), Pitti Islands (Lakshadweep), and the islands of Gujarat.

BirdLife International, its UK partner, the Royal Society for the Protection of Birds (RSPB) and the designated partner in India, the Bombay Natural History Society (BNHS), have come together to establish the Indian Bird Conservation Network (IBCN), which includes NGOs and individuals wishing to contribute towards bird conservation in India. One of the aims of the Network is to identify and protect Important Bird Areas (IBA) throughout the country, and an IBA Programme was officially launched in March 1999. For identified sites, the IBA programme collects information including bird populations, conservation issues, management problems and threats. Through this

programme BNHS has been working on wetland conservation since 1999, and has been involved with activities such as water-bird counts, education and public awareness work, and lobbying with the government, at both Union and State level. There is now a fully-fledged, sustained conservation programme focusing on wetlands which has evolved from these initial activities.

Analysis of the 466 IBAs shows that 425 sites have globally threatened species, 205 sites hold restricted range species, and 99 sites qualify as biome restricted assemblages, and 136 sites fit in the congregatory criteria. Many sites fit more than one criterion, and some sites such as Keoladeo National Park and Chilka Lake qualify for all four criteria (Islam & Rahmani 2004).

Around 90% of IBAs in India are important for one or more of the 78 globally threatened species in India, and 47% for the 74 restricted range species found in India. Almost all IBAs fall under at least one biome and hold some of the 374 bird species that fall in the biome criterion. The IBAs are also important for congregatory terrestrial birds, wintering and passage waterbirds and breeding seabirds, and almost 17% of IBAs have been identified for these.

However, identification of these important areas is alone not sufficient to conserve India's biodiversity. Even many protected areas face serious conservation problems, despite their status. Also, very few of India's protected areas were chosen to specifically conserve birds. The IBA approach is one of the ways to conserve bird species through the protection or conservation of important sites.

Most of the Red Data Book species are distributed across the Indian sub-continent, with 17 migratory species and 57 others that seasonally migrate within India. Migratory species face severe threats from hunting and loss of habitat. To protect those that cross one or more border, where conservation deficiencies in one country will affect the measures undertaken by other countries, the Indian IBA program, together with the Convention on the Conservation of Migratory Species of Wild Animals (Bonn Convention) will try to facilitate international agreements between countries to protect and manage migratory species with an unfavorable conservation status.

Béchet, A., Germain, C., Amat, J.A., Cañas, C., Martos, M.R., Garrido, A., Baccetti, N., Dall'Antonia, P., Balkız, Ö., Diawara, Y., Esquerré, F.V. & Johnson, A. 2006. Metapopulation networks as tools for research and conservation: the Greater Flamingo *Phoenicopterus roseus* in the Mediterranean and West Africa. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 688.

Observations in the 1990s of Greater Flamingos *Phoenicopterus roseus* banded as chicks in France and breeding in Spain and Italy, suggested that the French population was not closed. Rather, flamingos breeding at different colonies of the western Mediterranean were part of a metapopulation, i.e. important exchanges of breeding waterbirds occur among colonies. To enhance understanding of the population dynamics of this species and to propose sound conservation planning, a network was developed of partners working on flamingos at their main breeding sites.

The Greater Flamingo network was initiated in 2002 through a workshop uniting French, Italian, Spanish and Turkish partners, with Mauritania joining the network in 2003. The broad objective of the network is to study environmental and individual factors influencing juvenile and adult dispersal in order to provide sound conservation planning at an appropriate scale. The network core is a database of 400 000 resightings of more than 30 000 flamingos banded in four countries (France, Spain, Italy, Turkey) and eight colonies. The database is in four languages (French, Spanish, Italian, English) with life histories in five languages (including Turkish). Resighting efforts are coordinated over critical time-periods according to a standardized seasonal sampling scheme.

The Greater Flamingo network surveys a total of 19 breeding sites in five countries (France, Spain, Italy, Turkey and Mauritania). Of these sites, 36% are in active salinas and their existence relies on continued salt production together with appropriate island and water management. The main threat for other sites is water shortage, due to conflicts between agricultural and environmental requirements.

In the western Mediterranean, the number of Flamingo colonies has increased in the last decade, as well as an overall increase of the breeding population and numbers of chicks fledged. This increase probably resulted from the dispersal of juveniles and adults born at the large colonies of Salins de Giraud (Camargue, France) and Fuente de Piedra (Andalucía, Spain) where breeding has occurred every year for 25 and eight years respectively.

We made the hypothesis that the distribution of breeding flamingos among colonies of the western Mediterranean was despotic, following an age-related behavioural dominance where old experienced birds breed at large and long-established colonies (Salin de Giraud, France and Fuente de Piedra, Spain) and younger birds breed at small and recently-established

colonies (Rendon *et al.* 2001).

We tested the prediction that flamingos hatched at the major breeding sites of Salin de Giraud and Fuente de Piedra would breed younger at the smaller colonies i.e. Saline di Comacchio, Italy (<1 000 pairs), Salinas de la Trinitat, Spain (<2 000) and Molentargius, Sardinia (<7 000) than at Salin de Giraud and Fuente de Piedra.

The breeding status of banded flamingos was assessed from a hide. The following categories of birds were considered as breeders (i) flamingos incubating an egg, (ii) flamingos incubating more than 48 hr on a nest, (iii) flamingos with a chick on a nest or (iv) flamingos feeding a chick.

Flamingos hatched at Fuente de Piedra and then breeding at Salinas de la Trinitat were the same age as those breeding at Salins de Giraud (G-test,  $G = 3.8$ ,  $df = 2$ ,  $P = 0.14$ ).

Flamingos hatched at Salin de Giraud and breeding at Salinas de la Trinitat tended to grow older with time ( $G = 16.5$ ,  $df = 9$ ,  $P = 0.056$ ) which could be a consequence of an ageing pool of breeders. Contrary to predictions, these flamingos were no younger than those breeding at Fuente de Piedra (all paired G-tests non significant). At Molentargius, no temporal trend could be detected and French flamingos were no younger than those breeding at Fuente de Piedra (all paired  $\chi^2$  tests non significant). Finally, at Saline di Comacchio, French flamingos observed breeding in 2002 were younger than those at Fuente de Piedra ( $G = 74.7$ ,  $df = 3$ ,  $P < 0.001$ ). In 2003, only nine French flamingos were observed breeding at Comacchio, yet the trend was the same as that observed in 2002 ( $G = 30.9$ ,  $df = 3$ ,  $P < 0.001$ ).

Our results suggest that the smallest colonies, such as Saline di Comacchio, could allow early recruitment of Greater Flamingos into the overall breeding population. This implies that small breeding sites could play a critical role in the metapopulation dynamics of the Greater Flamingos and should thus be included in conservation planning.

## The globally threatened Lesser White-fronted Goose *Anser erythropus* and Red-breasted Goose *Branta ruficollis*: current status and future priorities for the Ramsar site network in Europe and Asia

Sergey G. Dereliev

Bulgarian Society for the Protection of Birds/BirdLife Bulgaria, PO Box 50, 1111 Sofia, Bulgaria. (email: dereliev@gmail.com)

Present address: AEW Secretariat, Hermann-Ehlers-Str. 10, D-53113 Bonn, Germany. (email: sdereliev@unep.de)

Dereliev, S.G. 2006. The globally threatened Lesser White-fronted Goose *Anser erythropus* and Red-breasted Goose *Branta ruficollis*: current status and future priorities for the Ramsar site network in Europe and Asia. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 689.

The Lesser White-fronted Goose *Anser erythropus* and the Red-breasted Goose *Branta ruficollis* are both globally threatened species, both categorized as Vulnerable (VU) (BirdLife International 2004). The global population of the Lesser White-fronted Goose (LWfG) is currently estimated at some 25 000–30 000 individuals, with three biogeographical populations recognised – European, Siberian-Caspian and East Asian. The single population of the Red-breasted Goose (RbG) has declined between 2000 and 2003 by more than 70% from 88 000 birds, although in the last season observed there were >52 000 birds counted within the winter range, suggesting a slight recovery. Both species are strongly dependent upon wetlands for their flyways. This analysis assesses the extent to which the sites important for conservation of these two species are covered by the Ramsar Convention's network of Wetlands of International Importance ("Ramsar sites").

A literature review of 47 publications was used to identify important locations for these geese, which was then compared with Ramsar Sites information (www.ramsar.org). Only data from the last two decades (1982–2002) were used. Information was summarized by species and by country with: name of site, area (ha), Ramsar designation status (yes/no, ha), statutory protection status (yes/no, overlap), goose numbers (max, year), % of biogeographical population, and numbers of other goose species observed (max, year). This preliminary information was circulated to national experts to verify and add to or correct the list of sites and other data. Only Ramsar site designation Criterion 2 (threatened species) and 6 (>1% of biogeographical population) were used to assess sites' potential qualification for Ramsar site designation.

A total of 115 sites worldwide were identified where the RbG has been known to occur and 215 sites where LWfG have been known to occur. The largest number of sites was in Europe and the smallest number in E Asia. Of these sites, 65% (LWfG) and 70% (RbG) qualify for Ramsar designation either under Criterion 2 (predominantly for LWfG) or Criteria 2 and 6 (predominantly for RbG). However, for quite a large proportion of the sites, information is deficient.

Less than one third of all sites which appear to meet the Ramsar criteria for either of the two species have been desig-

nated as Ramsar sites so far. Of the sites which are lacking Ramsar designation, more than half for each species qualify under Criterion 2 only, i.e. are sites where no significant congregations (>1% of the biogeographical population) have been observed. However, even for those sites with Ramsar designation, about 50% have only part of the relevant area for geese designated: site extensions should be considered in these sites. Only a few sites have full protection (10% for RbG and 20% for LWfG), while around one third (LWfG) and more than half (RbG) are lacking any statutory designation.

Many of the sites as important for the LWfG or the RbG, are also significant for other species of geese: around 40% of the LWfG sites and 60% of the RbG sites qualifying for designation under Criterion 2 and/or Criterion 6.

A few sites are of outstanding importance for the survival and conservation of LWfG or RbG populations, in that they support >10% of the biogeographical populations. For LWfG there is one site in Russia for the European population; four sites in three countries (Kazakhstan, Russia and Iran) for the Siberian-Caspian population; and seven sites in two countries (China and Russia) for the E Asian population. For RbG there are 14 outstanding sites in five countries (Bulgaria, Romania, Ukraine, Kazakhstan and Russia) with particular concentrations along the W-NW Black Sea coast and in NW Kazakhstan.

Future priorities for the conservation of these globally threatened species should be:

- the accession of Kazakhstan, Turkmenistan and Iraq to the Ramsar Convention and designation of Ramsar sites for these goose species;
- full designation of all wetlands qualifying as Ramsar sites (70% of RbG and 75% of LWfG sites);
- extension of the partially designated Ramsar sites (55% of RbG and 45% of LWfG sites);
- full statutory protection of all sites (79% of RbG and 60% of LWfG sites currently lack partial or complete protection);
- focusing on securing the future conservation of the outstanding sites (supporting >10% of a population) as a matter of urgency and priority; and
- updating information on goose populations for all sites.

### ABSTRACT

The Siberian Crane *Grus leucogeranus* is a critically endangered species dependent upon shallow wetland habitats along its migration routes. Three routes are currently known: a West Asian flyway that leads from breeding grounds in Western Siberia to the Caspian lowlands of northern Iran; a Central Asian flyway connecting Western Siberian breeding grounds to the wintering site in northern India; and an East Asian flyway leading from Yakutia to the central Yangtze floodplain lakes in China. A UNEP/GEF project involving four countries (People's Republic of China, Islamic Republic of Iran, Republic of Kazakhstan and the Russian Federation) is being implemented under the co-ordination of the International Crane Foundation, and aims to conserve key wetlands along the West and East Asian flyways. The Siberian Crane is a large, attractive bird of great cultural significance to many of the peoples along these flyways, and is being used to generate public awareness and support for wetland conservation. The project addresses threats at 16 internationally important wetlands along the flyways, and seeks to secure their ecological integrity for the benefit of the wide range of flora and fauna that they support. The project has a major international component, improving co-ordination and strengthening capacity for flyway conservation efforts, and supporting international flyway conservation efforts within the framework of existing strategies and agreements. The project facilitates the development of networks of wetland sites in Asia, and provides resources and training for the conservation of selected sites within these networks.

### INTRODUCTION

Over the past 25 years, the International Crane Foundation (ICF) has been working with a network of experts in a number of Asian countries to discover basic information about the Siberian Crane *Grus leucogeranus*, including the location of its breeding grounds, the migration routes that it uses, and the range of threats that it encounters. This research has resulted in a good understanding of the life history of the species, which is briefly summarized here (for further information, see Sauey 1985 and Meine & Archibald 1996). More recent work giving the results of satellite-tracking studies for the eastern population has been published by Kanai *et al.* (2002).

The Siberian Crane is the most specialized of the cranes, utilizing shallow wetland habitats at all stages of its migration cycle. It is Critically Endangered (BirdLife International, 2001), with a world population of less than 3 000 individuals, the vast majority of which belong to the eastern population. While recent winter counts (January 2001 – December 2006) at Poyang Lake Basin have exceeded this number, the accuracy of these counts

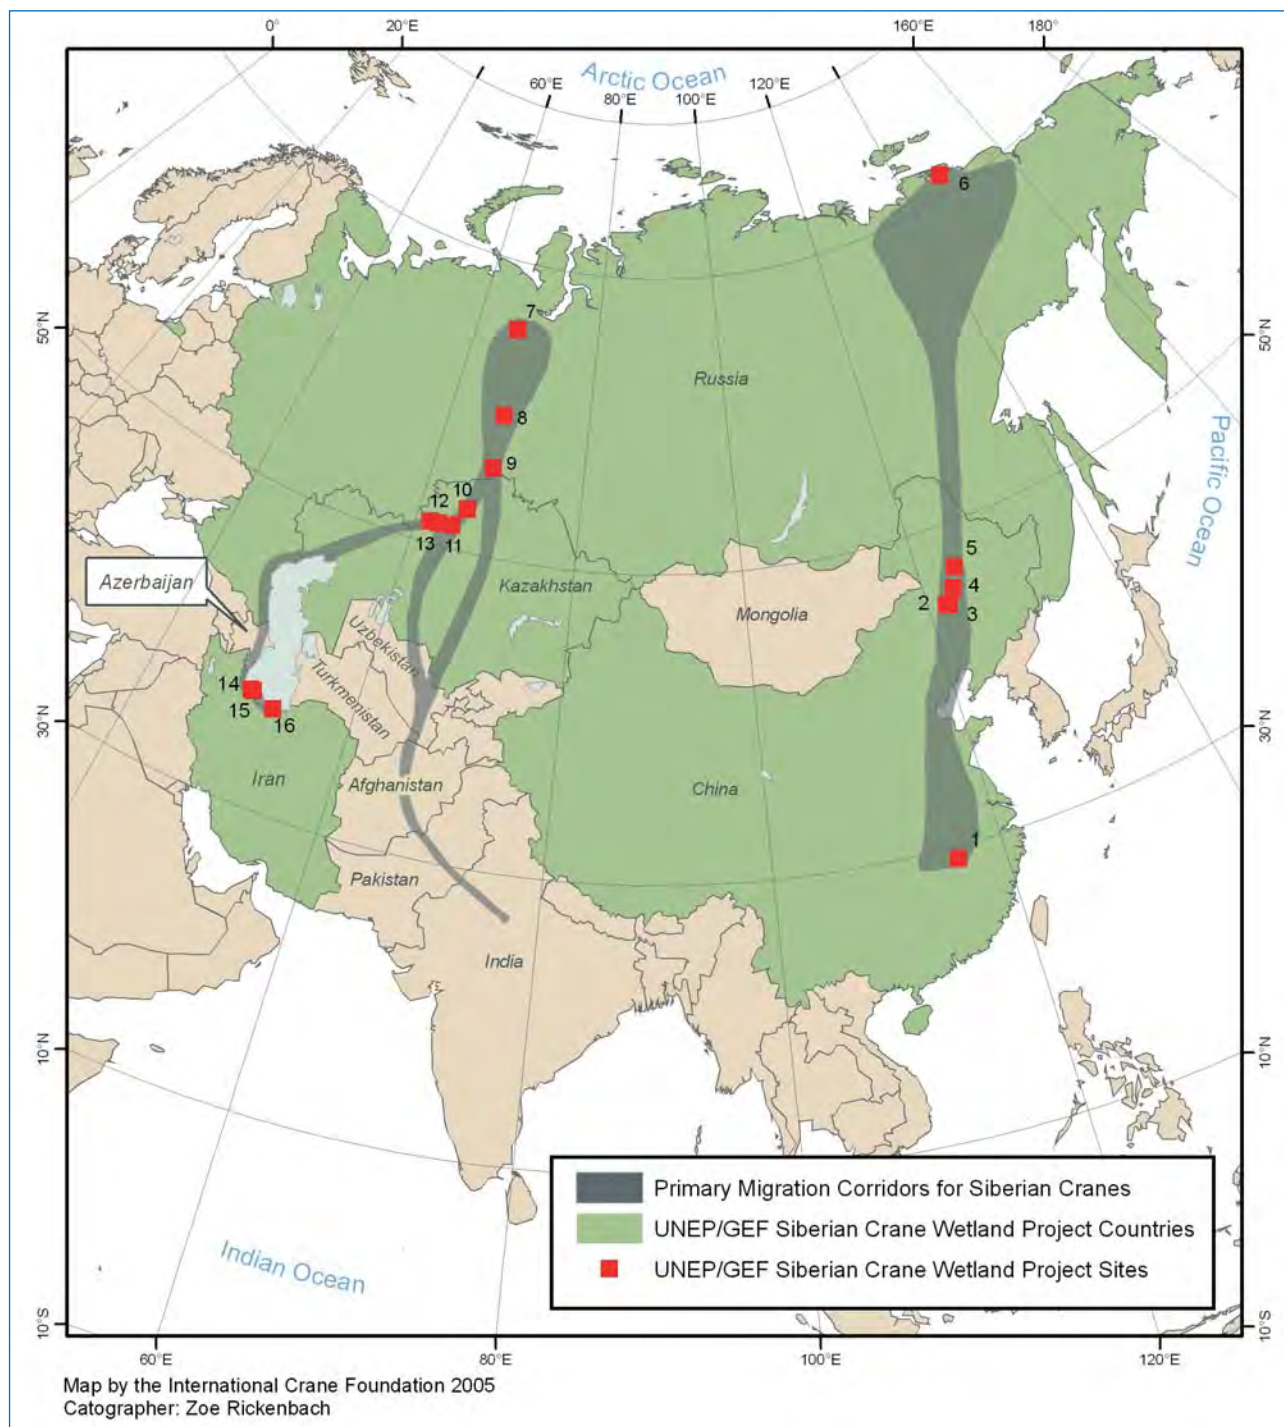

requires validation. The western population held between nine and 14 birds until the late 1990s, but has declined since then, with only two wild individuals being reported in winter 2005/6. The central population declined dramatically from perhaps 80 birds at the wintering site in the 1960s to a single pair in 2001. In the summer of 2002, a pair, presumably the same as that recorded in 2001, was observed for the last time on the breeding grounds in Russia. There have been unconfirmed reports, however, of several (four to seven) cranes in other areas within the breeding range of this population, and of a single crane along the migration route in Uzbekistan and Pakistan, and on the wintering grounds in India. The migration routes for the three populations are shown in Fig. 1.

Efforts for the conservation and recovery of this critically endangered species gained momentum in recent years through the Memorandum of Understanding concerning Conservation Measures for the Siberian Crane concluded under the Convention on the Conservation of Migratory Species of Wild Animals in 1993 (UNEP/CMS 2005). These measures have included substantial investment in captive-breeding programmes that support efforts to undertake re-introductions where population levels have declined to non-viable levels, in combination with habitat conservation and other measures.

### THREATS TO SIBERIAN CRANES AND THEIR WETLAND HABITATS

Due to the destruction and disturbance of key wetlands throughout Asia, numerous migratory waterbirds are in serious decline (APMWCC 2001, BirdLife International 2001). The deterioration in the integrity of wetland ecosystems and decline in waterbird populations are primarily due to the impact of human activities, including the killing and disturbance of waterbirds. The situation is extremely precarious for the Siberian Crane, necessitating urgent conservation measures: the bird itself, although protected throughout its range, relies on a series of shallow wetlands along its flyways that are under serious pressure from a range of human activities. Attrition of wetland habitat is a major phenomenon throughout Asia (for example, see Scott & Poole 1989). Threats at the local level include: over-utilization and disturbance from hunting, fishing, trapping, logging and grazing; reclamation for agriculture; overuse or diversion of water resources; development of oil and gas fields; construction of dams and other forms of river regulation; and degradation of watersheds. It should be noted that the types and levels of threat are highly site-specific, and that the risks posed by hunting also affect the birds outside their key sites.

The Siberian Cranes' wintering sites are used for prolonged periods and are most severely threatened due to high human popu-

**Fig. 1.** The west, central and east Asian migration routes of the Siberian Crane *Grus leucogeranus*, showing the locations of UNEP/GEF project sites along the west and east Asian routes.

lation density, habitat loss and disturbance. While the cranes can be concentrated into relatively small areas, changing hydrological conditions at Poyang Lake Basin in China often require the flocks to move to different locations during the winter or between different years. Wintering Siberian Cranes are territorial at Fereydoon Kenar in Iran and defend scarce resources; thus this small site can support only a few families. Alternate wintering sites in the Caspian lowlands must be identified and protected. The cranes' energetic balance on departure for spring migration can have an impact on breeding success, a factor largely determined by the quality of over-wintering habitats (Chavez-Ramirez 1996). In some Arctic-breeding goose species, there is evidence

that spring feeding conditions on the over-wintering grounds and migration staging areas affect breeding performance (for instance, in Barnacle Geese *Branta leucopsis* and Brent Geese *B. bernicla*). While multiple factors such as wind conditions during northward migration and predation by Arctic Foxes affect reproductive success in Brent Geese, heavier female birds in spring are more likely to return to the wintering grounds in autumn with offspring (Ebbinge 1989, Ebbinge & Spaans 1995, Prop & Black 1998). Maintaining the feeding quality of habitats used during the over-wintering and spring migration periods should therefore be carefully considered in site management for migratory waterbirds such as the Siberian Crane.

**Table 1. Protection status and international significance of wetlands selected as UNEP/GEF project sites.**

Country	Site name (numbers refer to points in Fig. 1)	International recognition & designations	National protection status	IUCN protected area category	Globally threatened and near threatened bird species recorded at sites. (see Table 2 for scientific names).
China	1. Poyang Lake Basin (Jiangxi)	Ramsar (part), NEACSN, Global 200 Ecoregion, AWI, IBA	NNR (part), MAB network site	IV (part)	Dalmatian Pelican, Oriental White Stork, Black-faced Spoonbill, Lesser White-fronted Goose, Swan Goose, Baikal Teal, Mandarin Duck, Baer's Pochard, Scaly-sided Merganser, Greater Spotted Eagle, Imperial Eagle, Siberian Crane, Hooded Crane, White-naped Crane, Swinhoe's Rail, Great Bustard, Grey-headed Lapwing, Saunders's Gull, Japanese Marsh Warbler.
China	5. Zhalong Nature Reserve (Heilongjiang)	Ramsar, AWI, NEACSN, IBA	NNR	IV	Oriental White Stork, Black-headed Ibis, Swan Goose, Lesser White-fronted Goose, Baikal Teal, Baer's Pochard, Greater Spotted Eagle, Siberian Crane, Hooded Crane, Red-crowned Crane, White-naped Crane, Swinhoe's Rail, Great Bustard, Grey-headed Lapwing, Far Eastern Curlew, Asian Dowitcher, Japanese Marsh Warbler.
China	3. Xianghai Nature Reserve (Jilin)	Ramsar, AWI, NEACSN, IBA	NNR, MAB network site	IV	Oriental White Stork, Swan Goose, Lesser White-fronted Goose, Baikal Teal, Baer's Pochard, Steller's Sea Eagle, Greater Spotted Eagle, Lesser Kestrel, Siberian Crane, Hooded Crane, Red-crowned Crane, White-naped Crane, Great Bustard, Grey-headed Lapwing, Far Eastern Curlew, Asian Dowitcher, Jankowski's Bunting.
China	4. Momoge Nature Reserve (Jilin)	AWI, IBA	NNR	IV	Oriental White Stork, Swan Goose, Baer's Pochard, Siberian Crane, Hooded Crane, Red-crowned Crane, White-naped Crane, Great Bustard, Grey-headed Lapwing, Far Eastern Curlew, Asian Dowitcher.
China	2. Keerqin Nature Reserve (Inner Mongolia)	AWI, IBA	NNR, MAB network site	IV	Oriental White Stork, Swan Goose, Baer's Pochard, Greater Spotted Eagle, Siberian Crane, Hooded Crane, Red-crowned Crane, White-naped Crane, Great Bustard, Grey-headed Lapwing, Far Eastern Curlew, Asian Dowitcher.

MEWI - Middle East Wetlands Inventory (Scott 1995);

NEACSN - NE Asia Crane Site Network (Chan 1999); Ramsar - Ramsar site;

NHA - Non-hunting Area;

NNR - National Nature Reserve;

MAB - Man &amp; Biosphere Reserve.

Siberian Cranes require migratory stopover sites to rest and replenish depleted energy reserves to complete migration and to breed successfully. Population pressure and conflicts with water and wetland use threaten the important sites on Songnen Plain in north-eastern China in particular. Summering areas for sub-adult Siberian Cranes (age 1-5 years) are largely unknown for all populations and must be identified, assessed and protected. Siberian Cranes are highly sensitive to disturbance on their breeding grounds and pairs require large territories. The main threats at these far northern sites are disturbance from human activities such as oil exploration, timber extraction and collection of natural produce.

**CAUSE OF THREATS**

The causes of many of the threats include: increasing human pressure on natural resources; unsustainable exploitation of wetlands by rural communities; lack of co-ordination among sectoral agencies; lack of capacity and financial resources for protected area management and species protection; poor levels of environmental awareness and understanding; weak legislation or enforcement related to nature protection; and a lack of integration of conservation concerns into development planning and water management. Also related to human impacts are the long-term implications of climate change on wetlands in the region. At the international level, existing international co-operation and capacity for international co-ordination of conservation efforts are limited, and limited information is available about migration routes and sites for many waterbird species. This problem includes a lack of systematically collected information on the status of wetland resources and threats to wetlands in Asia.

**GLOBAL ENVIRONMENT FACILITY (GEF) PROJECT**

Following on from the CMS Memorandum of Understanding, the next stage in the long-term conservation programme for the Siberian Crane was the development of an international project funded by the GEF and other donors and with the United Nations Environment Programme (UNEP) serving as the Implementing Agency (UNEP 2002). This project focuses specifically on the conservation of the international network of wetlands upon which the Siberian Crane depends, together with other migratory waterbirds and a wide range of other wetland fauna and flora. It aims to facilitate the development and expansion of a network of protected wetland sites and wider application of the approaches that have been developed in each participating country. The Siberian Crane is being used as “flagship species” for the conservation of large open wetlands, in the same way that other charismatic species have been used to attract public attention for conservation issues. The project area covers two of the three migration routes used by populations of the Siberian Crane in Asia, targeting key wetland sites located in China, Iran, Kazakhstan and Russia (Table 1, Fig. 1). It does not cover the Central Asian migration route of the Siberian Crane outside Russia and Kazakhstan, as this is being addressed by parallel conservation activities under the CMS Memorandum of Understanding.

The project's intervention strategy reflects the life history of the Siberian Crane in that the selection of project sites covers the main known breeding, wintering and staging areas for both western and eastern populations. Those sites that are of greatest importance for the species are given priority in the first three-year phase of the project. These include the eastern population's main breeding grounds (in Kytalyk) and main wintering site (at Lake Poyang), and sites under most immediate threat (staging areas at Zhalong and Xianghai in China). Similarly, protection measures at the western population's main wintering site at Fereydoon Kenar in Iran are being addressed. Targeted research designed to fill gaps in our knowledge of migration routes and to identify further critical sites is also given priority. Less urgent sites and activities will be addressed in a second three-year phase. Sites covered by other major projects have generally been omitted in order to avoid duplication of effort. Close co-ordination and exchange of information will be maintained to ensure that the requirements of the cranes will be incorporated into other programmes.

## IMPORTANCE OF SIBERIAN CRANE SITES FOR OTHER GLOBALLY THREATENED WATERBIRDS

The wetlands that have been identified as sites for project intervention all meet the criteria of the Ramsar Convention on Wetlands for identifying Wetlands of International Importance, and many have existing international designations (see Table 1). The flyways used by the Siberian Cranes are shared with many other species of migratory waterbirds, including at least 32 globally threatened or near threatened waterbird species (see Table 2), and thus have significance far beyond conservation of the Siberian Crane alone. For example, Zhalong Nature Reserve, one of China's project sites, supports at least 12 other globally threatened and near threatened bird species, including the largest breeding population of Red-crowned Cranes *Grus japonensis* in the world; Poyang Lake, another Chinese project site, supports at least 14 species of globally threatened and near threatened birds, including half the world population of White-naped Cranes *G. vipio* throughout the winter. These flyway site networks sustain millions of migratory waterbirds along their migration routes, which span the Asian continent between northern breeding grounds and southern wintering areas (see APMWCC 2001 for further information). These wetlands are also of considerable socio-economic and cultural importance, supporting the livelihoods of local communities, as well as contributing to regional and national economic development in many cases. (See Annex 9E in GEF Project Document for details).

## AIMS AND ACTIVITIES OF THE GEF PROJECT

The project aims to secure the ecological integrity of a network of globally important wetlands that are of critical importance for migratory waterbirds and other wetland biodiversity, using the globally threatened Siberian Crane as a flagship species. To address threats and underlying causes, the project will undertake actions principally at three levels, as described below.

### Site level

The project aims to address threats to key wetlands of international importance that are of critical importance for the conservation of the Siberian Crane and other migratory waterbirds (see Table 1). A range of measures will be undertaken at each site in relation to specific threats, in order to ensure its future ecological integrity. These measures involve a high degree of stakeholder participation, and will contribute to local community development through pilot sustainable livelihood projects where these are a priority. Site activities include strengthening legal protection and enforcement, developing and implementing site management plans, capacity building for site management, environmental education and public awareness programmes, and alternative livelihood projects. (See Annex 9B1 of Project Document for details). The timeframe for these activities is designed to allow adequate time for capacity building, education and community participation approaches to yield the targeted conservation results.

### National level

The project will undertake specific actions to strengthen the national legislative, policy and planning framework for wetland and waterbird conservation, strengthen capacity for international co-operation, and undertake national activities that support site conservation, such as monitoring, training, education and public awareness programmes. These activities are being co-ordinated

with UNDP/GEF national wetlands projects in China, Iran and Kazakhstan as well as other projects. They also aim to strengthen mechanisms for integrated wetland management through improved inter-sectoral collaboration. In China, improvements in the co-ordination of waterbird monitoring within the country will be a priority.

### International level

The project will focus on building capacity for the co-ordination of flyway networks of wetlands along the West/Central and East Asian flyways for migratory waterbirds, led by sites of importance for the Siberian Crane as a flagship species. These networks are being carefully co-ordinated with other flyway or regional conservation initiatives, such as the Asia-Pacific Migratory Waterbird Conservation Strategy 2001-2005 (APMWCS), Central Asian Flyway (CAF) project, Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA), Crane Working Group of Eurasia, and UNEP/GEF Econet project in Central Asia, in order to form an integrated programme, and will contribute significantly towards the implementation of international conventions. The networks will also contribute to the delivery of activities under the Conservation Plans of the CMS Memorandum of Understanding concerning Conservation Measures for the Siberian Crane. This component will be accompanied by applied field research (such as satellite telemetry studies) in support of flyway conservation.

A regional co-ordination centre has been established in Moscow, which links with the above-mentioned initiatives. A centralized database and GIS have been designed, which will facilitate exchange of information on waterbird species and the project sites and undertaking of regional assessments. The project is also strengthening capacity for co-ordination of the North East Asia Crane Site Network's activities in China and Yakutia; it supports the operation of a Task Force on the Siberian Crane under the Crane Working Group (part of the APMWCS co-ordination structure), and facilitates an enhanced level of flyway conservation activities in line with existing plans and institutional frameworks.

The project is working with other partners (CMS, Wetlands International and national governments) to develop a Western/Central Asia Site Network for Siberian Cranes (and Other Waterbirds) within the wider frameworks of the Central Asian Flyway project and the CMS Memorandum of Understanding. This effort will transfer experience gained by the North East Asia Crane Site Network and help towards the establishment of a wider network of waterbird sites for the Central Asian flyway.

Activities supporting the flyway site networks include the production and distribution of public education materials to support Crane Festivals (conducted at 28 sites in 2004), training in data management (workshop in Kazakhstan in September 2004), staff exchanges between sites, satellite telemetry research on Siberian Crane migration routes, and improved access to information through the regional database, English and Russian language web-sites, a newsletter and an email migration-tracking communication system.

## CHALLENGES FOR SITE NETWORKS

This project covers a selection of key sites for the Siberian Crane, and some other key sites are covered by other projects.

**Table 2.** Globally threatened and near threatened species of migratory waterbirds using wetlands selected as UNEP/GEF project sites. (Adapted from Asia Pacific Migratory Waterbird Conservation Committee, 2001).

Species <sup>1</sup>	English Name	Category of Threat <sup>2,3</sup>	Global (G) / Regional (R) Population Estimate <sup>3</sup>	Regional Population <sup>3</sup>
<i>Pelecanus crispus</i>	Dalmatian Pelican	VU	9 800-12 400 R	SW, S Asia

NOTES: **CR**=Critically Endangered **EN**=Endangered **VU**=Vulnerable **DD**=Data Deficient **LR**=Lower Risk **Lc**=Least Concern **Nt**=Near threatened

The birds, however, use additional sites that need to be identified through satellite tracking studies and surveys, and protected as appropriate.

The management capacity at the known key sites needs to be strengthened – a key aim of the present GEF project. Ecological research is focusing on habitat requirements of the eastern population on their critical wintering grounds at Poyang Lake.

Although hunting of Siberian Cranes is illegal in all four GEF countries, hunting still poses a significant threat to this species and other migratory waterbirds. The education of hunters throughout the flyways and improved legislation and enforcement are needed in order to allay this threat. High-profile projects in Asia similar to that undertaken by Operation Migration in the USA for the Whooping Crane *Grus americana* (migration of released birds led by hang-glider) would be a dramatic way of raising awareness, with education activities at stopovers along the route.

Finally, the only way to verify whether this multi-level conservation effort is being successful is through improved monitoring of waterbird populations throughout the flyways concerned. At present, coverage (for example, by the Asian Waterbird Census) is very limited in key regions such as China; the quality of data available has to be improved, and this is being addressed under the project.

#### ADDED VALUE OF THE FLYWAY APPROACH

The flyway approach increases the complexity of project co-ordination and management, and increases the level of risk for projects working at this level. This approach adds to the costs of conservation when combined with activities at national and site levels. Such an approach, however, is essential for enabling the comprehensive and effective management of migratory species throughout their life cycles. It also facilitates the improved representation of

wetland habitats in protected area systems along an entire flyway, supporting both wetland and waterbird conservation. Co-operation among a range of conservation initiatives at flyway, national and site levels should improve the efficiency of efforts by focusing attention on priorities and improving access to information on sites and species, and applying lessons learned to other sites.

## ACKNOWLEDGEMENTS

The authors gratefully acknowledge assistance from their colleagues at ICF, including George Archibald, Li Fengshan, Patricia Gleason, Dorn Moore, Elena Smirenski, Zoe Rickenbach and Luan Haiyan. This project would not have been possible without the support of UNEP Task Managers Mark Zimsky and Max Zieren. We are grateful to the national project teams and wish to acknowledge the valuable leadership of Wang Wei, Zhang Dehui and Qian Fawen (China); Anoushiravan Najafi, Mohammed Ayatollahi and Sadegh Sadeghi-Zadeghan (Iran); Sergey Yerokhov, Evgeny Bragin, Tatiana Bragina, Anatoly Kovshar and staff of the Forest and Hunting Committee, Ministry of Agriculture (Kazakhstan); and Alexander Sorokin, Anastassia Shilina, Victor Vlasenko, Alexander Ermakov, Tatiana Belyakova and Nikolai Germogenov (Russian Federation). Project design benefited greatly from the advice and assistance of organizations including CMS, UNDP, Wetlands International, Ramsar Convention Bureau, Cracid Breeding and Conservation Center, and the World Bank. Many other individuals and organizations assisted in the preparation of this project and we acknowledge them here.

### ABSTRACT

In a flyway approach to the conservation of waterbird populations, the sites used throughout the year provide us with one of the tangible conservation tools with which we can work. Sound management of these sites can safeguard waterbird populations as they move from breeding grounds to staging sites and on to wintering sites. All these sites have a role to play in the birds' annual cycle. The network of critical sites (or critical network of sites) is the minimum network that needs to be maintained to support waterbird populations indefinitely. The functions of the sites and the functional links between sites are important attributes of this critical site network, which is more than just a list of important sites. A lot of information exists on the numbers of birds using sites at various times of the year, particularly in mid-winter (January), but knowledge about the function of sites for waterbirds and their role in the annual cycle is rather poor, and needs to be improved. One of the aims of the UNEP-GEF African Eurasian Flyways Project is to bring together these various strands of information to compile a network of critical sites for waterbirds in African and Western Eurasia.

### INTRODUCTION: FLYWAY CONSERVATION

Migratory waterbirds can range over thousands of kilometres in their movements between breeding and non-breeding areas, relying on the availability of suitable habitat throughout their range. Most species are highly migratory, covering large distances and concentrating in large numbers at often a small number of places, making them vulnerable to external influences but at the same time attractive for bird-watching and ecological tourism. They are often an important resource for traditional sustainable use (Kanstrup 2006).

The definition of a flyway is generally understood to mean the entire range of a migratory waterbird species (or group of species, or distinct population of a single species) from the breeding grounds to the wintering areas, including the intermediate resting and feeding areas and the often relatively narrow corridor within which the birds migrate (see, for example, Scott & Rose 1996). The concept was first developed in North America, and is now widely used when attempting to define the overall problems that a migratory waterbird encounters in its life cycle and determine which countries should co-operate to protect and manage the populations on a sustainable basis.

The term "flyway" is to some extent a theoretical concept. It is not the same as a "migration route", which may be defined as the travel lanes of individual birds on their way from any particular breeding area to their winter quarters. Flyways, on the other hand, may well be conceived as those broader areas in which related migration routes are associated or blended in a definite geographic region. In addition, they have also become to have an administrative meaning (<http://www.birdnature.com/flyways.html>).

The term flyway can be used at various taxonomic, geographic and political "scales", as described in Boere & Stroud 2006, this volume.

The conservation of migratory waterbirds along a flyway poses a great challenge to international environmental co-operation. This is because of the vast distances covered by many species of waterbirds in the completion of their annual cycles and the large number of range states involved. Inadequate or inappropriate management measures by just one range state can jeopardize the conservation status of one or many species throughout the flyway. Thus, a high degree of international co-operation is essential throughout the areas used by the populations of the species involved: this is called the "flyway approach". Such co-operation requires international co-ordination at the levels of research, planning and monitoring, common standards for legislation, protected area designation and management, sustainable use, sharing of information and transfer of know-how. In this regard, the role of international conventions and agreements, such as the Convention on Biological Diversity (CBD), the Ramsar Convention on Wetlands, the Convention on Migratory Species (CMS) and the Agreement on the Conservation of African-Eurasian Migratory Waterbirds (AEWA) under the CMS, is essential.

Besides functioning at international, regional and national levels, an effective conservation programme for migratory waterbirds needs to focus right down to the site level, covering all scales in time (when are the sites used and by what) and space, and should provide tools to help the implementation of conservation actions at all appropriate levels.

At the species level, a flyway is in fact the entire ecosystem needed for a migratory waterbird in order to survive, including all the habitat types needed to accommodate breeding, resting and wintering during the whole annual cycle. As such, the concept fully supports the ecosystem approach required under the CBD.

Flyway conservation is the holistic approach to conservation of waterbirds and the systems they use – with their specific habitats – for the benefit of people and biodiversity. It evolves along four main axes: species, sites, habitats and people. A site network is one of the tools that bring together all four axes, and as such is a very important component of flyway conservation.

The flyway concept, by definition, requires close co-operation between all the Range States involved. It can strongly stimulate co-operation between states to build up networks of scientists, conservationists and reserve managers, and stimulate a wealth of small-scale initiatives in all fields of biodiversity and habitat conservation. Migratory waterbirds are a biodiversity resource shared by all countries of the world; conserving migratory waterbirds and using them on a sustainable basis helps to protect the biodiversity of many countries at the same time.

Migratory species really force Range States to work together because of the shared interest in conserving each other's

biodiversity and ensuring that the use of a species in one country is co-ordinated with that in other countries to avoid, for instance, unsustainable use of populations.

For many of these species, wetlands are the most important habitat type<sup>1</sup>. These habitats are usually rather discrete and separated from each other by vast areas of non-wetland habitat, causing waterbirds to concentrate at these sites. Wetlands are highly productive habitats and can therefore support large concentrations of waterbirds, despite their sometimes limited size. One of the ways to indicate the importance of individual sites is by the numbers of birds which habitually use them, year after year (see Scott & Rose 1996).

To complete their annual cycles, migratory waterbirds are dependent on a network of important sites throughout their range. Each site in the network plays a vital role, enabling the individuals that use it to reach the next (or another) site. Loss of one such site in the network could result in the distance between sites becoming too long, or in the location for a certain process (e.g. moult) no longer being available. This would “disconnect” the sites before and after it, and be equivalent to losing a link in a chain.

Wetlands are among the most threatened habitats in the world, having suffered losses exceeding 50% of the original area in many countries during recent decades (Millennium Ecosystem Assessment 2005). Large wetland complexes have been reduced in size, and some isolated wetlands have completely disappeared (Finlayson & Moser 1991). If, as a consequence of these losses, a site disappears from the network, the birds need to be able to find an alternative. The flexibility to be able to do this is determined by a complex of many factors. It is obvious that the network, if thinned beyond the species’ flexibility, can no longer support the population, leading to a decrease in numbers and eventually a crash. Waterbirds require the network of sites as stepping stones along their migration routes. This means that there is an absolute minimum size and configuration of this network that needs to be maintained to support waterbird populations indefinitely. This is what is meant by the network of critical wetland areas, or critical network of wetland areas<sup>2</sup>. This network may be considered as a minimum essential to ensure the survival of these species across their ranges should remaining habitat elsewhere be lost. Because all sites are, or may increasingly become, refuges, if any one of them is lost the consequences may be disproportionately large. Any comprehensive conservation initiative for migratory waterbirds should therefore take the safeguarding of this network of sites into account: without these sites, the species will not survive. As such, the network of critical sites is one of the pillars of the flyway approach to the conservation of waterbirds.

Waterbirds are not the only users of these wetland sites. In many cases, local communities depend on the goods and services provided by these wetlands. Changes in human activities caused, for example, by increasing population densities are resulting in more and more unsustainable use and in clashes of interest between human activities and waterbird requirements. However, in cases of sustainable use or through targeted intervention aimed at restoration, good conditions for wetland biodiversity, including waterbirds, can be maintained and population levels can stay or become healthy. Site-based conservation should strive at these “win-win” situations.

## NETWORK OF CRITICAL SITES AS A TOOL FOR CONSERVATION

From the above, it is clear that the network of critical sites is a powerful tool in an effective conservation programme for the benefit of populations of migratory waterbirds, the habitats on which they depend and the people sharing these habitats. It is a mechanism for incorporating internationally co-ordinated measures for site conservation, species monitoring and conservation, including sustainable use and regulation of any forms of harvest. Defining the network of critical sites sets the geographic priorities for the implementation of these conservation actions. Knowledge of this network is therefore a basic need for the implementation of policy tools such as the Ramsar Convention at the global scale and regional initiatives such as AEWA, Western Hemisphere Shorebird Reserve Network and East Asian-Australasian Flyway Site Network.

Although a list of sites covering a certain area is often referred to as a network, a network in the true sense of the word is more than this. In a network, the functions of sites and the functional links between sites are important attributes. Sites can serve various functions to birds, e.g. as breeding grounds, stopover sites (either for roosting, feeding, moulting or other ecologically important components of the life cycle such as pair bonding), wintering sites, and refuges in severe weather. It is well documented that birds are often quite traditional in their use of sites, not only on the breeding grounds and in the wintering areas, but also at staging areas along the migration routes. These functions of, and links between, sites will differ between and within species and may even change over the years, for example as a result of changing weather conditions. Although most waterbirds seem to be quite flexible in their response to changing environmental conditions, those with more traditional migration strategies and high site fidelity, such as the Lesser White-fronted Goose *Anser erythropus* and certain species of waders, are particularly vulnerable. Little is known about these aspects of a site network except in a few cases where in-depth research has been undertaken, e.g. in the case of the Greenland White-fronted Goose *Anser albifrons flavirostris* (Fox *et al.* 1994, Fox & Stroud 2002). For most species, more work is needed before it is possible to identify the critical sites and assess their roles in the annual cycle. In most cases, therefore, it would be too ambitious at the present time to aim at building site networks by relying heavily on knowledge of the functional aspects site linkages.

A temporary solution might be found at an intermediate stage, by subdividing the annual cycle into three main life-cycle components (breeding, passage and over-wintering) and analysing the network on this basis. Traditionally, waterbirds have mostly been counted in the month of January within the framework of the International Waterbird Census (IWC) co-ordinated by Wetlands International. Thus, for many sites information is lacking on their role in the migration seasons. In many cold regions, where most if not all sites are completely frozen over in winter (January), relatively little is known about the importance of sites for waterbirds. The Important Bird Areas (IBA) project and database of BirdLife International have, to some extent, mobilized information about numbers of waterbirds in periods other than mid-winter, and it is therefore important to combine this information with information from the IWC.

<sup>1</sup> It is important to note that some migratory waterbirds may also depend on non-wetland sites for part of their annual cycle.

<sup>2</sup> Both forms of wording contribute to an understanding of the concept: the network aspect as well as the site aspect are critical for the survival of the species

One specific role that sites can play in a site network is that of providing flexibility in case of shifting distributions. Against the background of climate change, this would appear to be an increasingly important characteristic of a site network (Boere & Taylor 2004).

The word “critical” in the strict sense implies that the removal of any one of the sites from the network would have a serious impact on the population of waterbirds that the network as a whole supports. This concept of a minimum configuration of sites is straightforward in itself, but difficult to apply in practice, because it cannot be underpinned by scientific data, and cannot be tested. To date, initiatives to establish conservation approaches based on site selection have therefore taken a pragmatic approach and expressed selection criteria in numerical terms, the most famous being the 1% criterion<sup>3</sup> as used, for example, in compiling lists of important sites under the Ramsar Convention and within the framework of the Important Bird Areas project.

The Ramsar Convention has adopted the following definition of the term “critical site”, as given in the *Strategic framework for the List of Wetlands of International Importance* published by the Ramsar Bureau: “Critical sites for mobile or migratory species are those which contain particularly high proportions of populations gathered in relatively small areas at particular stages of life cycles. This may be at particular times of the year or, in semi-arid or arid areas, during years with a particular rainfall pattern. For example, many waterbirds use relatively small areas as key staging points (to eat and rest) on their long-distance migrations between breeding and non-breeding areas. For Anatidae species, moulting sites are also critical. Sites in semi-arid or arid areas may hold very important concentrations of waterbirds and other mobile wetland species and be crucial to the survival of populations, yet may vary greatly in apparent importance from year-to-year as a consequence of considerable variability in rainfall patterns.”

Although these criteria for the identification of sites for inclusion in specific lists have been the subject of extensive discussion in the past, they do not consider “complementarity” between sites, or different “roles” of sites in the flyway. It is therefore worth looking at these criteria again, to evaluate whether there is scope for better incorporation of the functionality of sites in a network into the selection criteria.

It should be said that the creation and implementation of new criteria should only be promoted if there is clear indication that this will significantly improve the functioning of the resulting network. In other cases, it is preferable to adhere to existing criteria, to avoid loading additional burden on the shoulders of countries that will have to work with the criteria and to avoid losing the conservation value and credit build up with the existing sites. Instead of replacing existing criteria, it may therefore be necessary to define additional criteria to accommodate the functional component of the network.

There is also a need to look at the efficiency or effectiveness of the selected network. Evaluation of the effectiveness of a proposed network should be undertaken on a species (or species group) basis, and involves bringing together data from various

existing data sets to check to what extent the network covers the distribution of the species (or species group) and fulfils the various roles in the annual life cycle.

#### UNEP-GEF AFRICAN EURASIAN FLYWAYS PROJECT

For the effective conservation of migratory waterbirds, it is important to be able to make the step from lists of key sites to networks of critical sites. Inadequate knowledge and understanding of waterbirds and the way they use sites have, until now, hampered this step forward. UNEP-GEF and several major co-funders, including the German Government and the AEWA Secretariat, have therefore decided to support a flyways project for the African-Eurasian region. This project, entitled “Enhancing conservation of the critical network of sites required by Migratory Waterbirds on the African/Eurasian Flyways” (or UNEP-GEF African Eurasian Flyways Project in short) is being developed by Wetlands International and will run for the period 2006-2011. The project will address the issues mentioned above, and will develop a network of critical sites for the African-Eurasian region. The need for the development of such a network of sites of critical importance to migratory waterbirds is well established and supported by both the Ramsar Convention and AEWA.

Kushlan, J. 2006. Integrating waterbird conservation: populations, habitats and landscapes. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 700.

Orsoya fishpond, Bulgaria. The conservation of such traditional fishponds - which are subject to a low intensity of management - is important to maintain associated waterbirds included the globally threatened Ferruginous Duck *Aythya nyroca*. Photo: Nikolai Petkov.

The long-term conservation of waterbirds requires conservation activities to be undertaken at a wide range of scales and in respect to the different periods of annual life cycles.

Development of strategies and policies for effective conservation and/or management will vary greatly according to the ecology and distribution of different waterbird species. Species which are highly aggregating will occur at high densities at a few sites. The identification, protection and management of these key sites will be an effective means of conserving significant proportions of populations — especially where groups of such sites are managed as networks (as explored by the papers in the preceding section: Building effective ecological networks).

For species that aggregate less densely, wider measures may be necessary to secure their favourable status, especially where these species occur at low densities across wetland or other landscapes. For many species a mix of site-related and wider-countryside measures are needed. This will include species such as some geese and swans which roost at high densities on sites which can be protected as refuges or through similar site-related measures, but during the day then range more widely, at lower densities, to feed on farmland or other habitats. Integrated conservation approaches are needed in such circumstances.

Landscape-scale measures can be of either formal or informal nature. Formal measures include government-led agri-environment policies that seek to deliver environmental benefits through subsidies provided to farmers and other land-managers.

The development of wider policies for waterbird conservation is aided by clarity as to objectives and targets, and in this respect, Johnson *et al.* summarise the US experience in planning for bird conservation at landscape scales.

As with all conservation management, there is a need to monitor the effectiveness of wider conservation measures so that these policies may be adapted or modified in the light of changing circumstances. Such monitoring needs necessarily to be wide-scale, and Bart presents the development of the North American Program for Regional and International Shorebird Monitoring (PRISM) which aims to collect a range of population parameters on shorebirds at continental scales. Austin *et al.* summarise the development by the UK Wetland Bird Survey of a waterbird 'alerts' system. This provides annual feedback to conservation managers and others on the status of sites and species using objective analysis of trends and the application of pre-defined criteria to assess significant declines. The system has already been effective in guiding priority setting by conservationists in the UK.

Wider policies are valuable not just in the context of cropped habitats. Petkov highlights the value of traditional fishponds, managed at low-intensity in some eastern European countries, for the conservation of the threatened Ferruginous Duck *Aythya nyroca*. In this example, policies which might result in either the abandonment of current fish-farming practises on the one hand, or its intensification on the other, might be extremely damaging to the status of Ferruginous Duck.

Straw & Saintilan highlight the importance of tropical open shores for inter-tidal waders and highlight the implications of the loss of this habitat following invasion by mangrove species. This suggests that the development of proposals to afforest shores with mangroves should be approached with caution and always following an environmental impact assessment that considers wider implications such as this.

## The Program for Regional and International Shorebird Monitoring (PRISM) in North America

Jonathan Bart

Forest and Rangeland Ecosystem Science Center, US Geological Survey, 970 Lusk Street, Boise, Idaho 83706, USA.  
(email: jopn\_bart@usgs.gov)

Bart, J. 2006. The Program for Regional and International Shorebird Monitoring (PRISM) in North America. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 701-704.

The Program for Regional and International Shorebird Monitoring (PRISM) provides guidance on how to monitor shorebirds that regularly nest in Canada and the United States. PRISM has five goals, but work so far has focused on one of the goals, namely estimating trends in population size. An accuracy target has been adopted and a substantial amount of work has been completed to design surveys in the arctic, boreal, and temperate regions of Canada and the United States. Less work has been done on surveys to be conducted in winter.

### INTRODUCTION

National shorebird conservation plans in Canada (Donaldson 2001) and the United States (Brown *et al.* 2001), completed in the past few years, both recommended a comprehensive approach to monitoring shorebird populations in North America. These calls to action led to the formation of PRISM, the Program for Regional and International Shorebird Monitoring (Skagen *et al.* 2004, Bart *et al.* 2005a). The national plans identified 74 shorebird taxa, including 49 species, with populations in Canada and the United States large enough to warrant monitoring. PRISM has five goals:

- Estimate the size of breeding populations of shorebirds in Canada and the United States.
- Describe the distribution, abundance, and habitat relationships of shorebirds.
- Monitor trends in the size of shorebird populations.
- Monitor shorebird numbers at stopover locations.
- Assist local managers in meeting their shorebird conservation goals.

Estimating trends in population size was thought to be the most difficult goal to achieve, and so initial work has focused on this goal. PRISM has adopted the following accuracy target for trend estimation:

*80% power to detect a 50% decline in population size, occurring during no more than 20 years, using a two-tailed test with a 0.15 significance level, and acknowledging effects of potential bias.*

A three-part approach for trend estimation has been developed to achieve this goal:

- Surveys on the breeding grounds.
- Surveys on migration.
- Surveys on the wintering grounds.

Progress in the development of each of these surveys is described below.

### SURVEYS ON THE BREEDING GROUNDS

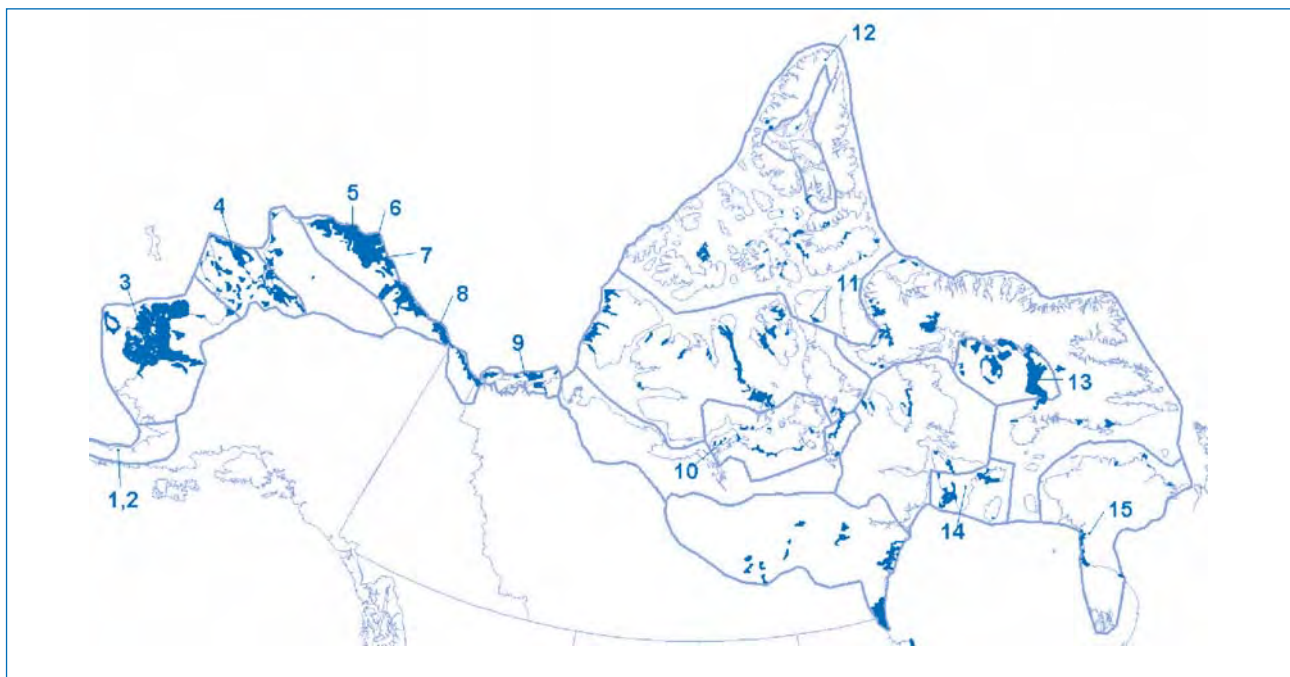

Separate programs are being conducted in arctic, boreal, and temperate regions. During surveys, all shorebirds encountered are recorded, but in each region, programs are designed to survey only those species for which one-third or more of the population occurs in the region. For example, surveys in both the arctic and boreal regions are designed to survey Red-necked Phalaropes *Phalaropus lobatus*, because more than one-third of their population is thought to occur in each region, but surveys in the Arctic are not designed specifically to monitor Semipalmated Plovers *Charadrius semipalmatus*, although they do occur in the Arctic, because more than two-thirds of their population are believed to breed in the boreal region.

#### Arctic regions

A great deal of work has been carried out in the arctic portions of Canada and Alaska during the past five years. Methods for surveying shorebirds were developed at a research station on the delta of the Colville River, using support from the US Fish and Wildlife Service and the US Geological Survey. The approach uses double sampling. A large sample of plots is selected, using formal probability methods, and surveyed a single time. A subsample of these plots is surveyed intensively to determine the number of shorebirds actually present. The number of birds “present” on a plot is defined as the number of territorial males whose first nest of the season, or territory centroid for non-nesters, is within the plot. This number is then doubled to obtain the estimate of population size. Other methods of estimation are needed if a substantial number of the males are non-territorial, but this is a situation that we have not yet encountered. The ratio of number recorded on rapid surveys of the intensive plots to number actually present is used as a correction factor to adjust results from the rapid plots and obtain an unbiased estimate of numbers actually present. Geographic information systems (GIS) methods are used to stratify the study area, and habitat-based models are used to extrapolate findings from the sample to the entire region. Two- or three-stage sampling is used to select survey plots depending on sampling intensity within the region. The field methods are described in Bart & Earnst (2002, 2005); the sampling plan and derivation of the estimators are described in Bart *et al.* (2005b).

Once the basic method was developed, tests were made to evaluate and refine it for use throughout the Arctic in Alaska and Canada. Trials were carried out in 15 sites, widely distributed across the Arctic (Fig. 1). A manuscript summarizing results and presenting a proposed plan for conducting the surveys during the next 10-20 years has been prepared and is undergoing peer review by a panel of experts. Following peer review, the plan will be revised as needed, submitted for publication in a scientific journal, and then implemented in the coming years.

**Fig. 1.** North American Arctic (i.e. Alaska and northern Canada), showing location of field sites at which the methods for the long-term survey were developed (numbers 1-15) and the regions (thick gray lines) which form the starting point for the sampling plan. Black areas are wetlands, as indicated by the Circumpolar Arctic Vegetation Map (CAVM Team 2003).

The next step in developing the PRISM arctic surveys is to broaden coverage, where appropriate, to include other birds and perhaps to collect data on other organisms and environmental parameters. A decision was made in 2003 that surveys in Canada would record all species, because many of the areas being surveyed have rarely if ever been visited by biologists on the ground. A commitment has also been made to contact other Arctic researchers to determine the importance of collecting other kinds of information.

### Boreal regions

The Boreal PRISM committee carried out an assessment of methods for surveying shorebirds in the boreal region (Aubry *et al.* 2004). They identified nine priority species, of 19 species that breed regularly in boreal regions, and considered how best to survey each one in each boreal Bird Conservation Region (BCR). A primary conclusion was that methods currently used to survey species other than shorebirds should be used rather than developing methods solely for shorebirds. The assessment discusses methods used for land-birds (North American Breeding Bird Survey, off-road point counts), waterfowl (helicopter aerial surveys of wetlands, roadside waterfowl surveys), marsh birds (Marsh Bird Monitoring), and migrant shorebirds (aerial and ground-based stopover site surveys). Their conclusions (Aubry *et al.* 2004, p. 33) were:

Because of differences among boreal species in geographic distribution and habitat use, no one survey type can be used to monitor all boreal shorebirds. For some species, such as the high alpine breeders Surf-bird *Aphriza virgata* and Wandering Tattler *Heteroscelus incanus*, adequate population monitoring

on the breeding grounds may not be feasible in the near future, and surveys during migration and wintering should be further investigated. For species with very limited breeding ranges, such as Hudsonian Godwit *Limosa haemastica* and Short-billed Dowitcher *Limnodromus griseus*, species-specific surveys may be required within small geographic areas. For some species, expanding coverage of the Breeding Bird Survey, which is well established and relatively inexpensive to conduct, to encompass the many roads within the boreal region that are not currently surveyed, may prove adequate for population monitoring. Roadside surveys which target wetlands, such as roadside waterfowl surveys and marsh bird surveys, may also be valuable, cost-effective tools for monitoring some boreal shorebirds.

Their report includes numerous recommendations on work needed to determine how the existing survey protocols and programs can best be used to survey each of their high priority species.

In Canada, bird monitoring in the boreal forest has recently gained prominence through programs initiated by both government (e.g. Canadian Wildlife Service) and non-government (e.g. Ducks Unlimited) agencies. Boreal PRISM is viewed as one part of a broader boreal bird monitoring effort. The PRISM program will collaborate closely with boreal monitoring by other bird groups to ensure maximum program efficiency. We anticipate proceeding with testing the adequacy of existing methods for monitoring boreal shorebirds in the spring of 2005.

### Temperate regions

Seventeen shorebird species nest in temperate regions in sufficient abundance to be focal species for this region. The PRISM accuracy target appears to be met for Piping Plovers *Charadrius melodus* and American Woodcock *Scolopax minor*, and may be met for five other species that are frequently recorded on the Breeding Bird Survey, although more work is needed to assess potential bias. A detailed survey has been made for American Oystercatchers *Haematopus palliatus* that nest within the United

States (Brown *et al.* 2005). In 2004, a three-year study was initiated to study Long-billed Curlews *Numenius americanus*. The results will achieve the PRISM trend monitoring target as well as providing information on habitat relationships and conservation priorities for this species. A comprehensive plan is needed for monitoring the other eight species. Comprehensive programs recently initiated in several States may be helpful, but work focused on these shorebird species will also be needed.

### SURVEYS ON MIGRATION

Most shorebird species can be monitored during migration, and much work has been carried out to develop rigorous surveys for this period. The International Shorebird Survey (Howe *et al.* 1989, Brown *et al.* 2001) and the Maritimes Shorebird Survey (Morrison *et al.* 1994, 2001) have collected information on migrating shorebirds since the mid-1970s, but without a well-defined sampling frame or written, site-specific protocols. PRISM investigators have developed approaches for defining the sampling frame and preparing survey protocols. Canada and the United States have been divided into bird monitoring regions, created by intersecting a Province and State map with a map of Bird Conservation Regions (BCRs) which were delineated by the North American Bird Conservation Initiative (NABCI 2000). This approach permits stepping up results either to the Province and State level or to the BCR level. Each bird monitoring region is partitioned into two or more strata. One stratum consists of “designated sites”, i.e. sites with a sufficient number of birds, and people to survey them, for them to be non-randomly selected for inclusion in the shorebird survey. The rest of the region is referred to as the matrix, and may be sub-divided into two or

Long-billed Curlew *Numenius americanus*. Photo: Gary Kramer.

more matrix strata depending on shorebird distribution and appropriate survey methods. For example, reservoirs might be common in one part of a region and might be surveyed by boat; another part of the region might contain extensive marshes where ground surveys would be needed, and the rest of the region might have too few shorebirds to be worth surveying.

**Table 1. Information recorded about each designated site in the PRISM migrating shorebird monitoring program.**

1. **Boundaries and ownership** – A brief description of who owns the land. If special permission or permits are needed to access the site, note this. Include local contact names and phone numbers, if appropriate. Briefly describe habitat at the site.
2. **Focal species using the site and timing of use** – Describe shorebird use of the site including species, numbers, and timing.
3. **Location of Type 1 and 2 habitat within the site** – Delineate the areas used most intensively by birds (Type 1 habitat) and areas used less frequently but often enough to warrant occasional surveys (Type 2 habitat). Try to define these areas so that >75% of the bird-days are in Type 1 habitat and >20% of the bird days are in Type 2 habitat.
4. **Access to Type 1 and 2 habitat and the visibility of the birds** – Describe access to the site, including observation points, boat access and permission requirements. Identify any areas that are inaccessible. Describe problems with seeing all birds during a survey, if any. If visibility is different for different species note this (e.g. “large waders are easily detected, but distances are too great to accurately identify smaller waders”).
5. **Past and current surveys** – Briefly describe past or current surveys at the site. Summarize any available survey data briefly.
- 6a. **Potential survey methods: description** – Identify and describe the best methods for surveying the site. Consider access, visibility and past survey results. Consider differences in survey methods among seasons, if appropriate. Consider when during the day surveys should be conducted. In general, all surveys in a site should be made during a single period. Timing of surveys is especially important at tidal sites but may be important at other sites due to the sun or other factors. Note that if the number of birds present varies rapidly, as is often the case with tidal areas, then the survey period should be brief. Otherwise, surveyors may gradually learn when surveys will yield the highest counts and may be tempted to visit at these times.
- 6b. **Potential survey methods: selection bias** – If some areas are not accessible, then discuss whether density in surveyable portions of the site may differ from the site-wide density and, if so, whether long-term trends might occur in the ratio: (density in the surveyable area)/(overall density). Any such trend will cause bias in the trend estimate. Consider whether occasional surveys might be conducted (e.g. from the air) of the entire site.
- 6c. **Potential survey methods: measurement error and bias** – Missing birds cause measurement error; a trend in the proportion of birds that are missed causes measurement bias. Discuss the potential for measurement bias and ways to minimize it (e.g. by intensive surveys on a sub-sample of plots).
7. **Needed Pilot Studies** – Identify any information needed to complete the sampling plan.

In such a case, three matrix strata might be distinguished. Sampling frames, following this approach, have been developed for the east coast of the United States (see <http://www.shorebird-world.org/fromthefield/PRISM/PRISM1.htm>) and several western States and areas (e.g. see [http://www.gbbo.org/abc\\_maps.htm](http://www.gbbo.org/abc_maps.htm)), and work in several other States is proceeding. A comprehensive list of designated sites and matrix strata is in the final stages of preparation for the continental United States.

Detailed guidelines have also been prepared for developing site-specific survey methods (Table 1). The guidelines include a description of the site (boundaries, habitat, ownership, access), species likely to be encountered, and survey methods. Particular attention is given, in the survey methods section, to the potential for selection bias (because some portions of the site are inaccessible), measurement error (because some birds in surveyed areas are not detectable), and measurement bias (because a long-term trend exists in the proportion of the birds detected). A final section identifies any pilot studies needed before the surveys can be fully designed. Examples of site descriptions are provided in Bart *et al.* (2005c) and at the internet sites above.

### SURVEYS ON THE WINTERING GROUNDS

Extensive surveys of wintering shorebirds have been carried out by Morrison *et al.* (1998) and Morrison & Ross (1989), and some species-specific surveys have been conducted. Most of this work preceded the formation of PRISM, or has been carried out independently of it. An exception is the detailed survey, mentioned above, of American Oystercatchers, carried out as part of PRISM by the Manomet Center for Conservation and colleagues (Brown *et al.* 2005). A comprehensive strategy for surveying shorebirds on their wintering grounds is still needed, and will need to be developed cooperatively with countries that would host these surveys. Collaboration between those who have developed PRISM and organizers of the Wetlands International mid-winter waterbird counts would be especially valuable. Such discussions should include the possibility of expanding those counts into the USA and Canada.

### ACKNOWLEDGMENTS

PRISM has been developed by dozens of shorebird experts and hundreds of dedicated technicians during the past five years. Reviews by S. Skagen and V. Johnston helped improve the manuscript. My work on PRISM has been supported by the US Geological Survey, the US Fish and Wildlife Service, and the Canadian Wildlife Service.

## The UK Waterbirds Alerts System

Graham E. Austin, Ilya M.D. Maclean, Philip W. Atkinson & Mark M. Rehfish

British Trust for Ornithology, The Nunnery, Thetford, IP24 2PU, UK. (email: Graham.Austin@bto.org)

Austin, G.E., Maclean, I.M.D., Atkinson, P.W. & Rehfish, M.M. 2006. The UK Waterbirds Alerts System. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 705-710.

### ABSTRACT

The UK hosts internationally important numbers of waterbirds, and to conserve and manage these populations effective monitoring protocols are needed. The Alerts System, by adopting a standardized method for identifying the direction and magnitude of changes in waterbird numbers at a range of spatial and temporal scales, provides an effective means of doing so. The system makes use of generalized additive models (GAMs) to produce smoothed indices of abundance, and is applied to assess trends at several spatial and temporal scales. To flag population changes, High and Medium Alerts are issued if population declines exceed 50% and 25%, respectively. Several of the key findings from the most recent Alerts analysis are presented.

### INTRODUCTION

Waterbirds, perhaps more than any other taxonomic group, have been used to select areas for conservation. Their sensitivity to environmental change, the relative ease with which they can be counted and their tendency to congregate at key locations make them effective proxies for aspects of wider biodiversity (Stroud *et al.* 2001). The UK holds internationally important numbers of non-breeding waterbirds (Stroud *et al.* 2001). Whilst some of these individuals breed within the UK, many originate from breeding areas in the Arctic and are attracted in such large numbers by the combination of relatively mild winters and extensive areas of inter-tidal mudflats (Davidson *et al.* 1991). Protecting these species is a high conservation priority, and the UK Government has agreed to international obligations to do so (Stroud *et al.* 2001). For example, the European Union's Directive on the conservation of wild birds (EC/79/409) requires Member States to take a range of actions to sustain bird populations, and includes establishing and maintaining a national network of sites, known as Special Protection Areas (SPAs) (Stroud *et al.* 2001). Numerous wetland sites have been designated on the basis of the number of waterbirds they contain, and there are legal obligations to ensure that their favourable status is maintained (Stroud *et al.* 2001).

The monitoring of wildlife populations is essential if they, and the sites on which they depend, are to be managed and conserved effectively (Greenwood *et al.* 1995). However, conservation resources are finite and effective means of identifying priorities are needed. One way in which this can be achieved is to monitor population changes at a variety of spatial and temporal scales. Through this process, resources can be targeted towards protecting the most threatened species and areas. In Britain, numbers of wintering waterbirds have been recorded as part of a national scheme called the Wetland Birds Survey (WeBS). This scheme has been in place since the winter of 1947/48, and coverage similar to that seen today has been maintained for over 35 years, providing one of the largest and most detailed, long-running biological data sets available.

The Alerts System was developed to provide a standardized method of identifying the direction and magnitude of changes in numbers at a variety of spatial and temporal scales for a range of waterbird species for which sufficient WeBS data are available. Species that have undergone major changes in numbers can then be flagged by issuing an Alert. Alerts are intended to be advisory and, subject to interpretation, should be used as a basis on which to direct research and subsequent conservation efforts if required.

### DATA COLLECTION METHODS

Waterbird data used in the calculation of Alerts are collected by a network of counters as part of the WeBS scheme (Pollit *et al.* 2003). This scheme is an amalgamation of two previous long-term monitoring schemes, the Birds of Estuaries Enquiry (BoEE) and the National Wildfowl Count Scheme (NWC), and aims to identify important sites and monitor changes in numbers and distribution of divers, grebes, cormorants, herons, wildfowl, rails, waders, gulls, terns and kingfishers in the UK, contributing data also to the International Waterbird Census. Whilst WeBS data are collected using several counting schemes, only data from counts termed "Core Counts" are currently used to calculate Alerts. Core Counts are made at approximately 2 000 wetland sites in both coastal and inland locations around the UK. Typically, these are conducted monthly on a synchronized date, and coastal sites are usually counted at high-tide. Whilst a wide variety of wetland habitats are included in the Core Count scheme, a large proportion of the total area covered consists of estuaries and large still waters of which over 70% are covered nationally. Many of the sites included in the scheme are, or have been proposed as, Ramsar sites, SPAs, or Sites or Areas of Special Scientific Interest (SSSIs/ASSIs).

### SPECIES AND SITE COVERAGE

The WeBS Alerts System is concerned solely with highlighting changes in the abundance of waterbirds outside the breeding season. The type of habitat in which many of these species breed is not covered by the WeBS scheme, and WeBS data from the breeding season are therefore generally not suitable for determining changes in the numbers of breeding waterbirds. Wildfowl (Anatidae) data have been collected from the majority of English, Scottish and Welsh sites since the winter of 1966/67, with wader (shorebird) data available from 1969/70. Earlier, less nationally complete counts date back to the winter of 1947/48, although these data have not been computerized. The survey was extended to include the Common Coot *Fulica atra* and Great Crested Grebe *Podiceps cristatus* from 1983/84, the Little Grebe *Tachybaptus ruficollis* from 1985/86 and the Great Cormorant *Phalacrocorax carbo* from 1986/87. Wader numbers have been recorded from sites in Northern Ireland since 1970/71, with numbers of other waterbirds recorded since

**Table 1.** List of species currently included in WeBS Alerts analysis.

Little Grebe <i>Tachybaptus ruficollis</i>
Great Crested Grebe <i>Podiceps cristatus</i>
Great Cormorant <i>Phalacrocorax carbo</i>
Little Egret <i>Egretta garzetta</i>
Bewick's Swan <i>Cygnus columbianus bewickii</i>
Whooper Swan <i>Cygnus cygnus</i>
European White-fronted Goose <i>Anser albifrons albifrons</i>
Dark-bellied Brent Goose <i>Branta bernicla bernicla</i>
Light-bellied Brent Goose (Canada/Greenland population) <i>Branta bernicla hrota</i>
Light-bellied Brent Goose (Svalbard population) <i>Branta bernicla hrota</i>
Common Shelduck <i>Tadorna tadorna</i>
Eurasian Wigeon <i>Anas penelope</i>
Gadwall <i>Anas strepera</i>
Common Teal <i>Anas crecca</i>
Mallard <i>Anas platyrhynchos</i>
Northern Pintail <i>Anas acuta</i>
Northern Shoveler <i>Anas clypeata</i>
Common Pochard <i>Aythya ferina</i>
Tufted Duck <i>Aythya fuligula</i>
Greater Scaup <i>Aythya marila</i>
Common Eider <i>Somateria mollissima</i>
Common Scoter <i>Melanitta nigra</i>
Velvet Scoter <i>Melanitta fusca</i>
Common Goldeneye <i>Bucephala clangula</i>
Red-breasted Merganser <i>Mergus serrator</i>
Goosander <i>Mergus merganser</i>
Common Coot <i>Fulica atra</i>
Eurasian Oystercatcher <i>Haematopus ostralegus</i>
Pied Avocet <i>Recurvirostra avosetta</i>
Common Ringed Plover <i>Charadrius hiaticula</i>
Eurasian Golden Plover <i>Pluvialis apricaria</i>
Grey Plover <i>Pluvialis squatarola</i>
Northern Lapwing <i>Vanellus vanellus</i>
Black-tailed Godwit <i>Limosa limosa</i>
Bar-tailed Godwit <i>Limosa lapponica</i>
Eurasian Curlew <i>Numenius arquata</i>
Common Redshank <i>Tringa totanus</i>
Ruddy Turnstone <i>Arenaria interpres</i>
Red Knot <i>Calidris canutus</i>
Sanderling <i>Calidris alba</i>
Dunlin <i>Calidris alpina</i>
Ruff <i>Philomachus pugnax</i>

1986/87. Of the species recorded during WeBS “Core Counts”, 40 (plus two additional populations of the Brent Goose *Branta bernicla*) are encountered frequently enough for inclusion in the Alerts System when considering national alerts. These are given in Table 1.

The numbers of some species of geese are not well monitored by monthly WeBS core counts and thus are not included.

Other waterbird species, including the Slavonian Grebe *Podiceps auritus*, Great Bittern *Botaurus stellaris* and Long-tailed Duck *Clangula hyemalis*, which, although recorded by WeBS, are either encountered too infrequently or in numbers too small from which to derive trends.

In addition to analysis of national trends, if possible, SPAs and SSSIs of importance for over-wintering waterbirds are assessed annually. Currently, sufficient data are available to assess trends on 68 SPAs and 26 SSSIs. A number of SPAs and many SSSIs cannot be assessed because count data for all cited species were unavailable or largely incomplete. Additionally, a few SPAs and many SSSIs cannot be assessed until ongoing work on establishing coincidence between WeBS count-sector boundaries and designated site boundaries has been completed. The areas surveyed during WeBS “Core Counts” at WeBS sites are matched as accurately as possible to designated site boundaries. Where WeBS count-sectors and SPA boundaries do not coincide, the optimum match is assessed. In many cases, there may be practical reasons for discrepancy. For example, most WeBS counts of estuaries are made at high tide because birds can be more reliably counted as they arrive or when they settle at roost, whereas some statutory site boundaries only encompass the inter-tidal habitat and exclude the adjoining areas where such roosts form. When birds are distributed across large expanses of inter-tidal flats, it can be extremely difficult to assess numbers accurately.

For each site, the species considered are those for which the site is important and thus for which decreases in numbers give cause for particular concern to conservationists. The suite of species was derived from Stroud *et al.* (2001), ignoring those cited as qualifying in a SPA due to important passage or breeding numbers. This selection process applies principally to SPAs. In the case of SSSIs, sites have often been designated for their “general waterbird interest” without specific information regarding the species composition being readily available. Consequently, species for SSSI assessment were selected on the basis that they were either listed specifically within the valid citation, or are likely to be a component of an undefined assemblage, such as “wintering waterfowl” listed in the citation.

## DATA ANALYSES

### Calculating annual indices

The index value for a particular winter is the number of birds present in that winter (summed monthly counts) expressed relative to the number of birds present in the most recent winter used in data analysis. Annual indices are calculated using count data collected between September and March, and within this period, the months for which the numbers of a given species are at their most stable are those used. This period differs between species, and further details can be found in Maclean *et al.* (2005). The same period is adopted for the assessment of Alert status.

Since it is often the case that sites do not contain complete time-series of count data, the Underhill indexing method (Underhill & Prŷs-Jones 1994) is used to estimate missing counts. The Underhill indexing method essentially imputes missing observations using other completed counts, but taking account of trends occurring elsewhere. These values are incorporated into the index, and serve as a complete data matrix for input into the General Additive Models used to generate smoothed trends.

### Calculating smoothed trends

Natural temporary fluctuations in numbers can differ in size and/or direction from longer-term trends, hindering their interpretation. Extreme values may trigger false Alerts due to misinterpretation of temporary, short-term declines as longer-term trends. Alternatively, long-term trends that may have led to Alerts being flagged could be obscured by short-term fluctuations. In order to avoid such misinterpretations and misidentifications when calculating Alerts, the Alerts System uses general additive models (GAMs) (Hastie & Tibshirani 1990) to fit a smoothed trend curve to the annual indices. The degree of smoothing depends on the number of degrees of freedom available to the GAMs. As the number of degrees of freedom is decreased from  $(n - 1)$ , which would be identical to the Underhill index provided data are complete, the trend becomes increasingly smooth until ultimately with one degree of freedom the smoothed curve becomes a linear fit. The WeBS Alert System adopts a standard  $n/3$  degrees of freedom (rounded up to the nearest integer) to produce a level of smoothing that, while removing temporary fluctuations not likely to be representative of long-term trends, captures those aspects of the trends that may be considered to be important (Atkinson *et al.* 2006).

Changes in numbers calculated using values from a smoothed GAM trend are less likely to be due to the effects of temporary fluctuations in numbers, or to counting errors, than results produced were annual index values to be used. Thus, the use of GAMs reduces the probability that a decline from a short-lived unsustainable peak in numbers would be responsible for triggering an Alert. A decline from a period of sustained high numbers, however, would trigger an Alert using GAMs, and clearly would be worthy of investigation. It should be noted that, because a standard degree of smoothing has been applied across all species and spatial scales, the arithmetic derivation could trigger alerts for species showing large year-to-year fluctuations in numbers. In these cases, knowledge of their ecology and population dynamics is essential for correct interpretation. This is addressed partially by the WeBS Alerts Biological Filter, the purpose of which is to fine tune the general rule for triggering an Alert in a species-specific manner.

### Biological filters

The smoothing used to produce the fitted trends goes some way towards preventing alerts being triggered when apparent decreases are due to natural fluctuations in numbers between winters. However, because the degree of smoothing has been standardized across all species, spatial scales and locations, it can be expected to achieve better results for some species than others. Rather than sustain the considerable extra processing costs that would be necessary to assess individually the optimal degree of smoothing for each species / spatial scale / location combination (itself is a process with a degree of subjectivity attached to it), a “biological filter” has been applied to reduce the chance of triggering false Alerts.

The aim of the biological filter is to attach a cautionary note to alerts being triggered when the observed decline for a given period is not uncharacteristic of that which might occur occurring due to inherent fluctuations exhibited by some species. The biological filter takes into account a number of aspects of the population dynamics and behaviour of each species that can be expected to affect the observed level of fluctuation. Several

sources of information are used to assess this. Full details are given in Maclean *et al.* (2005), but a brief summary is given here.

To address the issue of varying population stability amongst species, the mean absolute percentage change between subsequent winters has been calculated. Species have been assigned a *Fluctuation Score*, based on this value, such that those which show higher annual fluctuations scored low and stable species scored high. To address the issue of expected links between longevity and the degree of annual fluctuation, species have been assigned a *Longevity Score* by using ringing recovery data. Those which are longer-lived have been scored high, whereas shorter-lived species have been scored low. To address the issue of site-faithfulness between winters, ringing data have been used to assign a *Between Winter Movement Score*, based on the median distance of movements between winters. Site-faithful species have been scored highly, whereas highly mobile species are assigned a low score. To address the issue of site faithfulness within winters, ringing data have again been used to assign a *Within Winter Movement Score*. This was based on the median distance of within winter movements, such that site-faithful species scored high, whereas highly mobile species scored low. In all instances, only data from the UK are used. The overall *Biological Filter Score* (BFS) is calculated by summing the four contributing scores. In instances where contributing scores cannot be calculated, the maximum value (2) was used, thus adopting a conservative approach ensuring that no species is down-graded due to lack of information. Thus each species was assigned a BFS of between 0 and 8, with short-lived and/or fluctuating and/or highly mobile species being assigned the lowest score.

### Calculating Alerts

Proportional changes in the smoothed GAM trend in numbers over short-term (5-year), medium-term (10-year), long-term (25-year) and since site designation (variable) time-frames are calculated by subtracting the smoothed GAM trend value at the start of the time-frame from the smoothed GAM trend value in the penultimate winter. The final winter is not used, as GAMs have a tendency to exhibit disproportional upward or downward inflections at either end of the time-series used. Where data are not available for a 25-year period, the longest possible period (second to penultimate winter) is used instead. Calculated change values are expressed as a percentage of the index at the start of the period. Larger values therefore indicate larger proportional changes in numbers, with positive values equating to relative increases in the numbers, and negative values equating to relative decreases over the specified time period. These values are then categorized according to their magnitude and direction. Declines of between 25% and 50% inclusive are flagged as Medium Alerts and declines of greater than 50% as High Alerts. In order to facilitate comparison of decreases and increases in numbers, increases of between 33% and 100% are described as Medium increases, whilst increases of greater than 100% are described as High increases. This accommodates the fact that proportionally greater increases are required to return numbers to their former level following a given decrease.

The Biological Filter Score is then applied to provide a cautionary flag where required. For those species with a BFS of eight, cautionary flags are not applied. For those species with a

BFS of six or seven, cautionary flags are applied to short-term Medium Alerts. For those species with a BSF of four or five, cautionary flags are applied to short-term Alerts. For those species with a BSF of less than four, cautionary flags are applied except when medium and long-term High Alerts are issued.

After Biological Filter Scores have been applied, Alerts are considered at various spatial scales. All species currently included in the WeBS Alerts scheme are considered for Great Britain and Northern Ireland. Country-wide trends for each of Wales, England and Scotland are also considered for each species. The suite of species for which site trends are evaluated is restricted to those for which a designated site is considered important during the winter and for which there were sufficient data for evaluation. Regional trends are also calculated to enable comparison with site trends. To aid such comparisons, the proportions of both the regional and national populations hosted by each site are also calculated. This process goes some way to enabling downward trends driven by large-scale population or regional population shifts to be distinguished from those driven by adverse conditions on site.

### WHAT HAS WEBS ALERTS SHOWN US?

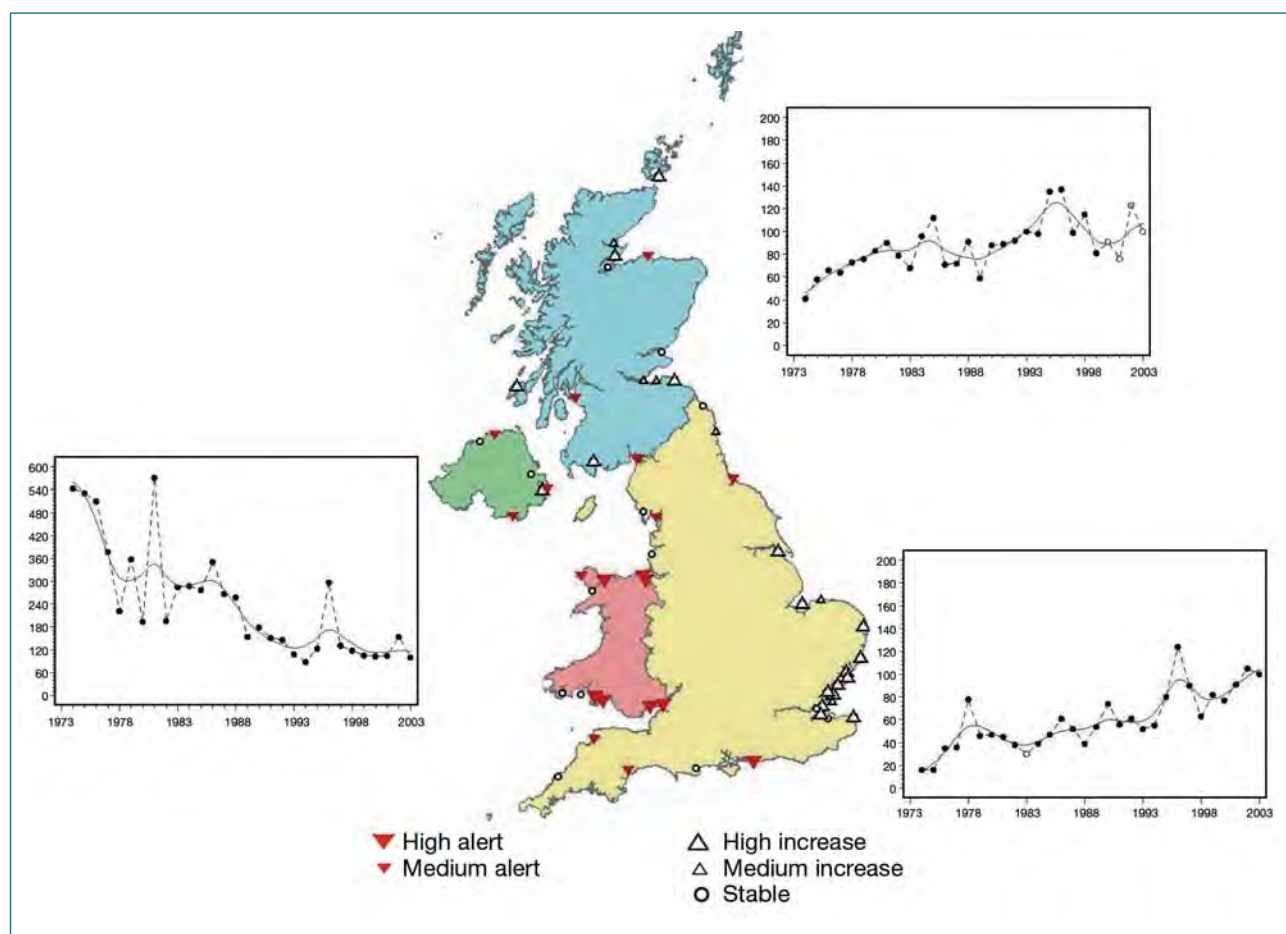

#### National population changes

The most recent Alerts analyses (Maclean *et al.* 2005) has revealed that High Alerts have been triggered for three species and Medium Alerts for a further three species. In the long term,

**Fig. 1.** Example of a plot generated by the WeBS Alerts analysis (Grey Plover *Pluvialis squatarola* on the Firth of Forth). The smoothed GAM trend shows a long-term high increase, a short-term decline triggering a Medium Alert, and no change in the medium term. The site was designated as an SPA in 2001, so insufficient time has elapsed to establish any meaningful change in the population trend over this period.

the smoothed trend reveals that the Bewick's Swan *Cygnus columbianus bewickii*, European White-fronted Geese *Anser albifrons albifrons* and Ruff *Philomachus pugnax* have all undergone declines of more than 50% and thus High Alerts have been triggered. The Mallard *Anas platyrhynchos* has undergone a

**Fig. 2.** Long-term trends in the number of Common Ringed Plover *Charadrius hiaticula* wintering on sites designated for this species ( $\Delta$  - >100% increase;  $\triangle$  - 50-100% increase;  $\circ$  - no change;  $\blacktriangledown$  - 25-50% decrease;  $\blacktriangledown$  - >50% decrease). Regional trends are also shown. In the long term, numbers have decreased in Wales and the south of England, and increased in Scotland and the east of England. The apparent shift in the population has been attributed to climate change.

decline of greater than 25%, triggering a Medium Alert. The Whooper Swan *Cygnus cygnus*, Eurasian Wigeon *Anas penelope*, Common Teal *A. crecca*, Common Eider *Somateria mollissima*, Common Goldeneye *Bucephala clangula*, Goosander *Mergus merganser* and Eurasian Coot have undergone moderate increases, and the Light-bellied Brent Goose *B. b. hrota* (Svalbard population), Gadwall *Anas strepera*, Greater Scaup *Aythya marila*, Pied Avocet *Recurvirostra avosetta*, Northern Lapwing *Vanellus vanellus*, Eurasian Golden Plover *Pluvialis apricaria*, Grey Plover *P. squatarola* and Black-tailed Godwit *Limosa limosa* have all undergone large increases. In the medium term, High Alerts have been triggered for Bewick's Swan and European White-fronted Goose, and Medium Alerts for Dark-bellied Brent Goose *B. b. bernicla* and Common Shelduck *Tadorna tadorna*. The Little Grebe, Gadwall, Eurasian Golden Plover and Black-tailed Godwit have undergone moderate increases, and the Light-bellied Brent Goose (Svalbard population) and Pied Avocet have undergone large increases. In the short term, High Alerts have been triggered for the Bewick's Swan and European White-fronted Goose, and a Medium Alert has been triggered for the Goosander. The Pied Avocet has undergone moderate increases and the Little Egret *Egretta garzetta* has undergone large increases. Some species, such as Little Egret (which has undoubtedly increased in the long term), have not been monitored by WeBS for sufficiently long to examine population trends over all time periods. It is noteworthy that several species, such as the Grey Plover (Fig. 1), have undergone short-term declines or increases against a background of long-term directional changes in the opposite direction. Such examples serve to illustrate the need to determine trends over a range of time periods.

### Large-scale population shifts

The Alerts System has also been instrumental in highlighting several species which have undergone marked re-distributions in their populations. For example, a number of wader species have undergone declines in the west of the UK, but are increasing in the east (Fig. 2). Such patterns, revealed through Alerts analyses at the site level but examined at larger spatial scales, have sometimes been the catalyst for further research. For example, it is now well established that population shifts first revealed through the Alerts process have occurred in response to climate change (Rehfishch *et al.* 2004, Austin & Rehfishch 2005, Rehfishch & Austin 2006). On average, estuaries on the south and east coasts of Britain have muddier sediments than those on the west coast, and thus support a higher biomass of invertebrate prey for waders. With the warming of winter temperatures by 1.5°C since the mid-1980s, the risk of weather-induced mortality on the colder east coast estuaries has diminished, and consequently populations have shifted in the expected easterly direction (Austin & Rehfishch 2005, Rehfishch & Austin 2006).

### Site-level changes

One of the primary aims of the Alerts System and subsequent reporting has been to establish important changes in waterbird numbers occurring on the UK's network of wetland and coastal SPAs. Numerous alerts have been triggered at the site level, but not all of these are indicative of unfavourable conditions at the site (Maclean *et al.* 2005). However, similar trends occurring within groups of species with closely related resource require-

**Fig. 3.** Trends in the numbers of Common Pochard *Aythya ferina* (a), Tufted Duck *A. fuligula* (b), and Common Goldeneye *Bucephala clangula* (c) over-wintering on Lough Neagh and Lough Beg. In the short term particularly, all three species have undergone major declines, with recent analysis suggesting climate-change-related distributional shifts (Allen *et al.* 2004).

ments can be a useful indicator that such sites may be experiencing problems. For example, in the most recent Alerts analyses, one of the most dramatic revelations has been the plight of diving ducks over-wintering on the Lough Neagh and Beg SPA. This site hosts nationally and internationally important numbers of the Common Pochard *Aythya ferina*, Tufted Duck *A. fuligula* and Common Goldeneye. Upwards of 25 000 Common Pochard, over 7.5% of the North-east and North-west European wintering population (Stroud *et al.* 2001) and over 50% of the UK population (Pollitt *et al.* 2003), were regularly

recorded at this site during the early 1990s. In a relatively short period of time (as revealed by the triggering of a short-term High Alert), the population has crashed and now numbers less than 7 000. Similar decreases have also been observed in the numbers of Tufted Duck and Common Goldeneye (Fig. 3). Recent detailed analysis triggered by these declines suggest that the declines are probably linked to climate-change related distributional shifts (Allen *et al.* 2004).

## CONCLUSIONS

The monitoring of wildlife populations and the sites on which they depend is an essential component of effective conservation management. The need to conserve and manage waterbird populations is evident, given the number of international treaties which place emphasis on waterbird populations. The Alerts System, by providing a standardized method for identifying the direction and magnitude of changes in waterbird numbers, provides one means of monitoring waterbird populations, and has already been instrumental in highlighting a range of conservation priorities.

## ACKNOWLEDGEMENTS

The monitoring of waterbird populations would not be possible without the combined efforts of the numerous volunteers who supply data. Our thanks also to Helen Baker, Peter Cranswick, Mel Kershaw, James Robinson, Rowena Langstone, David Stroud and Chris van Turnhout, who have all been instrumental in the development of the Alerts protocol. The Wetland Bird Survey is jointly organized by the British Trust for Ornithology, The Wildfowl and Wetlands Trust, the Royal Society for the Protection of Birds and the Joint Nature Conservation Committee (the latter on behalf of English Nature, Scottish Natural Heritage, Countryside Council for Wales, and Environment and Heritage Service in Northern Ireland).

### ABSTRACT

The magnitude of the challenge of conserving the full spectrum of migratory birds and their habitats dwarfs traditional wildlife management resources. To be successful, partnerships of government agencies and non-governmental organizations require explicit estimates of habitat objectives that are adequate to fulfill population conservation mandates, and cost-effective conservation strategies that are based on a systematic application of the best available science, and are therefore credible. In the United States, biological planning partnerships are an increasingly common means of developing shared visions and strategies for the community of conservation implementers. Biological planning is founded on the use of models describing population-habitat relationships, and the application of models to spatial data to reflect consensus-based management decision processes. An example of model-based biological planning is presented that illustrate how its use can: (1) increase management efficiency; (2) yield transparent and defensible conservation strategies; (3) serve as a framework for identifying and prioritizing among management information needs; (4) enable development of coordinated conservation strategies for multiple groups of wildlife; and (5) direct habitat restoration conducted with programs seeking diverse environmental and socio-economic benefits, but for which wildlife benefits are secondary goals, thereby enhancing the impact of these programs on bird populations.

### INTRODUCTION

The mandate to conserve bird populations in perpetuity is vast. Compared to this mandate, legal authorities and funding appropriated for habitat conservation are severely limited. In the United States, natural resource management agencies preside over a slow but inexorable deterioration of environmental function, including the capacity to sustain populations of most species. The challenges we face demand new approaches to the conservation enterprise – approaches based on applied science, coordinated conservation, and the cooperative communication of compelling conservation strategies.

The purpose of this paper is to illustrate (1) the importance of partnerships in affecting conservation at landscape-scales, and (2), more specifically, the role of biological planning in forging these partnerships and insuring that our collective conservation actions are effective and efficient. This paper is not intended to be a comprehensive description of the process of biological planning and evaluation, or of the diverse literature on various aspects of this iterative process.

### CONSERVATION PARTNERSHIPS

In the U.S., political boundaries – among states and various government programs – have contributed to a traditionally frag-

mented and piecemeal approach to conservation with needs expressed implicitly rather than explicitly. Our challenge in the conservation of migratory birds is to coalesce the pieces of the conservation puzzle vested in diverse agencies into a comprehensive international, multi-agency strategy for conservation. When a conservation strategy is developed and implemented through partnerships, it reflects a community vision, with each partner committing their programs and influence with external entities to delivering components of the whole.

One challenge in developing a community conservation strategy is that partners' jurisdictional boundaries often do not conform to a common theme. Most are based on states or aggregates of states. This facilitates program management but is not particularly conducive to the strategic management of populations and habitats. In the U.S., the geographic currency of partnerships is joint ventures initially formed under the banner of the North American Waterfowl Management Plan. Aligned along ecological boundaries, thereby transcending political barriers, joint ventures are partnerships of government agencies, non-governmental organizations, and others whose purpose is the efficient conservation of migratory birds.

Joint ventures are only valuable to the extent that they enable conservation that exceeds the sum of the potential actions of the individual agencies and organizations that comprise them. Joint ventures are uniquely structured to capture this added value. An ideal joint venture is comprised of two parts – a management board and a biological planning and evaluation team. The biological planning and evaluation team is charged with developing a science-based community conservation strategy. The role of management board members is to exert influence on the political process, and to shape how government agencies deliver their programs, to support implementation of the community strategy. Through this dual structure, joint ventures position themselves as a nexus for information between the scientific community and the agencies and programs seeking natural resource enhancement benefits through habitat conservation. Neither half of the joint venture can function effectively without the other. To use a different paradigm, a business is comprised of manufacturing and sales. A joint venture's product is a science-based conservation strategy. This product is marketed by the management board.

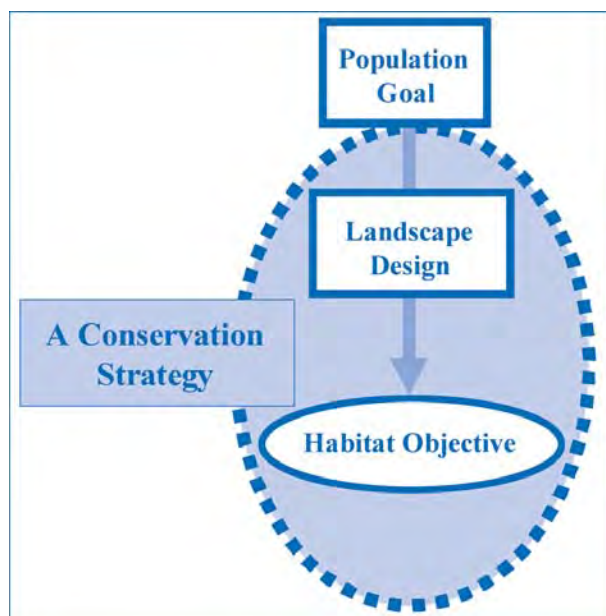

### BIOLOGICAL PLANNING AND EVALUATION

Most wildlife management agencies are charged with the conservation of populations. Habitat management on public and private lands is an important tool in attaining this goal. As land-use pressures escalate, the question "How much habitat is enough?" is being asked more and more often. To make a compelling case for additional conservation resources and

authorities, agencies need to articulate explicit goals and efficient strategies for attaining them.

Translating a population goal into an estimate of how much habitat is enough to attain this goal requires that we consider similarities and differences in the ways different species relate to habitats and respond to management, i.e. our planning must be spatially explicit, and we must design a landscape that maximizes collateral benefits and accounts for management conflicts. The development of spatial analysis techniques that integrate the biological foundation for management with digital spatial data using Geographic Information System (GIS) technology has been instrumental to science-based strategic conservation.

Collectively, a landscape design and habitat objectives predicted to sustain populations at desired levels constitute a conservation strategy (Fig. 1). The reliability of our assumptions about population-habitat relationships, and the degree to which managers are able to conform to the landscape design in delivering conservation, determine the relevance of our habitat objectives.

**Fig. 1.** A comprehensive biologically-based conservation strategy consists of explicitly stated goals and habitat objectives emanating from a landscape design predicted to sustain populations at goal levels.

This type of strategy is not a stack of papers that is bound and sits on a shelf gathering dust. It is a living suite of tools that are continually augmented, updated and refined through the iterative process of evaluation and planning anew. Different components of our strategy speak to different audiences. For example, regional or national habitat objectives mean little to a field-level manager; however, landscape designs that help managers decide where to apply management treatments, e.g. protect grass or wetlands, reforest, etc., are invaluable. The opposite is true for agency administrators that need clear statements of regional and national habitat objectives to gain support for conservation programs from elected officials.

The scientific foundation for a conservation strategy is inevitably imperfect. In practice, this foundation is a set of assumptions about how species are predicted to respond to landscape structure, patch-scale dynamics, and management actions.

Often, these assumptions are founded on very limited information. Yet the process of guiding management actions by articulating clear goals, applying the information that does exist, stating our underlying management assumptions (hypotheses) explicitly, evaluating the validity of our assumptions, and feeding refined assumptions into future management decisions is incredibly powerful. Most will recognize this process as adaptive resource management. Adaptive management of bird populations is founded on biological planning and evaluation for habitat conservation.

### Model-based approaches

Biological models are the vehicles for translating science into conservation strategies. The sole purpose of models is to improve the outcomes of management decisions. A model is simply a set of assumptions expressed in measurable terms. Models are commonly developed for focal species, i.e. priority species that are sensitive to landscape structure, patch-scale characteristics, and management that affects the structure of the plant community. Focal species are presumed to represent the habitat needs of a wider array of other species that are often less sensitive to these factors, although evaluation of this assumption is critical.

A model's value is measured by the extent to which it adds useful information to the management of focal species. Generally speaking, as model complexity goes up, so does the added value for decision making because model predictions move beyond our capacity for intuition. For example, models such as range maps or basic habitat associations offer managers little that they do not already know. In fact, if a species' habitat relationships are adequately described by a basic habitat type (e.g. emergent wetland or deciduous forest), it is probably a poor candidate for a focal species for biological planning, because it captures little of the more refined habitat needs of other species which respond to factors such as landscape configuration or patch size.

Models are applied to digital spatial data to predict the potential population impacts of delivering a particular management treatment at a specific place in the landscape. Typically, the potential of every unit of the landscape is assessed in developing these decision support tools (DSTs) for the management of focal species.

Biological planners commonly use models that fall into two broad categories. Conceptual models, which may or may not include empirically-based parameter estimates, are compiled from a variety of sources including the personal experiences of individuals knowledgeable about the interactions of a species and its habitat. Conceptual models are sometimes called heuristic models, in that they carry a heavy burden to evaluate their inherent assumptions and future improvement in model performance is expected accordingly. Conversely, empirical models are more initially data driven and are typically developed from discrete data sets. Empirical model coefficients also require regular assessment, but if their foundation is long-term, spatially extensive data sets – clearly the preferred source – evaluation and model updating are inherent components of the periodic data collection protocol. Both types of models are data driven in the iterative biological planning and evaluation paradigm.

Lastly, while assessing apparent habitat suitability is often useful, developing a comprehensive conservation strategy that

includes priority areas for specific conservation actions and habitat objectives requires that we use models that reliably predict carrying capacity or some other measure of population potential, developed in an awareness of the ecological factors or processes that limit populations.

### QUALITY CONTROL IN PARTNERSHIP-BASED CONSERVATION

Why do partnerships such as joint ventures invest in biological planning and evaluation? (1) It can increase their efficiency – vital, given the magnitude of their mandate relative to the resources available to them; (2) it is a transparent and defensible application of sound science which enhances the partnership's credibility – collectively and individually; (3) it is a framework for identifying critical information gaps for actual management decisions rather than things we would simply like to know more about, which has characterized much of our past statement of research needs; (4) it enables the development of coordinated conservation strategies for multiple groups of wildlife; and (5) it sets the stage for greater influence in the implementation of other State and Federal programs. To return to our business paradigm, biological planning and evaluation represent joint venture quality control.

#### Efficiency

The benefits of biological planning are predicated on the idea that every unit of a landscape, and every alternative management action at that location, has a unique potential to affect populations and unique costs to management agencies and society of doing so. Balancing these factors in pursuit of high impact per dollar expended is the essence of efficient conservation. While calculation of management costs may be relatively simple, assessing the probable impacts of applying a particular treatment at a particular location to populations of multiple species requires applications of science in a spatially-explicit environment.

#### Transparency and defensibility

Application of science to clearly defined management goals and information needs yields inherently defensible management strategies and decisions. The only question is whether the science is adequate to support a particular action that otherwise would not occur. In the U.S., biological planning serves two fundamental roles:

- targeting existing program resources and activities; and
- assessing the need for additional resources and programs.

When strategies and decisions are based on explicitly described assumptions, founded on the best available science, the decision-making environment is inherently transparent and defensible. Moreover, by acknowledging that our assumptions are based on imperfect knowledge, we isolate the decision process from its outcomes, and we set the stage for a productive dialogue on strengthening the biological foundation.

Finally, the maps and other products of biological planning are powerful tools that enable managers to communicate effectively with elected officials and the public, both to support their proposed actions and to resist actions that may be inefficient or undesirable.

### Building the biological foundation

A model is really just a set of assumptions described in measurable terms. All assumptions are imperfect. As we go through the biological planning process, it is often obvious which assumptions are the most tenuous. Furthermore, refinement of some assumptions will have little impact on the decision we make. Others will have a large impact. Assumptions that are the most tenuous and that have the greatest potential impact on our management decisions are the highest priorities for research. Thus, model-based biological planning is a systematic way of identifying and prioritizing information needs, i.e. identifying missing critical research and monitoring, and distinguishing these needs from things about which we are simply curious. This is a more strategic approach to building the biological foundation for conservation than traditional, more haphazard means of identifying research needs.

### Coordination of conservation for multiple species

When biological planning is conducted in a spatially-explicit context, collateral benefits for multiple species can be assessed and management conflicts can be resolved. Maximizing site-level collateral benefits, within the constraints of program purposes and priorities, and minimizing collateral adverse impacts at landscape or eco-regional scales are essential to efficient conservation. Furthermore, the process of spatially-explicit planning is open-ended, i.e. other environmental and socio-economic functions of habitats can be assessed in the same fashion and integrated with spatial decision support tools developed for wildlife.

### Greater influence

In intensively altered ecosystems, relatively little land is typically in public ownership. A private land conservation solution is required. A variety of Federal land management programs and environmental protection policies exert a profound impact on these landscapes. In the U.S., none is more important than the U.S. Department of Agriculture's "Farm Bill". The Farm Bill supports the apparently conflicting goals of sustaining high agricultural production by subsidizing farming operations, while simultaneously paying land owners to convert farmland into habitat for prevention of soil erosion, enhancing water quality, and providing wildlife habitat. In recent years, Farm Bill expenditures have exceeded by nearly 200 times the combined total of all Federal agencies for bird conservation. Clearly, influencing these farming subsidies and agricultural programs is of paramount importance in conserving birds. As the ultimate responsible entity for migratory bird conservation, the U.S. Fish and Wildlife Service (USFWS) has a special interest in Farm Bill policies and programs; however, in the political process of establishing these policies, the USFWS requires the support of state and non-governmental partners.

As noted, the products of landscape-scale biological planning can be compelling, because of their visual impact and because they are transparently derived and built on sound science. Being compelling, they provide a vehicle for reaching out beyond traditional conservation programs to other programs that affect public and private land-use management. Despite long-standing challenges in working with agriculture, bird conservationists in the U.S. have recently had success in targeting Farm Bill conservation programs, amounting to

millions of dollars each year, in regions of the country where the capability for biological planning and evaluation exists.

### A CASE STUDY

We illustrate these concepts in the following case study from an area of five counties in the Prairie Pothole Region of Minnesota. Although the models and maps of species-specific landscape priority areas are real, the population goals and some assumptions, and thus the integrated landscape design and habitat objectives, are hypothetical.

Our case study begins with the identification of an ecological perturbation (grassland habitat loss and fragmentation) and focal species that are sensitive to it. We consider the full suite of priority grassland-dependant birds in light of their response to stand height and density, patch size, and landscape structure. For our example, we chose three focal species. The Marbled Godwit *Limosa fedoa*, an apparently area-sensitive priority breeding shorebird, uses native or disturbed tame grasslands, studded with shallow wetlands, in landscapes with low terrain relief. The Greater Prairie Chicken *Tympanuchus cupido* is similarly sensitive to patch size and landscape structure. It requires short grass for nesting, but uses taller stands for brood rearing and other functions. Lastly, we chose to use the Mallard *Anas platyrhynchos* as a focal species. Mallards are grassland generalists and are relatively insensitive to grassland landscape structure; however, they require the juxtaposition of grasslands and wetlands, and there is great public demand for this species, with correspondingly high population goals.

A diverse conservation partnership is active in this five-county area. For each of our focal species, the partnership established population goals (Table 1). Above minimum viable population sizes, a partnership's population goals are value-based predictions of public demand for wildlife and public willingness to pay the costs of attaining those goals. Ideally, population goals should be established iteratively by setting goals, assessing costs, and revisiting goals and costs until an acceptable level of consensus is achieved.

We assembled models and other assumptions that relate focal species populations to grasslands. An empirical model for Greater Prairie Chickens that included only remotely-sensed variables was published by Niemuth (2003). This logistic regression predicted the probability of a site supporting a Greater Prairie Chicken lek. This model predicted relative habitat suitability, and it was necessary to make additional assumptions about average population size of leks, ratio of males to females in the vicinity

of leks, and size of the females' home range (Fig. 2).

A poisson regression was developed for Mallards from pre-existing field survey data. This regression predicted the capacity (in number of breeding pairs) of individual wetland basins, based on basin size and water regime. These estimates were combined with other data on the maximum travel distance of female Mallard from wetlands to upland nesting sites to estimate the number of ducks that could nest in a tract of grassland based on the number and characteristics of surrounding wetlands (Fig. 2).

Pre-existing survey data were inadequate to construct empirical models for Marbled Godwits. We developed a conceptual model in consultation with biologists with some expertise in habitat use by godwits (Diane Granfors, U.S. Fish and Wildlife Service, unpubl. model) (Fig. 2). As with the model for Greater Prairie Chickens, it was necessary to make additional assumptions to relate godwit populations to potential habitat.

Each of these models required assessment. We used pre-existing data, such as state Heritage Society data, to check model predictions, and, coincident with conservation delivery, collected additional field data to evaluate model assumptions and performance.

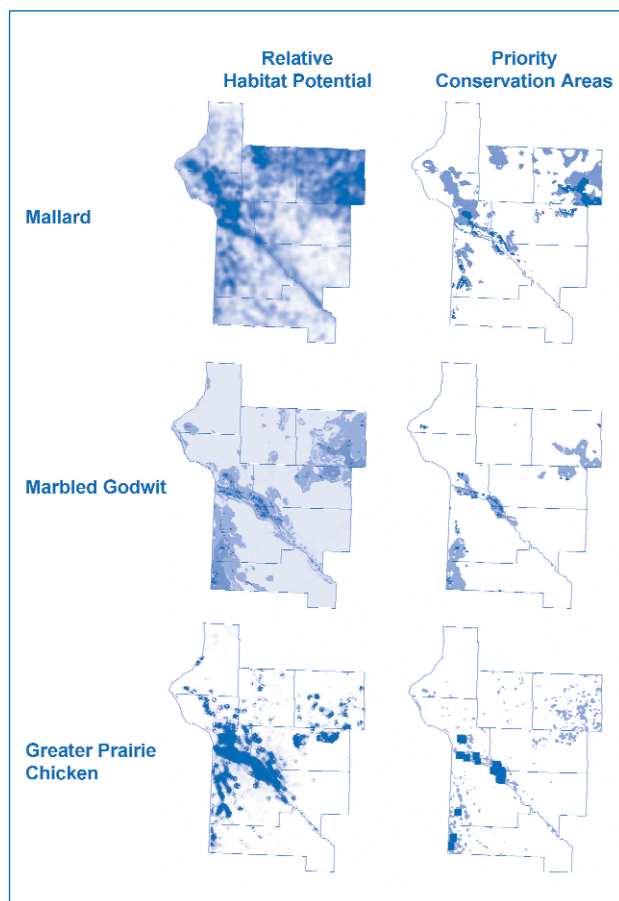

Models were applied to spatial data on grasslands and wetlands to:

- assess current eco-regional capacity to sustain populations of focal species;
- establish restoration objectives;
- assess contributions of lands currently in the conservation estate (Table 1); and
- identify priority sites and landscapes to protect and restore habitats in order to conserve populations as effectively as possible at goal levels (Fig. 2).

Establishing restoration objectives implies an awareness of current carrying capacity and assumptions about probable future loss of existing capacity. In most cases, it is unrealistic to try to protect all existing capacity. These losses must be offset by restoration. Furthermore, it is desirable to consider the amount of existing capacity that should be formally protected versus the amount that should remain in private, unprotected status. This proportion will depend on the importance of the landscape to a species' range-wide population and the risk of habitat loss over a finite time-scale. In our case study, we chose a strategy of perpetual protection of the full habitat potential needed to secure our population goals.

**Table 1.** Population goals may be crafted into habitat objectives for future conservation by assessing current landscape potential, collateral conservation impacts, and contributions of the existing conservation estate.

	Mallard (pairs/recruits)	Marbled Godwit (pairs)	Greater Prairie Chicken (hens)	Total habitat
Partnership's population goal	26 000/32 000	60	184	
Contribution of the existing conservation estate	9 163/9 536	32	104	
Conserved population deficit	16 837/22 464	28	80	
Species-specific habitat objectives (ha)	106 098	10 781	37 195	154 074
Collateral impacts				
Mallard		12	72	
Marbled Godwit	1 487/1 863		24	
Greater Prairie Chicken	4 365/5 675	16		
Integrated habitat objectives (ha)				115 027

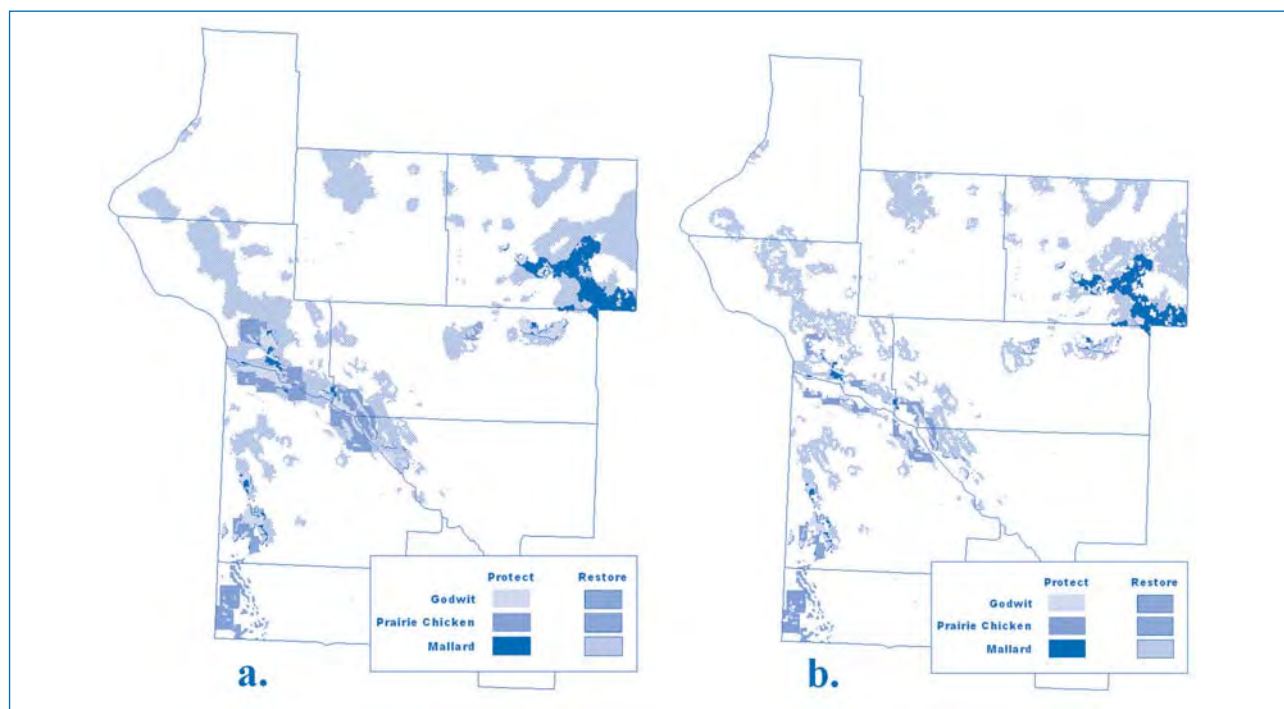

**Fig. 2.** The relative potential of different portions of the landscape to support populations of focal species, and priority conservation areas for each species based on population goals and relative potential to sustain populations. In the latter, priority protection areas are depicted in dark blue, and priority restoration areas in light blue.

By developing priority sites and landscapes for individual species, it is possible to develop species-specific habitat objectives (Table 1). Summing these species-specific habitat objectives indicates that approximately 154 000 ha of additional grassland must be conserved to attain our population goals.

Driven by program priorities, which are often defined in legislation, different agencies and organizations will play different roles in attaining goals for a particular focal species; however, implementation of one program often has collateral impacts, positive or negative, on other focal species (Table 1). An awareness of these collateral impacts is essential to efficient attainment of population goals. Therefore, we develop an integrated landscape design by combining priority areas for multiple focal species. This integrated landscape design is the foundation for our actual habitat objectives (Fig. 3).

This integration of species-specific priority conservation areas may result in conflicts based on impacts of grassland management on our focal species. For example, Marbled Godwits and Greater Prairie Chickens require native prairie or disturbed tame grasslands, while Mallards select tall, rank idled grasslands for nesting when available. This conflict was resolved in each area that is a priority for Mallards and for Greater Prairie Chickens or Marbled Godwits. We used an *ad hoc* process based on prediction of adverse impact on Mallards of managing grassland patches for prairie chickens/godwits and vice versa, and the relative importance of each conflicted geographic unit to each species in our integrated landscape design. This altered the predicted carrying capacity for each species of our landscape design, and required that the design, and our habitat objectives, be adjusted accordingly. Thus, like all other aspects of biological planning, the development of an integrated landscape design is iterative.

Based on our integrated landscape design, we estimate that approximately 115 000 ha of additional grassland habitat must be conserved, in the context of our integrated landscape design,

**Fig. 3.** (a) An integrated landscape design was created by merging species-specific priority conservation areas and reconciling management conflicts, based on differential responses to management of habitat structure. (b) The same integrated landscape design after the existing conservation estate was masked out. This is the foundation for habitat objectives, and for future grassland protection and restoration.

to attain the partnership's population goals (Table 1). Compared to our previous estimate of 154 000 ha, this represents a 25% increase in conservation efficiency. How close this habitat objective is to the amount of habitat we ultimately have to conserve to attain our population goals depends on how closely we are able to conform to our integrated landscape design. In practice, this habitat objective is a minimum estimate because some deviation from an optimal strategy is inevitable.

Despite our increased efficiency, restoring and providing some degree of protection to 115 000 ha of grassland habitat is still a massive challenge which underscores the need to capture the full wildlife conservation potential of the U.S. Farm Bill and other Federal programs.

### PREDICTED SPECIES RICHNESS MAPS

In some cases, the increased availability of remotely-sensed digital land-cover data and GIS technology has led to the use of simple habitat associations (e.g. emergent wetland or deciduous forest) in lieu of more informative models, and to the creation of maps of predicted species richness by overlaying deterministic predictions of apparent habitat suitability for large numbers of species. At best, these maps provide little information for management, and at worst result in a misallocation of program resources, for the following reasons:

#### *Process deficiencies*

- Overlaying deterministic species-specific predictions about habitat suitability results in high, but seldom estimated, uncertainties in predicted species richness.
- The product fails to provide information on what form conservation should take at a particular location. The implied action is protection of existing habitat, which is only one tool available to managers.
- The process does not acknowledge conflicting species responses to management, and does not accommodate resolution of potential management conflicts.
- The process does not consider populations, and does not result in defensible, population-based habitat objectives.
- Because of the simplicity of models and the failure of models to make explicit predictions of abundance or vital rates, the process does not connect management with research/monitoring.

#### *Model deficiencies*

- The need to use overly simplistic species-population relationships (models) because of the large number of species being considered.
- A failure to consider limiting factors or larger-scale habitat or landscape factors influencing actual habitat suitability, carrying capacity, or vital rates.
- A failure to consider population viability driven by "patch" and landscape-scale factors.

#### *Scale deficiencies*

- The scale of assessment is disconnected from the scale of management when species richness is "summed" for

larger units such as 7.5 quadrangles of 7.5 x 7.5 geographical minutes, or watersheds, which are almost always larger than the scale at which management is applied on the ground, thus violating the assumption that all of the species accounted for in the species richness estimate will be benefited by a single management action.

In short, single maps of species richness (biodiversity) are typically poor predictors of actual or potential species distributions, are often driven by local or landscape-scale habitat heterogeneity more than importance to populations, often are not useful for management unless they are dissimilated into the elements used to construct them, and as such, have little value for directing conservation actions. Nevertheless, maps of species richness are often compelling, as is the idea of using them to conserve biodiversity. As such, they can inadvertently impede more sophisticated approaches to landscape design, based on higher level critical thinking about trust responsibilities, limiting factors, management compatibility and spatial scales.

### CONCLUSIONS

Biological planning is critical to efficient, transparent, and credible management decisions. Planners and managers are forced to be explicit about their assumptions about population-habitat relationships. Thus, it provides a foundation for strengthening the biological foundation through evaluation which in turn contributes to reliable future conservation strategies. When conducted in a spatially-explicit environment, biological planning provides a means of integrating the conservation needs of migratory birds with other species of wildlife, and other environmental and socio-economic functions of habitat.

The magnitude of our mandate dwarfs traditional conservation resources. Wildlife conservation agencies must use their programs strategically to conserve the habitats that are most critical to their mission, and must develop the capacity to engage other government agencies and the public and more effectively harness their conservation potential. Partnerships for the development of community conservation strategies and for outreach are invaluable to conservation.

This implies that wildlife conservation agencies will rethink their roles and responsibilities. Rather than think of their roles as solely one of active habitat and population management, agencies have to view their role as equally one of nurturing, stewarding, and promoting the biological foundation and strategies for migratory bird conservation, i.e. we must provide leadership and an explicit strategy for the conservation of migratory birds, and coordination of conservation partnerships. The foundation for this leadership will be biological planning at landscape scales.

Straw, P. & Saintilan, N. 2006. Loss of shorebird habitat as a result of mangrove incursion due to sea-level rise and urbanization. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 717-720.

### ABSTRACT

Most migratory shorebird species require areas of open habitat such as tidal flats and salt-marshes where they can forage, rest and moult. The expansion of mangroves into shorebird feeding and roosting habitats due to sea-level rise and increased sedimentation is presenting a significant problem in closed situations such as estuaries in Hong Kong, Taiwan and eastern Australia. Seaward invasion of mangroves onto tidal mudflats as a result of excessive sedimentation caused by poor watershed management is affecting shorebird feeding areas. Landward invasion of mangroves in response to sea-level rise is affecting salt-marsh areas important as shorebird roosting and feeding habitat. Options for management intervention, such as the controlled removal of accreting mangrove seedlings and saplings from key shorebird feeding grounds, as well as the restoration and creation of mudflat and salt-marsh habitat, are discussed.

### SHOREBIRD HABITAT REQUIREMENTS

Most migratory shorebirds prefer to feed on open areas of undisturbed mudflats where they have a clear view of the approach of avian or terrestrial predators. Roosting sites are also selected to provide an open view and easy escape in case a predator approaches. Only under certain circumstances, where they have no alternative, will shorebirds utilize habitats close to tall vegetation or structures that obscure their view.

In a survey of 63 inter-tidal flats in nine New South Wales estuaries on the east coast of Australia, Lawler (1996) determined estuarine features which related to abundance in the feeding habitat of six species. The Bar-tailed Godwit *Limosa lapponica* selected large, low-lying flats for feeding; Whimbrel *Numenius phaeopus* favoured mangrove-lined flats in high-sediment regimes; and Far Eastern Curlew *N. madagascariensis* and Pacific Golden Plover *Pluvialis fulva* favoured large complexes of flats. Common Greenshanks *Tringa nebularia* frequented feeding areas of any size, provided they were wet, nutrient-rich and mangrove-fringed. Grey-tailed Tattlers *Heteroscelus brevipes* were more likely to feed adjacent to mangroves and on flats with some ground cover.

During high tide, when tidal flats are submerged, shorebirds require roosting sites such as beaches, sand spits, salt-marshes, and structures such as infrequently used jetties, barges, rock walls and oyster platforms. A few species, such as the Grey-tailed Tattler and Whimbrel, frequently roost on exposed branches of mangrove trees.

One of the most significant findings of Lawler (1996) was the extent to which most shorebirds avoided trees while roosting.

In a study of 134 sites used by roosting shorebirds in 18 estuaries in New South Wales, Lawler described the roosting habitat of five species with respect to a range of variables. Of the ground roosts, of which there were 93, only two were within 10 m of vegetation over 5 m tall, and 83% were at least 30 m distant from trees 5 m tall. Ninety percent of ground roosting sites were further than 10 m from 2 m high trees and bushes. Beaches accounted for 55% of roost sites, salt-marshes for 15%, mangrove trees for 19%, and artificial structures for 11%.

Studies of the Hunter Estuary in New South Wales have revealed that shorebirds abandon diurnal roost sites on sand spits and river-training walls where terrestrial predators, such as foxes, might be able to approach under the cover of darkness (Clarke & van Gessel 1983, Geering 1995, Straw 2000). The sites chosen at night are flooded back-swamps: usually salt-marsh or shallow lagoons where predators would be reluctant to stalk roosting shorebirds and where they would be more obvious. As there are few studies of nocturnal roost sites, it is unknown how widespread this practice is.

### THE MANGROVE ENVIRONMENT

Mangroves form an important part of the coastal ecology in southern Asia and throughout Australasia, together with sea-grasses and open tidal flats on the seaward side and salt-marsh communities on the landward side of the mangrove belt. The width of mangrove woodland varies from a few metres to several kilometres, depending on the latitude and coastal topography. The most extensive forests tend to exist in the tropics along shallow coastlines where there are many species of mangrove, whereas in temperate regions only one or two species occur.

The widespread loss and degradation of mangrove forests throughout South-east Asia and on the eastern coast of Australia are well documented. Logging and conversion for aquaculture are among the most frequently cited causes in South-east Asia, while the conversion of mangrove forests into waterfront residential and resort accommodation has been one of the main causes in Australia. Over the years, awareness regarding the ecological and economic importance of mangroves has grown. As a result, many authorities are engaged in efforts to restore this valuable resource, and this is reflected in the increasing number of publications and workshops dedicated to the subject (e.g. JAM 1994, Khemnark 1995, Field 1996). In New South Wales, the removal of mangroves without a licence now carries heavy penalties, with fines of AUS\$ 55 000 for individuals and AUS\$ 100 000 applying for corporations (Diver 2003). Any licences that are granted usually require the planting of at least one mangrove for every one removed in a place where they have a high likelihood of survival.

Unfortunately, many mangrove restoration projects move immediately into planting mangroves without determining why natural recovery has not occurred (Lewis 1998). Mangrove planting efforts have been conducted both in degraded former mangrove areas as well as in areas where mangroves have not previously occurred. Various South-east Asian countries have carried out large-scale planting of mangrove seedlings on inter-tidal mudflats (which cannot be considered “restoration”) as part of well-intentioned mangrove restoration programmes. Though limited in success, these efforts have resulted in afforestation of significant tracts of open tidal flats over the past decade, substantially reducing the area of inter-tidal mudflat habitat (Erftemeijer & Lewis 2000). Land-ownership issues appear to play a major role in targeting mudflats for such planting programmes, as mudflats are “easily” accessible (with no-one claiming ownership), while access to abandoned shrimp ponds in former mangrove areas - which should be the real target for restoration - usually involves complicated legal claims over land ownership. Furthermore, such areas are prone to land speculation, especially in coastal areas where there is need for room for expansion of industrial and residential areas.

#### LOSS OF HABITAT AS A RESULT OF MANGROVE INVASION

Another less well-known cause of the loss of shorebird habitat is the spread of mangroves through poorly understood processes in

both a seaward and landward direction. Recent studies have shown that mangroves have invaded large areas of salt-marsh and open tidal mudflats, two types of habitat utilized by shorebirds. This situation is most pronounced in areas of rapid coastal development where coastal wetlands, including tidal mudflats, have been substantially reduced. The accretion of mangroves onto tidal mudflats is thought to be a result of increased silt loads and nutrient levels due to uncontrolled development and soil erosion in upstream catchment areas. Mangroves follow such fertile areas of mud accretion, and their establishment in such environments may lead to a reduction in the extent of open tidal flat habitat available to shorebirds (Augustinus 1995). Mangrove expansion in a landward direction over the past five decades may be attributed to a rise in sea level, which has exposed upper inter-tidal environments to mangrove colonization. Wilton (2001) demonstrated that while salt-marsh losses in recent decades have been greatest in urbanized estuaries, the component of loss due to mangrove encroachment is relatively constant between estuaries, at a median figure of 30%. The overall sea-level rise in the period 1940-2000 (70 mm at the Fort Dennison datum in Sydney Harbour) represents approximately 30% of the vertical range of the salt-marsh. The consistency of the trend between estuaries, the similarity between the approximate degree of loss and the degree of sea-level rise, and the pattern of encroachment along drainage lines (Saintilan & Williams 1999), all suggest that at least some component of salt-marsh loss is related to sea-level trends.

**Table 1.** Mangrove increase/decrease over the past few decades at 31 selected sites in Australia.

Of 31 case studies in south-eastern Australia (Table 1), only four reported a decline in mangrove area. These were associated with construction and development works. Unfortunately, there are few data describing the distribution of estuarine macrophytes prior to the use of aerial photography.

This trend of mangrove proliferation has placed pressure on other estuarine habitat types. In a review of 29 photogrammetric surveys covering over 20 estuaries in Queensland, New South Wales, Victoria and South Australia, Saintilan & Williams (1999, 2000) described an increase in the area of mangroves, and a corresponding decrease in the salt-marsh habitat. In 70% of estuaries surveyed, salt-marsh losses due to mangrove incursion have exceeded 30%, and in some situations losses have approached 100%. These impacts have heightened pressure on salt-marsh already impacted by agricultural and urban developments (Kratochvil *et al.* 1972, Zann 1997, Finlayson & Rea 1999). In a world unaltered by humans, the movement of mangroves into salt-marsh habitat as a result of sea-level rise would be offset by a similar movement in a landward direction by salt-marsh. However, in many situations salt-marsh is being squeezed out of existence between an advancing front of mangroves on one side and landfill and development on the other.

Accurate mapping, and therefore measurement, of the loss of tidal flats due to the spread of mangroves has yet to be completed in Australia. Mapping of mangroves at Mai Po Nature Reserve in Hong Kong has shown that the mangroves are spreading seaward at a rate of 5 m a year, and have expanded from 197 ha in 1987 to 394 ha in 2000 (WWF Hong Kong 2003). A similar situation has occurred at Guandu Nature Park, Taipei (R. Fang pers. comm.).

The prognosis for coastal wetlands in south-eastern Australia in the context of further sea-level rise is continued mangrove expansion landward and on a much wider front in a seaward direction if sedimentation rates remain high (Stolper 2002).

## MANAGING MANGROVES

The loss of shorebird habitat continues throughout the Asia-Pacific region. The most dramatic loss is due to land reclamation by humans through increasingly larger projects, e.g. at Seamangeum in South Korea. The answer to the problem is clear, although at times seemingly impossible: the cessation or even the reversal of land-filling projects. However, the situation relating to mangrove incursion into shorebird habitat needs more study, and the solutions are less clear. At some sites, such as Mai Po Nature Reserve in Hong Kong and parts of the Hunter River estuary, New South Wales, Australia, teams of volunteers periodically remove mangrove seedlings and saplings from relatively small but critically important shorebird feeding habitat and roosting sites. However, such management interventions may not be viable in the long term and at larger scales. To prevent the continual re-colonization by mangroves through seeds from other coastlines, tidal mudflats may have to be restored to levels below that suitable for mangrove colonization.

In areas where space is limited, such as in Sydney, Mai Po and many places in the UK, alternative habitats have been created for shorebirds in the form of shallow ponds or "scrapes". These sites are manipulated to create wet, muddy shores through changing water levels, either through sluice gates from nearby tidal waters

or by pumping water in and out of the site. Constructed or modified sites such as these in South-east Asia and Australia have to be managed in such a way as to exclude mangrove seeds from entering the site from nearby mangrove forests. A number of systems are currently being designed to allow tidal flows and fish passage while preventing flotsam, including mangrove seeds and floating pollutants, from entering the site.

## CONCLUSIONS

For a long-term, sustainable solution to the problem of mangrove invasion into feeding and roosting habitats of migratory shorebirds, the underlying causes of sedimentation and sea-level rise should be addressed. Integrated river basin management approaches may help to reduce the problem of excessive sedimentation. Recent advances in ecological engineering have helped in the successful restoration and/or artificial creation of mudflat and salt-marsh habitats (Evans *et al.* 1999, Short *et al.* 2000, Simenstad & Warren 2002). Policies and interventions aimed at reducing the emissions of greenhouse gases may, in the long run, help to slow down the rate of sea-level rise. In the short term, the management of the spread of mangroves through weeding as seedlings appear and the construction of shorebird habitat excluding mangroves (two strategies being carried out in Hong Kong and Australia) are protecting threatened shorebird communities.

## Migratory waterbirds in the Bagga riverine wetland of central Sudan: challenges for integrated wetland management

Ali Kodi Tirba

Wildlife Conservation Administration, PO Box 336, Khartoum, Sudan. (email: [tirbakh@maktoob.com](mailto:tirbakh@maktoob.com))

Tirba, A.K. 2006. Migratory waterbirds in the Bagga riverine wetland of central Sudan: challenges for integrated wetland management. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 721-724.

### ABSTRACT

The River Nile is one of the most important flyways for migratory waterbirds moving between Africa, Europe and western Asia. Sudan has a longer portion of the Nile than any other country in the region and many wetlands that provide suitable conditions for migrant birds. These conditions are to a large extent dictated by the geomorphologic structure of the Nile and the prevailing human activities. One of the most important stopover sites for migratory waterbirds is Bagga riverine wetland in central Sudan, south of Khartoum. This wetland has six main habitat types: shrub-scrub, seasonally flooded grassland, permanently flooded swamps, papyrus swamp, riverbank habitat, and open water. Censuses in 2003 indicated the presence of 170 000 waterbirds of 50 species. About 5 000 people live in the area and utilize the wetland for fishing, cultivation, livestock grazing, papyrus harvesting, water consumption and woodcutting, while visitors from elsewhere engage in sport hunting and other recreation. The impact of some of these activities (over-fishing, over-grazing, illegal hunting) has resulted in a marked deterioration in the wetland. This is an issue that needs to be addressed through the implementation of a variety of management strategies aimed at ensuring sustainable utilization of the wetland resources.

### INTRODUCTION

#### Background

Sudan is the largest country in Africa, with an area of approximately 2.5 million sq. km. The country is gently sloping towards the north. It is generally flat with some scattered hills and mountains. There are nine major habitat types (ecological zones): desert; semi-desert; low rainfall woodland savannah; high rainfall woodland savannah; equatorial forest; the Sudd region; montane regions; floodplains; and the Red Sea coast. Wetland habitats make up 20% of the total area of the country. They include the Sudd swamps, the River Nile and its tributaries (a drainage network of 9 000 km), 750 km of coastline along the Red Sea, a number of inland lakes, 2 000 “haffirs”, and 10 000 km of canals in the Gezira irrigation scheme. In addition, there are innumerable seasonal swamps.

Wetlands in Sudan are vital to the global conservation of migratory waterbirds, as the country is situated on one of the main migration routes of waterbirds breeding in Europe and western Asia and spending the non-breeding season in Africa. Moreover, the wetlands contribute profoundly to the welfare of the people and wildlife in general.

The River Nile is one of the main flyways of migratory waterbirds moving between Africa, Europe and the Middle East. The Sudanese portion of the River Nile is longer than that in any other country in the region, and provides a considerable amount of suitable habitat for the migrant birds. The condition of the

wetlands is, to a large extent, dictated by the geomorphologic structure of the Nile and the prevailing human activities.

The principal uses of wetlands along the River Nile in Sudan vary according to location. South of latitude 12°N, the use of wetlands is largely confined to the direct exploitation of wetland resources, e.g. farming, fisheries, harvesting of minor wetland products, and other non-consumptive uses such as transportation and recreation. However, along the northern portion of the Nile, from latitude 12°N to the Egyptian border, the river runs through exceptionally dry areas characterized by excessively high temperatures, low relative humidity and low precipitation. Human activities in these areas are entirely dependent upon the wetlands. Here, in addition to fishing, human settlement, transportation and recreation, the wetlands are used as a source of water for irrigation, with water being abstracted in very large quantities to irrigate agricultural schemes along the riverbanks. This portion of the river is very densely populated, and wetlands are primarily confined to the river channel. The nearest extensive swampy area to this portion of the River Nile is Bagga riverine wetland to the south.

#### Policy and legislative framework

The Wildlife Conservation Act of 1986 governs and regulates practices inside the protected areas in Sudan. Thus declaration of Bagga riverine wetland as a protected area should be the foundation for ensuring the sustainable development of this important area.

Ratification of the Ramsar Convention on Wetlands (Ramsar, 1971) by Sudan in 2005 could now provide international recognition for Bagga wetland, especially as the last bird census in the area indicated the presence of 170 000 waterbirds of 50 species, which fulfils one of the criteria of the Ramsar Convention for the inclusion of sites in the List of Wetlands of International Importance.

Sudan is a Party to the Convention on the Conservation of Migratory Species of Wild Animals (Bonn, 1979), and therefore has obligations to conserve wetlands that harbour migratory waterbirds, such as Bagga wetland.

### BAGGA WETLAND

#### General information

##### Location, site definition and boundary

Bagga wetland is an extensive swampy area of about 250 sq. km along the banks of the White Nile south of Khartoum. The wetland is situated between latitudes 10°35'-10°56'N and between longitudes 35°11'-35°19'E. The principal components of the wetland are the main river channel and a number of small islands and peninsulas. There are nine villages scattered throughout the wetland, namely Tabour, Birka Island, Saafa, Argally Island, Shawal, Amgar Island, Um Shimayla, Gardood Island and

Um Nari Island. The wetland is a staging area for thousands of migratory waterbirds. Waterbird censuses in February and June 2003 indicated the presence of 168 572 birds of 50 species.

Bagga wetland has, for a long time, been subject to various types of human exploitation. The site has been designated by the Wildlife Conservation General Administration as a Bird Concession for sport hunting. Two safari companies, Decy Safaris and Blue-Sky Safaris, manage the sport hunting in the area, and bring tourists from various parts of Europe and Asia to the site, as well as Sudanese residents. The wetland is also used extensively by the local people for various purposes such as fishing, mechanized agriculture, “geref” farming, livestock grazing, transportation, drinking water and recreation.

All these activities have made the site attractive to a diverse range of competing economic activities. These activities need to be harmonized to ensure long-term sustainable utilization of the wetland resources. There is therefore a need for a long-term management plan that takes into account the interests of all the stakeholders in the decision-making process and subsequent management activities.

## Environmental information

### Physical characteristics

#### (i) Geology

The wetland is situated in a region of Precambrian metamorphic rocks that are dominated by gneisses and schists of the basement complex. Deposits of sedimentary rocks are clearly visible along the riverbanks.

#### (ii) Topography

The terrain is generally flat with some scattered sandy hills and depressions. There is a very weak drainage network, and the site is gently sloping towards the north. The soils are sandy to loamy.

#### (iii) Climate

The climate is typical of the low rainfall woodland savannah. The average annual precipitation varies between 300 and 700 mm; the rains begin at the end of May, reach a peak in the middle of August, and end in October. The relative annual humidity is between 55% and 60%. Average annual temperatures range between 30° and 35°C.

#### (iv) Hydrology

The hydrological regime of Bagga wetland is, to a large extent, linked to the hydrological regime of the White Nile, with the river being much the most important source of water for the wetland. The flooding period is between mid-August and mid-September. The inflow regime consists of discharge from the White Nile, the River Alaen and various small streams, as well as surface runoff, seepage and direct rainfall. The outflow regime consists of return flow into White Nile, evaporation and transpiration.

## Ecological characteristics

Bagga wetland can be broadly classified into six main habitat types: shrub-scrub, seasonally flooded grassland, permanently flooded swamps, papyrus swamp, riverbank habitat, and open water.

#### (i) Shrub-scrub

The shrub-scrub habitat occurs in peripheral areas of the wetland. It is composed of acacia trees and grasses. The ecological function of this habitat is to provide a shelter belt that protects the wetland from siltation by wind-blown sand and clay transported by surface runoff. This habitat also contributes to soil fertility by producing leaf litter and providing shade for soil micro-organisms. The common tree species associated with this habitat are *Acacia nilotica*, *A. tortilis* sub. *tortilis*, *A. tortilis* sub. *seyal*, *A. nubica*, *A. senegal* *A. seyal*, *Balanites aegyptiaca* and *Ziziphus spinocristi*. Common bird species include the Yellow-billed Kite *Milvus aegyptius*, pigeons, doves, warblers and crows.

#### (ii) Seasonally flooded grassland

This habitat type is located in the inner parts of the wetland from the shrub-scrub zone towards the main river channel. It consists of open grassland intermingled with scattered shrubs of *Acacia nilotica*, and provides grazing areas for domestic livestock and thatching material for the local houses. The main grass species are *Hyperrinia* sp. and *Cloris giana*.

#### (iii) Permanently flooded swamps

These are swampy areas adjacent to the river channel that retain water throughout the year. Various emergent and submerged macrophytes are found in this habitat type, including the Water Hyacinth *Eichhornia crassipes*, Red Water Fern *Azolla filiculoides*, Hippo Grass *Vossia cuspidata*, Reed Mace *Typha capensis* and *T. domingensis*. Common bird species include the Great White Egret *Egretta alba*, Intermediate Egret *E. intermedia*, Little Egret *E. garzetta*, African Openbill *Anastomus lamelligerus*, Woolly-necked Stork *Ciconia episcopus*, Sacred Ibis *Threskiornis aethiopicus*, Glossy Ibis *Plegadis falcinellus*, African Spoonbill *Platalea alba*, Egyptian Goose *Alopochen aegyptiacus* and African Jacana *Actophilornis africana*.

#### (iv) Papyrus swamp

Pure stands of papyrus occur as scattered patches within the permanently flooded swamps. Various types of fish species are found in this habitat. The main bird species include Maccoa Duck *Oxyura maccoa*, White-backed Duck *Thalassornis leuconotus*, Southern Pochard *Netta erythrophthalma*, African Jacana and Little Tern *Sterna albifrons*.

#### (v) Riverbank habitat

This habitat is created between the swamps and the river when the flood waters recede. The main bird species found in this area include the Black-winged Stilt *Himantopus himantopus*, Pied Avocet *Recurvirostra avosetta*, Little Stint *Calidris minuta*, Ruff *Philomachus pugnax* and gulls *Larus* spp.

#### (vi) Open water

This habitat comprises the open waters of the main river channel. The river is normally 4-6 m deep from October to July, and varies between 10 m and 15 m deep during the height of the flood in August and September.

### Land tenure system

The land tenure system in Sudan is governed by the Land Act of 1943, in which all unregistered lands are the property of the State. Bagga wetland is under state ownership, except for areas of the riverbanks that are seasonally flooded and cultivated after the flood recedes. Such areas are in the ownership of certain families who inherited them from their grandfathers a long time ago. The Land Act of 1943 recognizes this land ownership as property under legal ownership. Other forms of land ownership within the wetland, i.e. as found in the small villages, are not recognized by the Land Act of 1943. However, the Department of Land Planning normally tackles such cases and formalizes registration procedures to legalize ownership on the basis of the Land Act. Research needs to be undertaken to determine the percentages of land given over to each of the various main uses. This could be carried out in collaboration with the national remote-sensing authorities.

### Management infrastructure

The area is managed by Bagga Local Council, which is part of the White Nile State managerial structure. Some areas have been allocated as sites for bird shooting concessions under the responsibility of the Wildlife Conservation General Administration. Bagga Local Council is responsible for providing a better livelihood for the local community. It collects government revenue and taxes, and pays for public services such as schools and hospitals. The Wildlife Conservation General Administration has the power to invest in all government owned lands throughout the country in collaboration with the local authorities. The Wildlife Administration generates revenue from sport hunting, and the revenue is divided between the Wildlife Administration and the local councils, with 40% going to the department and 60% to the local councils.

### Cultural characteristics

About 5 000 people live in and around the wetland. These belong mainly to the Hassania tribe, Gaafra, Hawaweer, Hamr and Bederia, but there are also some individuals from western Sudan, mainly the Nuba tribe, Four, Masaleet and Bargoo, while others from northern Sudan include the Shaygia, Gaalia, Mahas and Danagla.

### Wetland benefits

Various direct benefits are drawn from the wetland, e.g. fishing, farming, grazing of livestock, water consumption, harvesting of papyrus, woodcutting, sport hunting and recreation.

### Fishing

Fishing is carried out in the wetland by a variety of methods. The fish catches are either transported fresh for marketing in nearby urban centres such as Kosti and Doeum, or dried using traditional techniques. The dried fish are either canned and sold in urban centres such as Khartoum, or packed in special bags and used to feed labourers in the rain-fed mechanized agricultural schemes in central and eastern parts of the country.

Over-fishing is a problem, and there is an urgent need for research to establish an annual fishing quota. Otherwise, fishing activities will have to be banned to allow the situation to improve.

### Farming

Seasonally flooded areas are used to raise cash crops when the flood waters recede. These areas have very fertile soil that has been deposited by the flood waters from the Nile. Furthermore, this soil retains moisture for a very long time after the floods have receded, thus reducing the need for irrigation using diesel pumps.

### Livestock grazing

The local people own large herds of domestic livestock of various types, but mainly sheep, as these are adapted to the local climate and provide the favourite meat of the Sudanese. The wetland provides grazing areas for livestock especially during poor rainy seasons, when the natural pastures support very little vegetation. The livestock provide large quantities of milk for domestic use and a flourishing cheese industry, and the area is well known for the unique quality of its cheese.

### Water consumption

Water from the wetland is used for various purposes: for domestic use in the nearby villages, for irrigating agricultural crops, and for drinking by livestock. The river is used for boat transportation to carry people and their products from the wetland to the various villages, and to bring products from remote areas to centres with transport facilities to other areas.

### Papyrus harvesting

The patches of papyrus are used by the local community for roofing material and to make various types of handicrafts, such as mats and baskets. The papyrus industry is an important source of revenue for the local community. Loaded trucks move daily to various parts of central Sudan including Khartoum, which is the main market for these products.

### Woodcutting

The shrub-scrub habitat surrounding the wetland is the main source of firewood, charcoal and building materials for the local community. Bagga wetland is located in the semi-desert region of the country, and vegetation is fairly scarce. Thus, the wetland plays a vital role in providing the local community with a source of fuel.

### Sport hunting

Hunting licenses for the sport hunting of waterfowl are issued to tourists by the Wildlife Conservation General Administration. Several professional safari companies are involved in this type of hunting, and bring clients from many parts of the world to shoot waterfowl in the area. The revenue generated from this sport hunting has a perceptible impact on the overall revenue generation of the Wildlife Administration.

### Recreation

Camping sites at various places in the wetland are used for recreation. Some sites are natural, while others are constructed by tour operators. People are brought from the urban centres during their vacations and on public holidays to spend time along the edge of the wetland.

## STRATEGIES FOR THE MANAGEMENT OF BAGGA WETLAND

There is a need for the effective participation of all stakeholders in addressing the problems that face the management of Bagga wetland. The following strategies will therefore be adopted to enhance the participation of all stakeholders in the management of the wetland.

### Partnerships

The involvement of all stakeholders in the decision-making process will help to achieve community empowerment and enhance public trust. To achieve this goal, government officials should be encouraged to accept members of the local community in the decision-making process.

### Ecosystem approach

There is a need to adopt an ecosystem approach to environmental management in Bagga wetland. The implementation of this strategy requires co-ordinating initiatives and data from various sectors.

### Management structure

The implementation of the management strategy needs to operate within a sound overall management structure that supports participation by all stakeholders. There is a need for flexibility in dealing with diverse interests and sectors, and the development of participation regimes that can adapt to changing circumstances is of primary importance.

### Zonation

The management plan should recognize the multiple functions that the wetland can provide in combining biodiversity, wilderness and aesthetic values with compatible forms of sustainable development activities. The concept of Biosphere Reserves, as developed by UNESCO through the MAB Programme, will be

used to guide zonation. Three zones will be delineated: a core zone, a buffer zone and a transitional zone.

### Core zone

The core zone should include areas of high sensitivity to exploitation which have to be protected to ensure the conservation of ecological processes and life support systems. Priorities for the core zone include:

- conservation of biodiversity and scenery;
- realization of the maximum potential of the educational and research values;
- realization of the recreational values without jeopardizing higher priorities.

### Buffer zone

The buffer zone provides protection for the core zone. Activities in this zone should be carried out as pilot projects subject to research, and should be regulated so that they do not interfere with the priorities of the core zone. All activities within this zone should be subjected to environmental impact assessment prior to implementation.

### Transitional zone

The transitional zone covers the rest of the wetland. In this zone, multiple uses will be encouraged. All activities should be subjected to environmental impact assessment to ensure compatibility with the priorities in the core and buffer zones.

## CONCLUSION

The area is facing real challenges, and a balance needs to be adopted between the need to cater for the growing demands of the local population and the stringent need for wetland conservation. Proper management and utilization on a sustainable basis are urgently required.

## ABSTRACT

Until the 1960s, the hydrology of the lower Senegal delta in Mauritania was basically determined by the natural flooding of the Senegal River and tidal action. Each year, the area experienced periods of drought and flood with water that was alternately fresh, brackish and saline. Thousands of migratory waterbirds of both Palearctic and Afrotropical origin occurred in the area when conditions were favourable. With the construction of the Diama Dam and impoundment of the right bank of the Senegal River, the former floodplain between the island of Mboyo and Keur Macène was deprived of a freshwater supply for approximately 10 years. This resulted in a reduction in the numbers of migratory waterbirds to a few dozens or hundreds during the period 1986 to 1993. Water management projects undertaken in the Parc National du Diawling have been aimed at restoring the previous conditions in the lower delta through recreating the normal hydrological cycle and thereby restoring the ecological values (bird, fish and plants) and socio-economic values of the park and its surroundings.

## INTRODUCTION

Wetlands in the lower Senegal delta (situated between 16°10'-16°35'N) were formerly amongst the richest and most extensive in West Africa. This delta system was comprised of a mosaic of floodplains and estuaries, alternately flooded with fresh, brackish and saline during the natural flood cycle of the Senegal River. This variation in salinity favoured the development of a rich diversity of plant species (Diawara *et al.* 1998). The floodplains were important spawning grounds for the fish fauna in the lower delta, and important foraging and nesting areas for a wide variety of waterbirds (Hamerlynck *et al.* 1997). These diverse ecosystems have long sustained a population of hundreds of thousands of people who were closely dependent upon the natural resources of the wetlands.

Since the beginning of the 1970s, the natural ecosystems of the lower Senegal delta have changed considerably, firstly because of deterioration caused by environmental factors (drought and soil degradation), and secondly, because of the construction of the Diama Dam and other water impoundments in the Senegal River valley. The environmental and social impacts of these developments were underestimated, and degradation of the ecosystems increased, especially downstream from the Diama Dam. Since the construction of the dam, the future of the lower delta ecosystem has been the subject of a number of debates at national and sub-regional level. The government of Mauritania eventually resolved in favour of the preservation of a sample of the lower delta ecosystem. Consequently, on 11 January 1991, a decree (Decree 91-005) was enacted, establishing a National Park, the "Parc

National du Diawling", on 16 000 ha of the former floodplains (Fig. 1). The general objectives of the National Park are the conservation and wise use of the resources of a sample of the ecosystem of the lower Senegal delta. In particular, the park seeks to ensure the harmonious and sustainable development of the activities of the indigenous people.

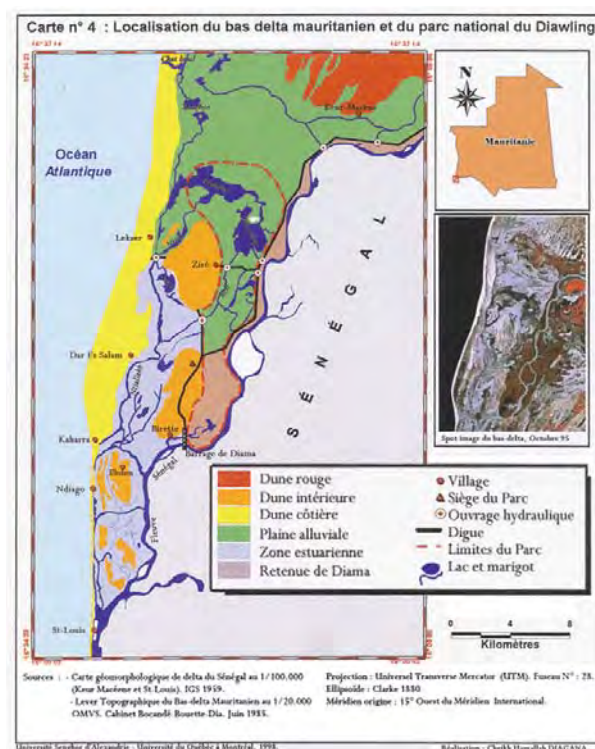

Fig. 1. Location of the lower Senegal delta and Parc National du Diawling in Mauritania.

## HYDROLOGY OF THE PARC NATIONAL DU DIAWLING

Before the construction of the two dams, Manantali and Diama, upstream and downstream on the River Senegal respectively, the hydrology of the lower delta was mainly dependent upon rainfall. It is important to highlight the exceptional nature of rivers in the Sahel zone which are located in an area where, because of the imbalance between rainfall and evaporation, no permanent surface water exists for long periods of time. The natural flood waters (freshwater) reach the delta between mid-August and September. Water movements in the lower delta were formerly complex and could change direction depending on water levels in the coastal zone. In years of low rainfall (a situation which has often occurred since 1970), seawater could penetrate up to 300 km inland from the mouth of the river.

In order to simulate the previous hydrology of the lower delta, the Parc National du Diawling has installed, with the involvement of the local population, six hydraulic structures (two for water supply, and four two-way structures) and dikes of 1.5 to 2.0 m IGN that make it possible to divide the park into three great basins (Diawling, Bell and Gambar).

The Gambar basin is currently an integral part of the Diamas reservoir. The management of the dam prevents any incursion of salt water, thus ensuring that water bodies upstream of the dam remain fresh. This basin, which was formerly a fishing, gathering and grazing area for the indigenous population, has now become unavailable because it has become completely overgrown with an invasive plant, *Typha australis* (as a consequence of the freshwater reservoir). This has had a detrimental effect on the biodiversity and productivity of the environment, and has resulted in the disappearance of *Nymphaea lotus*, *Sporobolus robustus* and grazing areas.

The management of the park is currently focused on the hydrological functioning of the other two major basins: Bell and Diawling. The Diawling basin is gradually filled by the Cheyal structure upstream and the Berbar and Lekseir structures downstream. The aim has been to attain a water level of 1.0 m IGN in August and increase this to 1.30 m IGN by the end of the season, i.e. in September and October. The Bell basin is supplied by the Lemer structure upstream and the Bell 1 and Bell 2 structures downstream. The aim has been to attain a water level of 1.05 m IGN two weeks after the opening of the structures, and then to maintain this level for nearly one month, to enable the vegetation to develop. The level is then increased gradually to 1.20–1.30 m IGN. The basin has to be drained quickly starting from November, as directed by the management plan, to reflect the normal receding of water under natural conditions.

### MAXIMUM WATER LEVELS IN THE BASINS

Since the filling of the basins in the national park and its surroundings in 1995, the maximum water levels have fluctuated from one year to the next (Fig.2). A number of factors are involved in these variations in water level; in particular, the opening date of the structures, the head of water, the opening of gates, the high level of water in the lower part of the park, and the management of minor works.

The management of water levels has been better in the Bell basin than in the Diawling basin. In the Bell basin, it has always been possible to reach the planned water level at a given period, whereas in the Diawling basin, it has rarely been possible to exceed a level of 1.20 m IGN because of the size of the basin and its opening to other depressions starting from one metre IGN, such as the Tombos marshes and the Aftout (a depression over 50 km in length). The low water levels in both basins in 1996 (Fig. 2) correspond to low opening of the gates because of maintenance works on the left bank dike, and the high levels in 1999 correspond to an exceptional flood year when it was impossible to control water levels from downstream.

### BIRD FAUNA IN THE PARC NATIONAL DU DIAWLING

The wetlands in the lower Senegal delta are one of the first sites to be reached by migratory waterbirds from the Western Palearctic after crossing the Sahara in autumn. The freshwater and brackish marshes in the delta also support large numbers of Afrotropical waterbirds, and are important nesting sites for several bird species.

In 1995, the Parc National du Diawling began flooding the basins. With this resumption of the hydrological cycle, the park and its surroundings have once again become an internationally important area for waterbirds. The area has held over 1% of the West African population of several species, notably Great White Pelican *Pelecanus onocrotalus*, Great Cormorant *Phalacrocorax carbo*, Greater Flamingo *Phoenicopterus roseus*, Eurasian Spoonbill *Platalea leucorodia*, Black Stork *Ciconia nigra*, and some Palearctic and Afrotropical Anatidae, e.g. Northern Pintail *Anas acuta*, Northern Shoveler *A. clypeata*, Garganey *A. querquedula* and White-faced Whistling-Duck *Dendrocygna viduata*.

The series of waterbird counts conducted in Parc National du Diawling and the surrounding area began well before 1995. The first results of waterbird counts in the lower Senegal delta in Mauritania were provided by the International Waterfowl and Wetlands Research Bureau (IWRB) even before the creation of the national park in 1991. Park personnel then benefited from the support of IWRB during the international census periods until 1996. Since 1997, the census in the lower Senegal delta has benefited from the support of the Office National de la Chasse (ONCSF) in France. From January 1996 to 1999, the international census results revealed a significant increase in the numbers of Palearctic ducks wintering in the delta (Fig. 3). However, since 2000 the numbers of Palearctic and Afrotropical ducks (Northern Pintail, Northern Shoveler and White-faced Whistling-Duck) have been relatively low (Dodman & Diagana 2003). This change in numbers is mainly related to changes in water level in the different basins in the park.

The annual waterbird counts were generally conducted between 14–16 January. At this time of the year, the water level in the basins can often be favourable for ducks, as was the case in the years from 1996 to 1999. At the beginning of the implementation of the Parc National du Diawling management plan, water management was mainly aimed at restoring the ornithological values of the lower Senegal delta. The emphasis was then shifted to other values, such as fish fauna, flora and the activities of the local population on the periphery of the park. When all these other values had been taken into consideration, the water levels in January were no longer suitable for large concentrations of waterbirds in the great lakes, as little foraging habitat was available around the lakes (especially in the Bell basin, where the water level varies between 1.0 m and 1.15 m IGN). Since 2000, large concentrations of ducks have not been

Fig. 2. Fluctuations in water level in two basins in the Parc National du Diawling, Mauritania: 1995–2003.

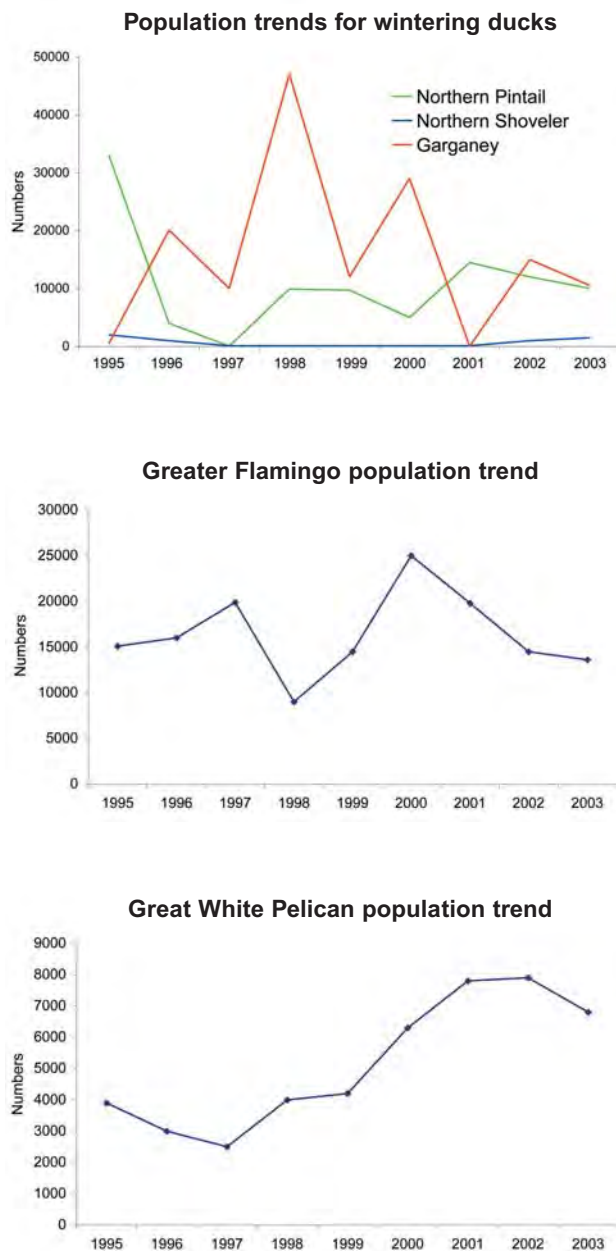

Fig. 3. Numbers of three species of ducks, Greater Flamingos *Phoenicopterus roseus* and Great White Pelicans *Pelecanus onocrotalus* in the Parc National du Diawling, Mauritania: 1995-2003.

observed until February, except in the case of the Northern Pintail which occurs mainly in November and December.

### ORNITHOLOGICAL VALUES AND ECONOMIC BENEFITS

The most important breeding bird colonies in the Mauritanian part of the lower Senegal delta were found in the mangrove forests along the tidal creeks of the delta. Colonies of fish-eating birds were present in the Gueyeloube area, as well as at the Bell-Khurubam confluence. This area was colonized by a mangrove forest (*Avicennia germinans* and *Rhizophora racemosa*) and a plant community in which *Tamarix senegalensis* and *Sesuvium portulacastrum* predominate. As elsewhere in the delta, in the mid-1960s the Diawling area hosted several breeding species, e.g. African Darter *Anhinga rufa* (c. 10 000), Great Egret

*Egretta alba* (10-100) and Sacred Ibis *Threskiornis aethiopicus* (10-15). The breeding success was related to the richness of the environment in nutrients (fish, shellfish, amphibians and insects). The lower delta was not only important for breeding birds, but also for large numbers of wintering Palearctic ducks (e.g. Garganey) and Afrotropical ducks and geese (e.g. White-faced Whistling-Duck, Egyptian Goose *Alopochen aegyptiacus* and Spur-winged Goose *Plectropterus gambensis*).

With the construction of the right bank dike along the Senegal River, the floodplains were cut off from the natural flooding from the river. As a result, there was a gradual deterioration in the natural resources, including waterbird populations which disappeared almost completely (only one or two waterbirds were present in 1991), until artificial management restored the flood cycle to a part of the lower delta. Since the flooding of the basins in 1995, hundreds of thousands of waterbirds have again been observed in the Parc National du Diawling and surrounding areas (205 000 waterbirds were counted in 1996, and 135 000 in 1998).

The local people living around the periphery of the national park have a tradition of fishing in the wetlands throughout the year, and soon became aware of the interest that there was in the bird fauna in the lower delta. It has now become usual for the fishermen from neighbouring villages to organize themselves and establish a series of fishing areas, and this has been of benefit to fish-eating birds in particular.

The ornithological resources of the Parc National du Diawling and its surroundings are today the main attraction for tourists in the area, hence the creation of an important sector, that of eco-tourism. Initially, the national park studied the feasibility of different types of tourism, including mass tourism and beach tourism, but in the light of the park's objectives, eco-tourism seems to be the most relevant. Since 1998, this sector has been receiving nearly one thousand visitors per season through Mauritanian and Senegalese private operators. Currently, there are only a few local operators who take advantage of the benefits that can be derived from eco-tourism, and with the private sector controlling most of the new activities (tourism, market-gardening, handicrafts, needlework, etc.), there has been scarcely any perceptible change in the incomes of the local population.

### CONCLUSION

The hydrological management of the Parc National du Diawling remains complex, considering the varying water requirements for the restoration of the ecosystem and the demands of the local population for socio-economic activities at various times of the year. Currently, the Parc National du Diawling is the only area available for the grazing of hundreds of livestock (cattle, goats and camels) that spend the rainy season on the red dunes of the Trarza. The people living on the periphery of the park are requesting that the basins be flooded in two phases. The first phase coincides with the natural flood period, and the second phase with the dry season. This dry-season flooding would make it possible to sustain livestock during the lean period. However, after more than four months of inundation by natural flood waters, all the depressions become invaded by noxious aquatic plants. There are already several zones of invasive plants (*Typha australis*, *Potamogeton nodosus* and *Utricularia inflexa*) in the Diawling and Bell basins that had, until recently, been spared.

The implementation of dry-season flooding would favour the colonization of the open water areas of the lakes and, consequently, reduce the resting and foraging areas for several species of migratory waterbirds (ducks, waders, etc.) as well as some sedentary species. Furthermore, the conditions would favour invasive plants to the detriment of other plant species such as *Sporobolus robustus*, an herbaceous perennial much sought after by the local people for use in handicrafts. The third basin in the national park (Dama impoundment) exemplifies the systematic reduction in biodiversity caused by the permanent presence of water, which favours colonization by invasive plants.

Hötker, H. & West, R. 2006. Population size, population development and habitat use of Avocets *Recurvirostra avosetta* in Western Europe at the end of the 20th century. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 729-730.

After having been at very low levels at the end of the 19th century, populations of Avocets *Recurvirostra avosetta* breeding in Western Europe have shown a dramatic increase in recent decades (Glutz von Blotzheim *et al.* 1977). In this paper we try to investigate whether this increase is continuing, and whether it has occurred at the same time and with the same speed at all sites. We also try to give an overview of population size, population development and habitat use of Avocets breeding in Western Europe. The paper is based on a workshop "Understanding population dynamics of Avocets" held during the annual conference of the International Wader Study Group in 1999 (see Hötker & West 2005 and other papers in Wader Study Group Bulletin 107).

By the end of the 1990s, the total population of Avocets breeding in Western Europe was 29 658 pairs (Table 1). The most important countries were The Netherlands, Germany, Spain and Denmark; the single most important site was the coast of the Wadden Sea, shared between Denmark, Germany and the Netherlands, where about 12 000 pairs bred. Given that the present population is nearly 30 000 breeding pairs in the East Atlantic Region, we calculate that the total population of western Europe may reach 90 000 individuals.

On the coasts of the North Sea and the Baltic Sea, Avocets mainly breed on saltmarshes, and in some places colonies are asso-

ciated with coastal engineering works. Coastal lagoons and embankments with freshwater or brackish water are also important in certain regions. On the coasts of the Atlantic and the Mediterranean salt pans both used and disused are by far the most important habitats. In the central European hinterland and also in inland Spain, Avocets mainly breed at alkaline lakes and fishponds.

Avocets were very rare at the beginning of the 20th century, but from that time populations began to recover in many countries (Glutz von Blotzheim *et al.* 1977, Fig. 1). From about 1940 onwards, many populations increased exponentially until the late 1980s; exceptions occurred in Portugal, the Mediterranean part of France, and Austria where populations remained stable (although fluctuating annually) for long periods.

In the late 1980s, the population dynamics changed within a very few years but the overall population has remained more or less stable since then. From the peak of population trend, developments in different countries started to diverge. In the core area of the breeding distribution in the Wadden Sea and the delta of the Rivers Rhine, Maas and Schelde, the population declined significantly between 1989 and 1998 (annual rate of loss 265 pairs,  $t=-3.27$ ,  $p=0.01$ ), while populations continued to be stable in those areas where Avocet populations had not changed much before, such as Portugal, Mediterranean France and Austria. In other parts of Western Europe, the population is still increasing, although less quickly, for example in Estonia, Lithuania, United Kingdom, France, Spain, and Italy. Moreover, there are breeding attempts in formerly uncolonised countries, for example, Norway (BLI/EBCC 2000) and Poland (Chylarecki pers. comm.).

Although the reasons for the population recovery in the 20th century are not entirely understood, the most likely is better protection of Avocets from hunting and egg collecting. Many reserves with a ban on hunting have been established, at first in the breeding sites but later also in wintering sites, and more than 90% of the western European Avocet population is now breeding in nature reserves. Avocets can thus be regarded as a nature protection success story. Other factors which may have had an effect on the increase of the population throughout the 20th century include the eutrophication of coastal waters, climatic changes and habitat change through coastal engineering. Several authors relate numbers of Avocets in non-breeding sites to the degree of water pollution (van Impe 1985, Prop 1998) which has caused a general increase in density in many estuarine invertebrates (Beukema & Cadée 1986). In particular polychaetes, an important part of the diet of Avocets, have profited from the increase of nutrients in the water (Reise *et al.* 1989).

However, the population is still relatively small compared to many other wader species, and Avocets tend to congregate in

**Table 1.** Most recent estimates of Avocets *Recurvirostra avosetta* breeding in Western Europe (BirdLife International & European Bird Census Council 2000).

relatively few estuaries outside the breeding season where they may be threatened by environmental disasters like oil spills. Many nesting habitats sites require “hands-on” habitat management, and part of the population is therefore conservation dependant. Habitat loss occurs in particular in southern Europe where salt pans are disused or transformed into fishponds without suitable breeding habitats for Avocets. Global temperature increases leading to rising sea levels will probably destroy much of the breeding habitats of the Avocets nesting on salt marshes.

## Transboundary management of Kura Basin wetlands as an important step towards waterbird conservation in the South Caucasus region

Karen Jenderedjian

Head of Division of Animal Resource Management, Agency of Bioresource Management of the Ministry of Nature Protection, Government Building 3, Republic Square, Yerevan 375010, Armenia. (email: jender@arminco.com)

Jenderedjian, K. 2006. Transboundary management of Kura Basin wetlands as an important step towards waterbird conservation in the South Caucasus region. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 731-732.

This paper describes current initiatives to establish and co-ordinate multi-lateral planning for landuse and conservation management in the Kura-Arax river basin within the Caucasus Region.

Situated between the Black Sea and Caspian Lake, the Caucasus is among the planet's 25 most diverse and endangered areas. It covers 580 000 km<sup>2</sup> including parts of Armenia, Azerbaijan and Georgia, the North Caucasus portion of the Russian Federation, north-eastern Turkey and part of north-western Iran. Landscapes in the Caucasus range from high mountains to semi-deserts and wetlands; vegetation types include snowfields and glaciers, steppe, broadleaf and coniferous forests, alpine and subalpine meadows, and alder and Caucasian wing-nut swamp forests. The 2002 IUCN Red List identifies one species of plant and 50 species of globally threatened animals in the Caucasus. Of 11 species of globally threatened birds, six are waterbirds: Lesser White-fronted Goose *Anser erythropus*, Red-breasted Goose *Branta ruficollis*, Marbled Teal *Marmaronetta angustirostris*, White-headed Duck *Oxyura leucocephala*, Corncrake *Crex crex* and Sociable Plover *Vanellus gregarius*. Large numbers of waterbirds from Eastern Europe and Western Siberia migrate across the Caucasus to the Middle East and East Africa: of those, 115 species are listed in Annex II of the AEWA. One waterbird species, the Armenian Gull *Larus armenicus*, is endemic to the region.

Important wetland ecosystems are found throughout the Caucasus, and wetland vegetation covers large areas along the coastal zones of the Black and Azov seas, Caspian Lake and Terek, Sulak, Kuban, Samur, Rioni and Kura rivers. The catchment of the Kura River is of exceptional international importance, and is shared between five countries - Armenia, Azerbaijan, Georgia, Iran and Turkey (Fig. 1). The Kura River is the largest hydrological watercourse in the South Caucasus, originating on the northeast slopes of Kizil-Giadik (Turkey) and flowing through Georgia and Azerbaijan into the Caspian Lake. The river is 1 515 km in length and the area of the basin is 205 037 km<sup>2</sup>. Together with its major tributary the River Arax, the entire basin occupies the greater part of the South Caucasus, and supports a population of 6.8 million people. The waters of the river system are used for drinking, hydropower and irrigation, especially in Armenia, Georgia and Azerbaijan. Although wetlands make up only 0.9% of the river system, 21 wetland-dependent Important Bird Areas (IBA) have been identified, of which Lake Arpi (3 139 ha) and Lake Sevan (489 100 ha) in Armenia and Agh-Ghol (500 ha) in Azerbaijan are designated Ramsar sites.

Unfortunately, the waters of the Kura-Arax river system are extensively polluted, with the concentrations of impurities

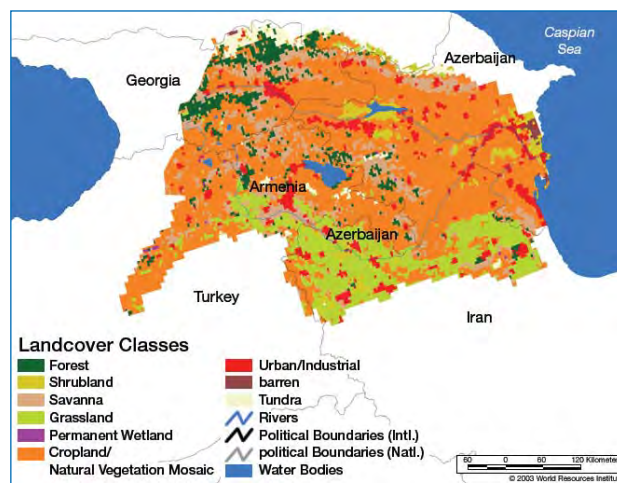

Fig. 1. Landcover classes in the Kura-Arax basin.

exceeding allowable limits by as much as 10 times for phenol, 14 times for phosphate and 20 times for oil. Pollution plus drastic political and economic upheaval, uncontrolled use of water resources and poaching have brought ecological instability and loss of biodiversity in general and of waterbirds in particular. The situation is aggravated because of the absence of a common approach between Armenia, Azerbaijan, Georgia, Iran and Turkey towards integrated management of water and wetland resources. Problems arise due to:

- limited capacity of the institutions responsible;
- underdeveloped environmental legislation at national and regional levels;
- inefficient control and lack of financial mechanisms to prevent pollution;
- weak system of water monitoring and lack of reliable data on pollution; and
- lack of mechanisms for co-operation and co-ordination of action plans.

There are several ongoing programs initiated by the European Commission and the UNDP to improve water management in Kura-Arax basin through the harmonization of legislation, monitoring and regional planning. The "Eco-regional Nature Protection Programme for the South Caucasus Region", part of the Caucasus Initiative launched by the German Ministry of Co-operation and Development aims to promote cooperation on the development of a coherent strategy to ensure biodiversity conservation in the region. A number of wetlands will be given the status of protected areas on the both sites of Armenian-Georgian

border, while the following activities will be financed from the recently approved €2 200 000 programme “Establishment of Protected Areas in the Armenian Javakheti Region”:

- to establish a National Park in accordance with IUCN guidelines including Lake Arpi and its water catchment areas bordering Georgia and Turkey;
- to investigate the potential for possible establishment of wetland sanctuaries (such as Akhuryan and others);
- to integrate the National Park into the land use of the project area;
- to develop selected support programs to decrease the pressure on the National Park and sanctuaries and to foster acceptance by the population; and
- to promote transboundary cooperation in the biodiversity conservation in the Javakheti Region.

The Critical Ecosystem Partnership Fund (CEPF) is developing a strategy based on the results of stakeholder workshops and background reports coordinated by the WWF Caucasus Programme. The strategy is underpinned by targets against which the success of investments can be measured, namely species (extinctions avoided), sites (areas protected) and landscapes (corridors created). Four strategic directions guide CEPF’s approach in the Caucasus:

- support society efforts to promote transboundary cooperation and improve protected area systems;
- strengthen mechanisms to conserve biodiversity of the area with emphasis on species, site and corridor outcomes;
- implement models demonstrating sustainable resource use; and

- increase the awareness and commitment of decision-makers to biodiversity conservation.

The CEPF provides special attention to wetlands and international cooperation, and the Wetland Management Training Course for the Staff of Sevan National Park (Armenia) and Kolkheti National Park (Georgia) has recently been approved for funding. Prospective wetlands for transboundary conservation are Ararat Valley fish-ponds and floodplain marshes on Mount Ararat, shared with Armenia, Turkey and the Nakhichevan enclave of Azerbaijan and Iran.

There is no doubt that cooperation on transboundary conservation of the Caucasus and Kura Basin wetlands will positively influence not only waterbird diversity but will also mitigate the effects of the uneasy political situation in the South Caucasus Region.

## The importance of extensive fishponds for Ferruginous Duck *Aythya nyroca* conservation

Nikolai Petkov

BirdLife International Ferruginous Duck Conservation Team, c/o Bulgarian Society for the Protection of Birds/BirdLife Bulgaria.  
(email: [nicky.petkov@bspb.org](mailto:nicky.petkov@bspb.org); [www.bspb.org/nyroca](http://www.bspb.org/nyroca))

Petkov, N. 2006. The importance of extensive fishponds for Ferruginous Duck *Aythya nyroca* conservation. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 733-734.

This paper reviews the importance of the extensive fishponds as a basic wetland habitat for Ferruginous Duck *Aythya nyroca* in Europe. The data for this evaluation are taken from the BirdLife International IBA database and the Ferruginous Duck workshop in Sofia, Bulgaria in October 2002.

The Ferruginous Duck is listed as Near Threatened by BirdLife International (2000). Once one of the commonest breeding duck species in Europe, it is now declining in most of its European breeding grounds. The largest breeding populations known are in Romania (2 000-6 000 pairs) and Croatia (1 000-3 000), although it is declining in both countries. In Asia, the species is scattered and little is known about actual breeding numbers. Currently the European population is estimated at 12 000 – 18 000 pairs (BirdLife International 2004). It is found in shallow and eutrophic wetlands, and in Central and Eastern Europe, where many of the natural wetlands and habitats of the species have been destroyed, it has adapted to using extensive fishponds. It is presumed that the species breeds in 41 countries and the estimates for the trends in 18 countries suggested declines of 20-50% (Robinson 2002). In many parts of its European range it has populated artificial wetlands such as extensively managed fishponds. In 2002 an international workshop was held in Sofia, Bulgaria to re-evaluate the threats and status of the species and develop a Species Action Plan under the AEWA (African-Eurasian Waterbird Agreement). Though it is now considered that over half of the population breeds in Asia, there are no real data on breeding sites with significant breeding populations that can confirm this suggestion. The breeding population in Europe is much better known and the largest breeding populations depend on artificial wetlands especially fishponds.

Extensive fishponds are fishfarms that were created 40-60 years ago for fish farming in Central and Eastern Europe and due to less intensive management have evolved into semi-natural wetlands supporting high biodiversity including important bird populations. They are mostly used to grow Carp *Cyprinus carpio*. To some extent they have replaced the natural marshes which they resemble, and they shelter a high diversity of aquatic macrophytes and emergent vegetation, a far cry from the more intensive fish farming systems of Western Europe.

Croatia, Serbia, Romania, Hungary and Bulgaria account for nearly 63% of the European population of Ferruginous Duck (BirdLife International 2004); the most important breeding habitat is the fishpond with more than half of the breeding sites. A total of 186 IBAs for Ferruginous Duck have been identified in Europe, of which 126 are fishponds (BirdLife International IBA database, 2004). The fishponds are the only wetlands beside large river deltas where moulting and migration concentrations occur (Petkov *et al* 2003).

Fig. 1. Protection status of sites important for Ferruginous Duck *Aythya nyroca* in Europe

The abandonment and change in management of extensive fish ponds has brought a significant reduction in Ferruginous Duck breeding numbers in some countries and in some specific fishponds. For example, in Poland the breeding population has decreased from 400 pairs in the 1980s to 40 pairs currently, with much of this decline attributable to the drainage and/or intensification of the fishpond management (Wieloch 2003). In Croatia, the Crna Malaka fishpond, where over 4 000 birds concentrated for moulting and migration in the 1990s (Schneider-Jacoby 2003), is one of the most important breeding and moulting sites in Europe. However, as a result of management changes, numbers there have dropped significantly and the species population in Central and Eastern Europe is endangered. In Bulgaria, Mechka Fishpond (IBA BG024), the most important breeding site with over 30 pairs and with moulting and migration concentrations in the 1990s up to 3 000 Ferruginous Ducks, currently holds 10-20 pairs and no more than 80-100 birds on migration. Within the five years from 1997 to 2002, fishponds in Bulgaria lost their key position as the most important wetlands for the breeding of the species with the percentage of the breeding pairs occurring in them dropping from 49% to 42% (Petkov 2004).

The main problems identified for the fishponds are:

- transformation into intensive fishfarms due to low profitability of more extensive management;
- abandonment because of transformation of the ponds for arable cultivation;
- mismanagement and deterioration after privatisation resulting in overgrowing vegetation and consequent reduction in wetland biodiversity;

- lack of state policy to support extensive fishponds, and policy preferences that lead to their abandonment or transformation to other types of agriculture;
- reed cutting and burning during breeding season leading to loss of clutches, low breeding success and high mortality of reed breeding species;
- drying up of basins in key periods during migration; and
- illegal hunting of Ferruginous Ducks in unprotected fishponds, resulting from a desire of fishponds owners to increase income.

Currently the existence of the breeding population in Europe is under severe threat due to neglect or poor management of the fishponds; if these are transformed or intensified this will lead to a significant decrease in the Ferruginous Duck population in Europe, driving it to the brink of extinction in a number of countries in Europe.

There is a need for conservationists, fishpond managers, state nature conservation and aquaculture and fisheries institutions to combine their efforts to formulate best practice guidelines for the management of extensive fishponds which combine fish farming and Ferruginous Duck conservation. Sustainable fish-farming should be included in the priority measures of the national agri-environmental programmes of the new Member States of the EU where much of these habitats are found. For others it should be a priority to develop state funds and policies and systems of incentives and compensation, both financial and nonfinancial.

## Monitoring needs and landscape level planning for conservation of waterbirds in Abu Dhabi, United Arab Emirates

Sálim Javed, Shahid Khan, Yasser Othman, John Newby & Frederic Launay

Environmental Agency – Abu Dhabi, PO Box 45553, Abu Dhabi, United Arab Emirates. (email: sjaved@erwda.gov.ae)

Javed, S., Khan, S., Othman, Y., Newby, J. & Launay, F. 2006. Monitoring needs and landscape level planning for conservation of waterbirds in Abu Dhabi, United Arab Emirates. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 735-736.

The mudflats of the southern Gulf support several million waterbirds during spring and autumn migration and an estimated 250 000 shorebirds use the vast inter-tidal zone of the United Arab Emirates (UAE) at peak periods (Evans 1994, Butler *et al.* 2001). The Emirate of Abu Dhabi, with nearly 70% of the total land area of the Emirates, a 340 km coastline and nearly 40 big and small islands, supports a rich assemblage of birds, particularly waterbirds and nationally and regionally important breeding colonies of seabirds. Nearly 40% of all bird species recorded in the Emirate are waterbirds.

On several islands in the Emirate breeding colonies of the regionally endemic, and globally threatened, Socotra Cormorant *Phalacrocorax nigrogularis* are of global significance. Breeding colonies of Crab Plover *Dromas ardeola*, restricted to only two islands, are internationally important. Important breeding populations of White-cheeked Tern *Sterna repressa* and four other terns *Sterna* spp., Sooty Gull *Larus hemprichii* and Red-billed Tropicbird *Phaethon aethereus* are also found in the Emirate (Aspinall 1995, Aspinall 1996). Fifteen key islands in the Emirate contain 85% of all the IBAs, 85% of all tern colonies in the UAE, almost the entire breeding populations of five terns (*Sterna* spp.), nearly 80% of the Socotra Cormorant breeding population and all the breeding population and colonies of Crab Plover and Red-billed Tropicbird in the UAE (Javed & Khan 2003). Fifteen globally, and several regionally, threatened species are found in the country (BirdLife International 2005, Hornby & Aspinall 1996).

Rapid urban and industrial infrastructure development in the country, mostly along the coast and islands, has put many breeding colonies under threat (Evans 1994). Between 1995 and 2002 numbers of Socotra Cormorant breeding colonies have declined by more than 50%, from 13 colonies in 1995 to only six by 2002 (Aspinall 1996, Javed & Khan 2004). However, inconsistencies in methods, timings and data gaps do not allow any meaningful comparison of trends in overall breeding seabird numbers.

Conservation of waterbirds in the Emirate has three inherent weaknesses. First, information on waterbird populations is inconsistent and sporadic. Second, the network of protected coastal and island sites is inadequate. Third, the coastline and many islands are under severe developmental pressure and are being altered rapidly due to the absence of any policy or Coastal Zone Management Plan.

Systematic, long-term population monitoring is fundamental to acquire information on important bird populations, both to monitor changes and recommend actions. Abu Dhabi's Environment Agency (EAD) waterbird programme is a step in that direction. Such monitoring programmes, initiated locally,

should also develop into bigger programmes for the entire region. The Middle East is, and will remain, a political hotspot because of strategic oil reserves and increasing global energy demands, and will pose threats to waterbirds from oil spills and conflicts such as the Gulf War (Evans & Keijl 1993, Symens & Suhaibaini 1993). A regional waterbird monitoring programme with networks of individuals and organisations will be important for capacity building, monitoring and rapid response to oil spills and other events.

The long-term future of species and sites cannot be guaranteed without protection. Important islands for waterbirds should be declared as protected immediately (Javed & Khan 2003), to add to the existing protected areas under the Morrawah Marine Protected Area (MMPA) which currently has nine islands with an area of 4 225 km<sup>2</sup>. IBAs or areas listed in the Directory of wetlands in the Middle East (Scott 1995) do not guarantee protection for sites, but they do provide international recognition to sites and it is imperative to further protect them.

Landscape patterns influence bird assemblages, and the understanding of such patterns provides opportunities and challenges (Clark *et al.* 2004). As migratory waterbirds use large geographical areas and move across them, a landscape based approach to monitor and conserve the wintering, staging and breeding waterbirds and their habitat is essential. However, management of areas along the coast is not only very difficult, but also extremely challenging due to such areas often being of high economic value for property development, tourism and industry. A landscape-scale management approach is needed to secure the conservation of waterbirds while enabling the UAE, and the Emirate in particular, to develop sustainably through maintaining natural ecosystem processes and the integrity and well being of coastal and inland ecosystems.

## 5.5 The marine environment: challenges for conservation implementation. Workshop Introduction

**John Croxall**

Chair of Global Seabird Programme, BirdLife International, Wellbrook Court, Girton Road, Cambridge, CB3 0NA, UK.

Croxall, J. 2006. The marine environment: challenges for conservation implementation. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 737-738.

Royal Albatross *Diomedea* sp. in New Zealand. The conservation of pelagic seabirds such as albatrosses and petrels is both a pressing and urgent conservation challenge. Photo: Colin Galbraith.

This workshop, the only one of the conference devoted exclusively to a marine theme, recognised that some of the world's greatest conservation challenges are in the marine environment, both within territorial (Exclusive Economic Zone) waters and on the high seas.

Amongst the biggest challenges for marine conservation are:

- a) implementation of precautionary ecosystem-based approaches to sustainable use of resources; and
- b) minimization of the environmental consequences of human activities.

Progress on both topics requires the identification of species, sites and areas needing particularly sensitive management, including the context and scope of Marine Protected Areas.

The presentations illustrated some current approaches to these issues, both methodological and practical, mainly focusing on sea ducks and coastal areas in the Northern Hemisphere.

Two presentations illustrated the use of new methods and instrumentation. Mosbech *et al.* describes the use of satellite telemetry to define migration routes and offshore key habitats during winter for King Eiders *Somateria spectabilis* in arctic Greenland by attaching transmitters to birds from three moulting sites in west Greenland and a breeding site in arctic Canada. With increasing potential human impacts from oil activities and fisheries more knowledge on the key habitats outside the breeding areas is needed. Surveys by plane or ship can give snapshots of distribution and provide important data for population estimates. However, offshore surveys whether by plane or ship are costly and are limited by light and bad weather during the Arctic winter, where ice also limit the accessibility for ships. Therefore satellite telemetry provides an important supplementary tool. West Greenland though in the Arctic, provides areas of open water during winter and is an important wintering area for Arctic marine birds.

Garthe & Skov report that the German Baltic Sea was one the first areas in which the Special Protection Areas (SPA) of the

EC Directive on the conservation of wild birds were selected on the basis of offshore concentrations of seabirds. In 2002, a GIS and geostatistical procedure was applied to define concentration areas for seabirds, mainly sea ducks. From this exercise it was concluded that it is possible to describe offshore aggregations of seabird species exhibiting high aggregations by applying geostatistical routines. For species showing widespread distributions this procedure is much more difficult and needs to be further developed. For modelling purposes, co-variables (*e.g.* water depth) should be taken into account in the future. Also, the spatial variation of the boundary lines describing concentrations should be calculated to estimate the reliability of the data as well as the relevance of the areas selected.

Nikolaeva *et al.* reported that although the present system of Russian protected areas has established over 100 strictly protected nature reserves (*zapovedniks*), these do not currently include marine protected areas. An important goal is to establish 13 strictly protected reserves with offshore areas for protection of seabirds and waterfowl and coastal marine habitats. Recently the combined efforts of experts have resulted in a set of proposed Marine Protected Areas with special reference to seabird and sea duck conservation. Some of the most important proposed protected areas in the Barents and White Sea include: (1) east Murman coast including the archipelagos of the Kandalaksha state strictly protected reserve and the most important seabird colonies; (2) the main moulting, migrating and stopover areas of waterfowl in the Pechora Sea area; (3) the main breeding moulting, migrating and wintering areas in the White Sea area. In the very near future rapid oil and gas development and transportation on the Russian arctic shelf will come into conflict with the existing habitat protection strategy for seabirds and waterfowl. It is evident that development of an appropriately designed network of marine protected areas is urgently needed as an effective way

to mitigate the environmental impact of the above activities and to maintain normal ecosystem functioning.

Overall, the workshop agreed that sufficient data, expertise and relevant methodological approaches now exist to identify key sites for protecting breeding and wintering concentrations of seabirds and sea duck within coastal areas, notably Exclusive Economic Zones (EEZs). The challenge here is primarily to integrate the necessary species and habitat protection into an appropriate overall system for managing all aspects of such habitats in a way that will provide suitable protection against pollution, over-fishing and other ecosystem-destabilizing influences. Even within coastal areas and EEZs, however, much more work is needed to identify important staging areas and to define key habitats for species which are not congregatory.

For high seas areas and pelagic marine systems, however, considerable new work is required to develop approaches for identifying critical habitats and biodiversity hot-spots for marine vertebrates, especially seabirds. This will require combining existing data from at-sea surveys with records from remote-tracking sources and developing new analytical and modeling approaches for visualizing and integrating such data with information from other marine taxa and with data on the physical and biological marine environment. New standards of management and governance of the high seas will also need to be implemented, particularly by Regional Fisheries Management Organizations and others with high seas jurisdictions, closely linked to parallel initiatives and equivalent standards being implemented in adjacent areas within EEZs under coastal state jurisdiction. This will entail large-scale multinational initiatives and will need to involve data holders and stakeholders from both conservation and resource exploitation constituencies, together with relevant government, intergovernmental and non-governmental organizations if open-ocean areas are to be managed and protected in appropriate ways.

With issues to address in both terrestrial and marine environments, birds such as penguins present challenging conservation problems. More than 3 000 Magellanic Penguins *Spheniscus magellanicus* at Harberton, Beagle Channel, Argentina. Photo: Chris Wilson.

## Selection of suitable sites for marine protected areas for seabirds: a case study with Special Protection Areas (SPAs) in the German Baltic Sea

Garthe, S. & Skov, H. 2006. Selection of suitable sites for marine protected areas for seabirds: a case study with Special Protection Areas (SPAs) in the German Baltic Sea. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 739-742.

### ABSTRACT

This paper is an abbreviated and updated version of two publications: Garthe (2003), Verteilungsmuster und Bestände von Seevögeln in der Ausschließlichen Wirtschaftszone (AWZ) der deutschen Nord- und Ostsee und Fachvorschläge für EU-Vogelschutzgebiete, and Garthe (2006), Identification of areas of seabird concentrations in the German North Sea and Baltic Sea using aerial and ship-based surveys. It gives a brief overview of the field methods used to study the distribution of seabirds at sea in the German Baltic Sea. It also shows how the data were analysed, how seabird concentrations may be delineated, and how suggestions for protected areas were derived from the data.

### INTRODUCTION

Marine protected areas (MPAs) for seabirds are currently being established under various international instruments and marine conventions (e.g. OSPAR, HELCOM), and also under the main nature conservation directives of the European Union. When Germany adopted its Federal Nature Conservation Act in April 2002 in order to select Natura 2000 sites including sites within the Economic Exclusion Zone (EEZ), the need arose to obtain an up-to-date overview of the distribution and status of seabirds in German waters of the North and Baltic Seas. This paper briefly describes the field methods used in studying the distribution of seabirds at sea, how the data were analysed, how seabird concentrations may be identified, and how suggestions for protected areas were derived from the data.

### FIELD METHODS

Seabird distribution in the south-western Baltic Sea was studied by transect counts from ships and aircraft. This method basically aims at assessing distribution patterns and numbers of seabirds at sea, but ships and aircraft are differently suited for these purposes (see Camphuysen *et al.* 2004 and Garthe *et al.* 2004 for recent reviews). Aerial surveys are able to cover a much larger area in a much shorter time and at a lower cost per kilometre than surveys from ships. However, they are only feasible under conditions of low wind speed, and there are limitations to species identification from the air (e.g. groups such as grebes, gulls, terns and auks cannot usually be identified to species level). Ship-based surveys enable the collection of additional information on the behaviour of the birds and usually allow for sampling environmental data, such as hydrography, which proves very useful for understanding species distribution patterns.

The methodology for counts from ships was first described by Tasker *et al.* (1984) and has been largely standardized internationally. Due to the presence of high densities of birds that quite often fled from approaching ships, it proved necessary to

search regularly or continuously for birds using binoculars and to deploy at least two observers, as suggested by Webb & Durinck (1992) and Garthe *et al.* (2002). Birds were counted from either the top deck or the bridge-wing, usually on 300 m wide transects set to one or both sides of the vessel. Flying birds were counted employing the “snapshot” method (Tasker *et al.* 1984, Garthe *et al.* 2002). The position of the survey vessel was recorded automatically by onboard or portable GPS instruments.

Seabirds were counted from aircraft using a transect methodology recently described by Diederichs *et al.* (2002). Flights were conducted from twin-engine aircraft (e.g. Partenavia P-68) flying over German waters from the coast to the outer limit of the EEZ. Transects were usually set perpendicular to the coast to obtain variation over major habitat features such as water depth, distance to coast, and frontal systems. Transects were 10 km apart in the North Sea (20 km in areas far from the coast) and mostly 8 km apart in the Baltic Sea. Flights were conducted at an altitude of 250 ft (78 m) and a speed of 100 knots (185 km/hour). During the counts, all bird observations were recorded on a portable voice recorder; the data recorded included: time (to the nearest second), species, number, general behaviour (five categories) and also, if possible, age and sex. Geographic position was recorded every five seconds onboard the aircraft.

### SPECIES SELECTION

Gellermann *et al.* (2003) catalogued those species occurring in German waters which must be considered in the selection of SPAs. They distinguished three different levels of importance for species. In the selection of SPAs, only those species that were categorized in their list as of high or medium importance were used. Three groups of bird species comprised this category. The first group comprises the species that are listed in Annex I of the EU Birds Directive (species that shall be the subject of special conservation measures) and that occur regularly in the offshore waters of the German parts of the Baltic Sea. These are Red-throated Diver *Gavia stellata*, Black-throated Diver *G. arctica*, Slavonian Grebe *Podiceps auritus*, and four species of terns. The second group comprises migratory species that regularly occur in offshore areas. The EU Birds Directive does not define “migratory species”, and the definition used in practice is the one provided by the Convention on Migratory Species of Wild Animals (Bonn Convention). This Convention defines migratory species as species in which a significant proportion of the population cyclically and predictably crosses one or more national jurisdictional boundaries. In both study areas, this includes all seabird species. For these species, especially those that occur in major concentrations, the most important areas (or a few of the most important areas) were recommended for selection as SPAs.

The identification of SPAs focused on the German EEZ, and preferably on areas that were important for more than one species. The third group comprises rare offshore species and species occurring only along the coast (e.g. diving ducks, geese and swans).

Analysis of the data was equal for the first two groups, i.e. Annex I species and migratory species. However, concentrations of Annex I species were considered to be much more important and were thus more decisive for the designation of SPAs than areas with only migratory bird species. The third group (i.e. species that were rare offshore or confined to the coast) was not relevant to the SPA selection process in the EEZ because of the virtual absence of these species in this area.

### SPECIES DISTRIBUTION

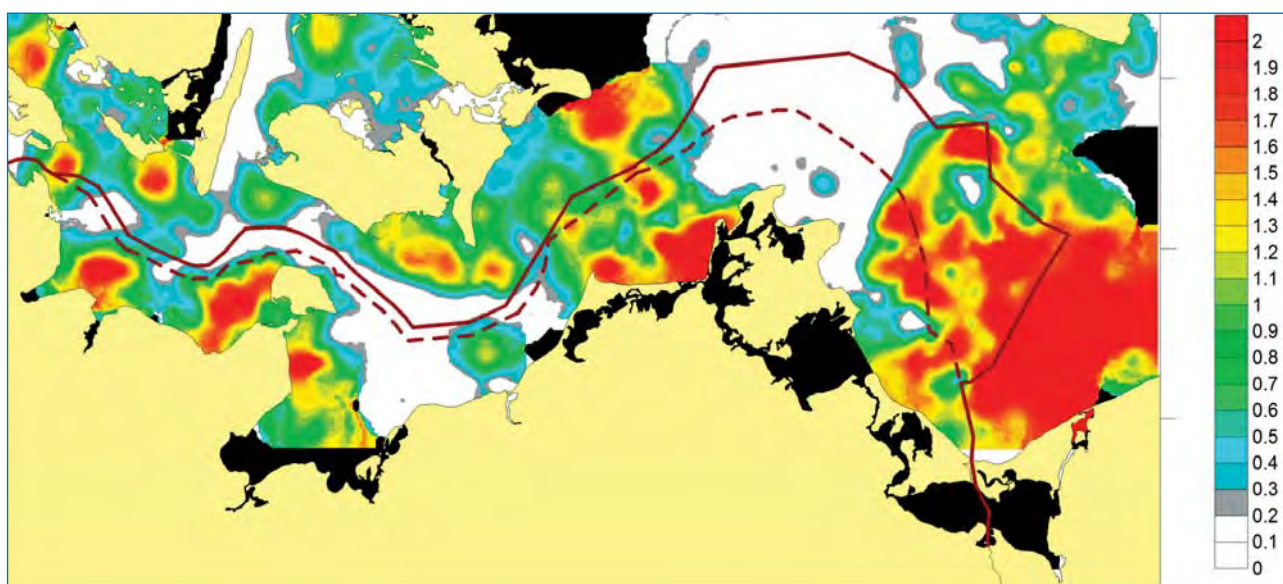

All species distribution maps are based on densities, i.e. the number of individuals per unit area. Some species are distributed over large areas and usually exhibit only short-term aggregations (e.g. gulls), while other species are often densely concentrated and are predictable in their distribution (e.g. seaducks). For all relevant species in the German Baltic Sea, a spatial interpolation procedure based on ordinary kriging (Kitanidis 1997) and used by Skov *et al.* (2000) was adopted and further developed (Garthe 2003, Garthe & Skov in prep.). With this procedure, distributional data were interpolated and smoothed between survey lines on the basis of the species-specific spatial abundance structure (which is measured by the software in use). Fig. 1 gives one example for the Long-tailed Duck *Clangula hyemalis*.

### SPA SELECTION

The boundaries of areas of bird concentration were determined by an analysis investigating the gradient of density change over space. In order to do this, the modelled distributional data were projected into a two-dimensional map. In each case, the modelled isoline of bird density (i.e. the line drawn through the same level of bird density) located just outside the strongest gradient in spatial density was chosen as the boundary of a

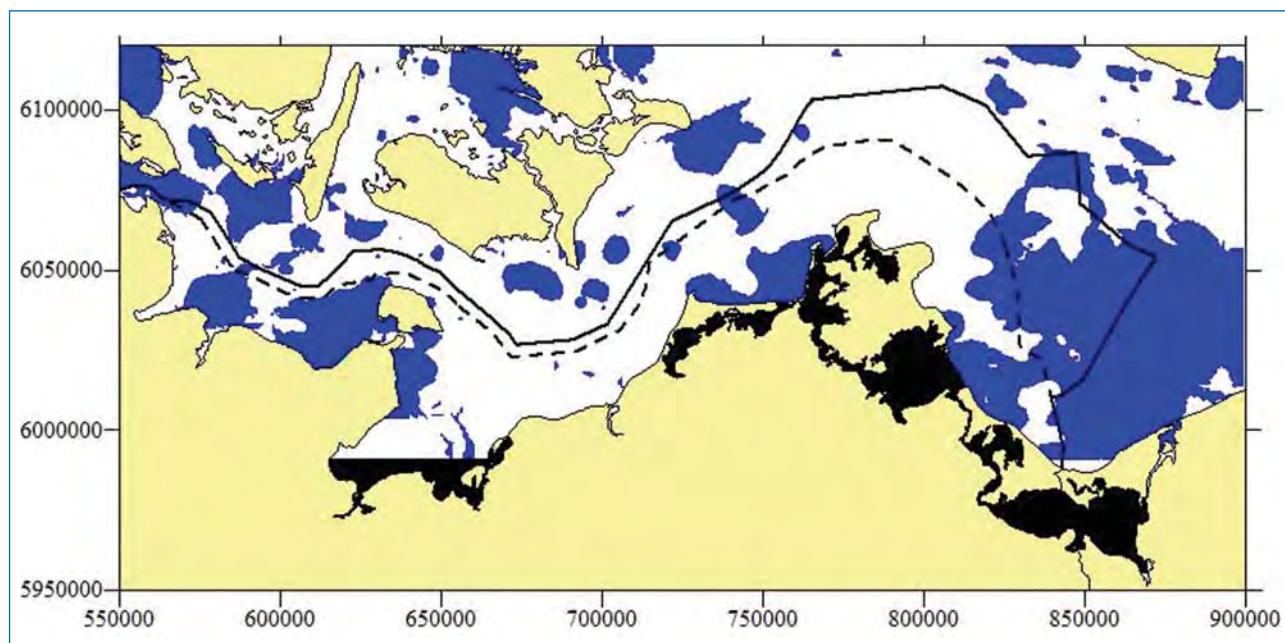

**Fig. 1.** Distribution of the Long-tailed Duck *Clangula hyemalis* in the German Baltic Sea in winter (December-March); 1986-2002. Colours represent different densities (values as logarithmic density; see legend). Black areas were not studied sufficiently. The dashed red line indicates the seaward limit of German territorial waters; the continuous red line indicates the seaward limit of the German EEZ.

**Fig. 2.** Distribution of the Velvet Scoter *Melanitta fusca* in the Pomeranian Bay in winter (December-March); 1986-2002. Colours represent different densities (values as logarithmic density [ $\log(\text{density} + 1)$ ]; see legend). The dashed red line indicates the seaward limit of German territorial waters; the continuous red line indicates the seaward limit of the German EEZ.

**Fig. 3.** Overlay of all areas exhibiting concentrations of the species of interest in this study in the south-western Baltic Sea (blue colour). Black areas were not studied sufficiently. The dashed line indicates the seaward limit of German territorial waters, the continuous line indicates the seaward limit of the German EEZ.

concentration (see Fig. 2 for one example). In this way, the major part of the concentration is included in the selected area. The density value of the boundary line was noted and used as the species- and season-specific minimum density defining a seabird concentration. This value was then taken for plotting the contour line showing the spatial extent of the respective concentration.

The areas of concentration and contour lines for each of the species of interest derived from the list of Annex I and migratory bird species were then combined so that a set of areas for potential conservation was identified (Fig. 3). From this map, one potential SPA was suggested.

## DISCUSSION

The data collected by ship-based and aerial surveys have been extremely useful for describing the current distribution patterns of all seabird species in the two study areas. Both field methods have their advantages and disadvantages because of their different characteristics. A combination of both methods is ideal for most purposes, including those discussed in this paper. It is important to select these field methods carefully, with respect both to the spatio-temporal scale envisaged for such a study and to the species under consideration.

The robustness of the results has been the focus of considerable attention by various groups in the light of proposals for two large SPAs within the German EEZ in the Baltic and North Seas (Garthe 2003). Most promising was the finding that all surveys carried out after finalization of the SPA proposals (i.e. all surveys in 2003 and 2004) identified the same areas of major concentration as in previous years. This demonstrates that even if the boundaries of the areas of concentration shift slightly, as might be expected in seabirds living in a dynamic environment, the major results are stable and reproducible. However, on a larger time-scale it is possible that the distribution of seabird species could change, especially if environmental conditions change. In the Baltic Sea, this could be the case, for instance, in

relation to winter ice distribution, since nearly all of the data collected for this study were from mild and normal winters only. In the North Sea, recent major changes in food availability (which have led to breeding failures in the north-western North Sea) may influence distribution patterns in the German Bight, at least in those species ranging over wide areas of the North Sea.

The analytical methods outlined in this paper are still at an early stage in being adopted as standard procedures for designating SPAs, since most Member States of the European Union have not yet delineated such protected sites in offshore areas. However, these methods have been very useful for selecting areas of seabird concentration and SPAs. More recent work by British colleagues highlights the way forward (e.g. McSorley *et al.* 2004, Webb *et al.* 2004). For species exhibiting a widely dispersed distribution, the procedure for identifying areas of concentration is much more difficult than for aggregated species. To date, no proposals have been made as to how to deal with sea areas in which the only species present are rather evenly or at least widely distributed. In such cases, vast areas would need to be designated to capture a meaningful percentage of bird numbers. This is often politically impossible and might also be less easy to justify scientifically. This problem needs further consideration. For modelling purposes, e.g. in future site selection, covariates (e.g. water depth) should be included. Also, attention might be given to the reliability of data by calculating (statistically) the spatial variation of the boundary lines describing concentrations. If such boundary lines vary substantially over space (e.g. within a standard deviation), then the baseline data and/or aggregation characteristics of the bird species may be less evident than when the boundaries are more stable over space.

## ACKNOWLEDGEMENTS

This work is based on several projects that have been conducted in recent years. Funding has been received primarily from Bundesamt für Naturschutz, Bundesministerium für Umwelt,

Naturschutz und Reaktorsicherheit, Freunde und Förderer der Inselstation der Vogelwarte Helgoland e.V., Ornithologische Arbeitsgemeinschaft für Schleswig-Holstein & Hamburg e.V. and Forschungs- und Technologiezentrum Westküste (FTZ) der Universität Kiel. Field observations have been carried out by many observers over the years. Many private and governmental institutions permitted work on their boats. Furthermore, many people have contributed to this work by collecting, summarizing and analysing data, by helping to shape the procedures for SPA designation, and by general comments. From these, at least, the following need to be mentioned: C.J. Camphuysen, V. Dierschke, O. Engelhard, N. Guse, O. Hüppop, J. Kotzerka, J. Krause, U. Kubetzki, K. Ludynia, N. Markones, T. Merck, M. Scheidat, P. Schwemmer, H. Skov, N. Sonntag, A. Webb and T. Weichler.

### ABSTRACT

The present system of Russian protected areas has resulted in the establishment of 100 strictly protected nature reserves. However, Russia has not yet established any system of marine protected areas. The most important goal of the 12 existing strictly protected reserves that include marine waters is the protection of waterbirds and their coastal habitats. During the last few years, various experts working together have produced a proposal for a series of marine protected areas with special reference to the conservation of seabirds and seabirds. Some of the most important proposed marine protected areas in the Barents Sea region include: 1) the eastern Murman coast, including the archipelagos of Kandalaksha State Strictly Protected Reserve and the most important seabird colonies; 2) the main moulting and staging areas for waterbirds in the Pechora Sea; and 3) the main

breeding, moulting, staging and wintering areas in the White Sea. In the near future, rapid oil and gas development and transportation on the Russia Arctic shelf will come into conflict with the existing strategy for the protection of seabirds and waterbirds. The development of an appropriately designed network of marine protected areas is proving to be an effective way to ensure that the normal ecosystem functions are maintained.

### INTRODUCTION

The present system of protected areas in Russia has a history of almost 90 years, and has resulted in the establishment of 100 strictly protected nature reserves (zapovedniks). Some of these are Ramsar sites and a few others are protected under the World Heritage Convention. A characteristic of Russian zapovedniks is the presence of research departments that

**Fig. 1.** Russian protected areas with offshore areas: (1) Kandalaksha Reserve in the Barents Sea and White Sea; (2) Nenets Reserve in the Barents Sea; (3) Ust'-Lena Reserve in the Laptev Sea; (4) Commander Islands in the Bering Sea; (5) Magadan Reserve in the Sea of Okhotsk; (6) Kuril Reserve in the Sea of Okhotsk; (7) Far Eastern Marine Reserve in the Sea of Japan; (8) Franz-Josef Land Reserve in the Barents Sea.

**Fig. 2.** The most important wintering areas for some seabirds along the north coast of the Kola Peninsula (pink shading), and the three most important breeding areas for the Common Eider *Somateria mollissima*: (1) Ainov Islands; (2) Gavrilovskiye Islands; (3) Seven Islands in Kandalaksha State Strictly Protected Reserve.

conduct a programme of monitoring biological observations (the so-called “Chronicle of Nature”). However, Russia has not yet established any system of marine protected areas.

Existing reserves that are of special importance for the protection and investigation of seabirds and seabirds are the strictly protected reserves of Kandalaksha (White Sea and Barents Sea), Nenets (Barents Sea), Ust'-Lena (Laptev Sea), Commander Islands (Bering Sea), Magadan (Sea of Okhotsk), Kuril (Sea of Okhotsk) and Far Eastern Marine (Sea of Japan), and the Franz-Josef Land Reserve (Barents Sea) (Fig. 1). Amongst other protected areas that either do not have a high protection status or are under regional jurisdiction, the Solovki and Kuzova Islands (White Sea), Beringia Nature Park and several small coastal reserves in the Russian Far East are worthy of mention.

During the last few years, the joint efforts of a number of experts on marine wildlife, including experts on seabirds and waterbirds, have culminated in the mapping of several important and especially sensitive areas. A series of marine protected areas (MPAs) has been proposed on the basis of a gap analysis, with special attention being given to conservation targets for seabirds and seabirds. Of particular importance is the establishment of marine protected areas and introduction of other conservation and management measures along the East Atlantic Flyway in the Barents Sea and White Sea (Krasnov *et al.* this volume). Data on the abundance, population dynamics and distribution of seabirds and seabirds were collected using various methods. These included land-based stationary observations and aerial surveys

by helicopter and special aeroplane in the coastal and open waters of the Barents and White Seas.

According to Russian national legislation, marine waters are under federal jurisdiction, and only those marine areas given federal protection may be considered as marine protected areas in the strict sense. Thirteen of the strictly protected reserves (IUCN category I) in Russia include offshore areas, and four others have marine buffer zones. In addition, there are eight federal reserves which include marine areas, and most of these have been designated as Ramsar sites or are potential Ramsar sites. The most important management goal of most of these reserves is the protection of seabirds and waterbirds and their coastal habitats.

The increasing human activity in the waters surrounding the islands which already have some protection is poorly regulated, resulting in a need for the establishment of other protected areas (especially marine) within the Barents and White Seas to ensure that there is a representative and functional network of marine protected areas. A set of marine protected areas for the conservation of seabirds and seabirds has therefore been proposed for the Barents and White Seas. Some examples of the most important of these proposed protected areas are considered below.

#### **EASTERN MURMAN COAST FROM THE RIBACHIY PENINSULA TO SVYATOINOS CAPE**

The coastal waters off the north coast of the Kola Peninsula (Fig. 2) are an extremely important wintering area for several species of seabirds (Bianki *et al.* 1993). Over 70 000 seabirds,

**Fig. 3.** Proposed marine protected areas along the north coast of the Kola Peninsula: (1) Gorodetskiy seabird colony and surrounding waters off the Rybachiy Peninsula; (2) Yarnishnaya Inlet with Krutik Cape and Dalnezelenetskaya Inlet; (3) Dvorovaya Bay.

including large numbers of Steller's Eider *Polysticta stelleri*, spend the winter in this area (Nygård *et al.* 1995). Two of the most abundant wintering species are the Common Eider *Somateria mollissima* and the King Eider *S. spectabilis*, while the Common Eider also breeds here (Belopol'skii 1957). As many as 6 000–7 000 pairs of Common Eiders have been found nesting (Karpovich 1987). The wintering population of this species is about 50 000 birds, and thus greatly exceeds the number of breeding individuals. However, nothing is known about the origin and breeding areas of the wintering birds as there are no ringing recoveries. At present, the most important threats include illegal egg-collection and disturbance in the breeding areas, but oil spills and chronic oil pollution may pose a serious threat in the future. The most important breeding areas for the Common Eider are situated on the islands of three archipelagos: Ainov, Gavrilovskiye and Seven Islands (Fig. 2) in Kandalaksha State Strictly Protected Reserve in the Barents Sea (Karpovich 1984). Unfortunately, in the last few years a strict protection regime has not been maintained at these islands because of serious management problems in the reserve. Furthermore, the wintering grounds of the Common Eider are unprotected. Thus, the main priority for this area is to re-establish a real protection regime in the islands.

There are three important seabird colonies on the coast of the Kola Peninsula without any protection status. Gorodetskiy seabird colony on the Ribachiy Peninsula (Fig. 3) is the largest colony along the entire Kola coast, with over 50 000 Black-legged Kittiwake *Rissa tridactyla* nests and about 4 000 guillemots *Uria*

spp. This seabird colony and the surrounding waters off the Rybachiy Peninsula deserve federal reserve (zakaznik) status.

Farther east, Krutik Cape supports 4 000 Black-legged Kittiwake nests and Dvorovaya Bay supports 32 000 Kittiwake nests and over 1 000 guillemots. The main limiting factor influencing the dynamics of seabird colonies in recent years has been the state of the food resources, such as Herring *Clupea harengus*, Capelin *Mallotus villosus* and sand eels *Ammodytes* spp. (Krasnov *et al.* 1995, Krasnov & Barrett 1995). The size of the fish stocks is determined not only by environmental factors, but also to a considerable extent by fisheries activities. Because of the low level of the Capelin stock in 2003, Black-legged Kittiwakes failed to breed at the colonies along the Kola Peninsula coast. Thus, the depletion of food resources, oil spills and chronic oil pollution have been identified as the most important threats to seabird colonies in this area.

Another marine area which requires special protection status (e.g. specially protected marine waters) is the Yarnishnaya Inlet together with Krutik Cape and Dalnezelenetskaya Inlet near Dalniye Zelentsi settlement (Fig. 3). This area has been a scientific study area of the Murmansk Marine Biological Institute for many years. A third important area in this region is Dvorovaya Bay (Fig. 3), where federal reserve (zakaznik) status combined with a monitoring programme would be desirable.

## THE PECHORA SEA

The establishment of marine protected areas in the Pechora Sea is a high priority. The area is of great importance for seabirds

**Fig. 4.** Proposed marine protected areas in the Pechora Sea: (1) the waters around Dolgiy Island; (2) the Pechora Estuary; (3) the waters off the south coast of Kolguev Island.

and waterbirds because of its extensive breeding grounds, moulting sites and staging areas for birds on migration (Krasnov *et al.* 2002). The problem of the Pechora Sea is that it is a mosaic of local oil fields, which makes it difficult to design effective protected areas. In the proposal for the establishment of protected areas, we will compare the pros and cons of two possible ways of developing a protected area: 1) through nomination of the Nenetskiy Zapovednik for UNESCO Biosphere Reserve status and establishment of a cluster of biosphere polygons in offshore areas; or 2) through the establishment of a network of protected areas with some other status, under the special control of the Russian maritime and environmental authorities. We consider the first option below.

#### Dolgiy Island

The waters surrounding Dolgiy Island (Fig. 4) hold the largest concentration of moulting and migrating seaducks in north-western Russia. King Eider and Common Scoter *Melanitta nigra* are two of the most abundant species. Flocks of over 10 000 seaducks have been observed in the area (Isaksen *et al.* 2000). At the same time, this area borders on the Prirazlomnoye oil field, and the seaducks could therefore be at great risk of exposure to oil spills, chronic oil pollution, human disturbance and degradation of food resources during oil exploration.

#### Pechora Estuary

The Pechora Estuary (Fig. 4) is the only marine staging area for swans *Cygnus* spp. along the migration route to their wintering

areas. During autumn, large flocks of Bewick's Swans *Cygnus columbianus bewickii* and Whooper Swans *C. cygnus* numbering several hundred birds pass through the area (Krasnov *et al.* 2002). In addition, some seaducks and dabbling ducks spend the winter in the estuary. Current threats include illegal hunting and human disturbance, while chronic oil pollution from oil exploration could pose a threat in the future. The presence of the Nenetskiy State Zapovednik provides a good opportunity to develop offshore protected areas through raising the status of the zapovednik to Biosphere Reserve and adding some offshore areas as biosphere polygons with a special management regime. Some areas could be directly associated with the Nenetskiy Zapovednik, or at least with the Nenetskiy Zakaznik, particularly an area in the Pechora Estuary and the waters surrounding Dolgiy Island.

#### Kolguev Island

The waters off the south coast of Kolguev Island (Fig. 4) are an important moulting area and staging area for migrating seaducks. The King Eider is the most numerous species in these waters, while the Bean Goose *Anser fabalis* and Greater White-fronted Goose *A. albifrons* are present during autumn (Ponomaryeva 1995, Krasnov *et al.* 2002). The main threats are hunting, human disturbance, and the increasing possibility of oil spills and chronic oil pollution. The original model territory of Kolguev Island that combined local, traditional use of natural resources and modern oil exploration led to the establishment of a specially protected ethno-ecological territory. The possible

Fig. 5. The proposed marine protected area near Novaya Zemlya, including Bezimyannaya and Gribovaya Bays (1).

addition of a 12-mile marine zone and marine reserve around the island is under discussion.

#### NOVAYA ZEMLYA

The largest and most important colonies of Common Eider and seabirds (including c. 1 000 000 Brunnich's Guillemot *Uria lomvia*) in northern European Russia are situated along the south-west coast of the Novaya Zemlya archipelago (Uspenskiy 1956, Uspenskiy & Khakhin 1993). Two bays on the south-west coast of Novaya Zemlya (Bezimyannaya and Gribovaya Bays; Fig. 5) hold the majority of the breeding population of Common Eiders and some seabird species, but these were under strict protection only until 1952. The current number of breeding Common Eiders, their systematic status and their wintering areas are unknown. The main threats in the area are human disturbance on the eider breeding grounds during future development of mineral resources along the coast, depletion of the food resources of seabirds (e.g. over-fishing of Polar Cod *Boreogadus saida*, one of the most important food items of seabirds in the area), and possible pollution of coastal waters from the Shtokmanovskoye gas field. The proposed protection regime for the breeding, moulting and possible wintering areas of seaducks and seabirds includes establishing a network of protected areas of various types in the waters surrounding the most important bird habitats on Novaya Zemlya, and re-establishing the strict protection status of Bezimyannaya Bay.

#### THE WHITE SEA

The most abundant species of seaduck in the White Sea is the Common Eider. The isolated population of eiders in this area is

estimated to be about 40 000-60 000 birds (Bianki & Karpovich 1983, Bianki 1991).

#### The Terskiy coast

The Terskiy coast of the Gorlo in the White Sea (Fig. 6) is one of the most important staging areas for migrating birds in the East Atlantic Flyway and one of the most important moulting and wintering areas for seaducks in the region. In summer, moulting seaducks, mainly Common Eiders (c. 6 000 birds) and Steller's Eiders (c. 4 000 birds), congregate in Terskiy coastal waters (Krasnov *et al.* 2006). The Terskiy coastal zone is the only area in the Russian Arctic that supports a large population of Steller's Eiders throughout the year (Krasnov *et al.* 2006) and, at the same time, is a key moulting area for this species (Kokhanov 1979). The system of polynyas along the Terskiy coast supports huge wintering flocks of Common Eiders (c. 16 000 birds), King Eiders (c. 6 500) and Steller's Eiders (4 000) (Strøm *et al.* in press), and is currently one of the most important wintering areas for the King Eider in northern European Russia. Most of the potential problems in the area are thought to be related to unregulated tourism, oil spills, chronic oil pollution and shipping (during transportation of oil from the Kandalaksha, Onega and Arkhangelsk oil terminals to the Murmansk oil terminal). One possible location for the proposed pipeline from Siberia to Murmansk would pass through the area. An offshore federal reserve (zakaznik) encompassing the moulting and wintering areas of seaducks has been proposed for the Terskiy coast of the White Sea.

Fig. 6. Proposed marine protected areas in the White Sea: (1) the Terskiy coast of the Gorlo in the White Sea; (2) Onega Bay; (3) Kandalaksha Bay.

### Onega Bay

Almost half of the White Sea Common Eider population breeds on islands in Onega Bay (Fig. 6), and the majority of males moult within this region. In autumn, numerous flocks of seabirds and waterbirds in the East Atlantic Flyway stop over in Onega Bay (Bianki 1991) on passage to their wintering grounds. In winter, polynyas in Onega Bay hold the majority of the White Sea Common Eider wintering population. The most serious potential threats in the area include human disturbance, illegal hunting and egg-collection, and chronic oil pollution during oil transportation from the Onega Bay ports. Detailed proposals will be developed concerning the boundaries and protection regime for offshore marine reserves (zakaznik) in the wintering areas of the Common Eiders and off the Solovetskiy Archipelago.

### Kandalaksha Bay

The archipelagos of small islands in Kandalaksha Bay (Fig. 6) support over half of the breeding population of Common Eiders in the White Sea. Thousands of seaducks spend their moulting period in this area, and during autumn, numerous flocks of migrating seaducks and flocks of Whooper Swans and Bean Geese stage here (Bianki 1991). The main threats to seabirds and waterbirds in the bay are illegal egg-collection, human disturbance, and oil spills and chronic oil pollution during oil transportation from Kandalaksha oil terminal to Murmansk. Since 1975, Kandalaksha Bay has been one of Russia's Ramsar sites. The Kandalaksha State Nature Reserve in Kandalaksha Bay includes four separate archipelagos. However, as in the Barents Sea branch of the Kandalaksha Reserve, a strict protection

regime has not been enforced at some of the protected islands in recent years, because of serious management problems in the reserve. Thus, the main priority for this area is to re-establish an effective protection regime in the islands within the reserve.

### CONCLUSION

The potential contamination of marine habitats by oil pollution could be the most important threat for seabirds and waterbirds along the Russian part of the East Atlantic Flyway. Significant deficiencies in regulatory documents defining an ecological policy for Russian oil and gas companies on the marine shelf were identified in the course of this analysis. There is no doubt that the rapid development of oil and gas resources on the Russia Arctic shelf and the transportation of these products will, in future, come into conflict with the existing protection strategies for seabirds and waterbirds based on establishing and broadening protected natural areas. Nevertheless, it is evident that development of an appropriately designed network of marine protected areas could prove to be an effective way to mitigate the environmental impact of the oil and gas industry and secure a normal functioning ecosystem.

## Revision of Danish EU Bird Directive SPAs in relation to the development of an offshore wind farm: a case study

Ib Krag Petersen

National Environmental Research Institute, Grenåvej 14, DK-8410 Rønde, Denmark. (email: ikp@dmu.dk)

Petersen, I.K. 2006. Revision of Danish EU Bird Directive SPAs in relation to the development of an offshore wind farm: a case study. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 750-751.

Danish marine inshore waters are major staging and wintering grounds for huge numbers of migratory waterbirds. At least five to seven million individuals of more than 30 species winter in these areas, and much greater numbers exploit them for staging on migration (Laursen *et al.* 1997). In some cases, these concentrations constitute the entire breeding or flyway populations of northwest Palearctic species and are of major international importance (Rose & Scott 1994, 1997, Laursen *et al.* 1997, Delany & Scott 2002). As a consequence, Denmark has obligations under international legislation and as a signatory to international conventions, such as the African – Eurasian Migratory Waterbird Agreement under the Bonn Convention, the Ramsar Convention and the EU Birds Directive. Such treaties require states to protect the habitats and maintain the populations of migratory birds using the territory of those states. The majority of Danish SPAs (Special Protection Areas) under the EU Birds Directive are marine, all of which were classified in 1983.

As part of a programme to develop renewable energy sources, a government action plan launched five offshore demonstration wind farm projects in Danish waters in 1997. The aim of the projects was to provide information about their engineering and economic feasibility as well as assessing their effects on the environment, especially the potential impacts on waterbirds. All projects were obliged to undertake full Environmental Impact Assessments (EIAs) prior to construction, as well as post-construction monitoring. Results from these projects would provide background information to support the development of policy relating to future offshore wind farm developments.

One such wind farm, consisting of 33 wind turbines spread over an area of approximately 20 km<sup>2</sup>, was planned south of the island of Læsø. Bird numbers and distributions were studied within a 5 600 km<sup>2</sup> survey area. This large study area was chosen because of the intention of extending the windfarm and developing capacity to exploit up to 2 000 MW of wind power in the area. In addition, these shallow waters were considered to constitute a single biogeographical unit for Common Scoter *Melanitta nigra*.

Between 1999 and 2001 a total of 15 aerial surveys were conducted by the National Environmental Research Institute (NERI) using a high winged, twin-engined Partenavia P-68 Observer, designed for general reconnaissance purposes. Survey flight altitude was 76 m and cruising speed approximately 185 km/h (100 knots). The whole study area was covered by a total of 30 north-south parallel transects, flown at 3 km intervals, covering a total linear track of 1 800 km.

The surveys revealed huge concentrations of wintering, as well as moulting, Common Scoter (Figs. 1 & 2). Although the existence of these concentrations were already known (Laursen *et al.* 1997) and previous aerial surveys had encountered up to 900 000 Common Scoters in the study area, this was the first survey to

establish their total extent and detailed geographical distribution. Data presented from this study are based on the number of birds encountered from the line transect samples, so the actual number of birds is expected to be at least two or three times higher than the number of individuals encountered (Petersen *et al.* 2003).

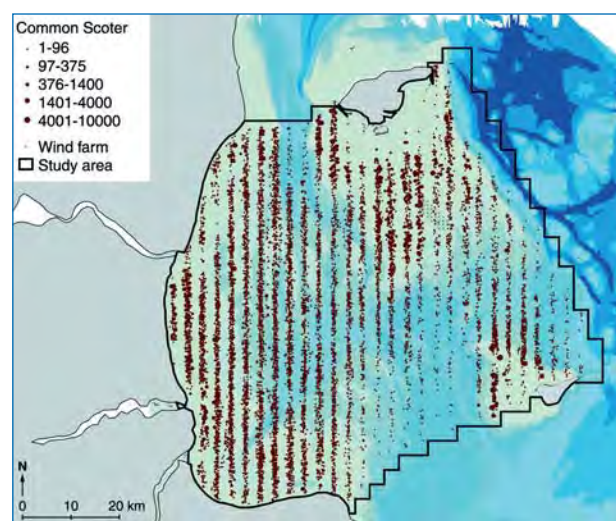

Fig. 1. Distribution of wintering Common Scoter *Melanitta nigra* in the survey area (October to April).

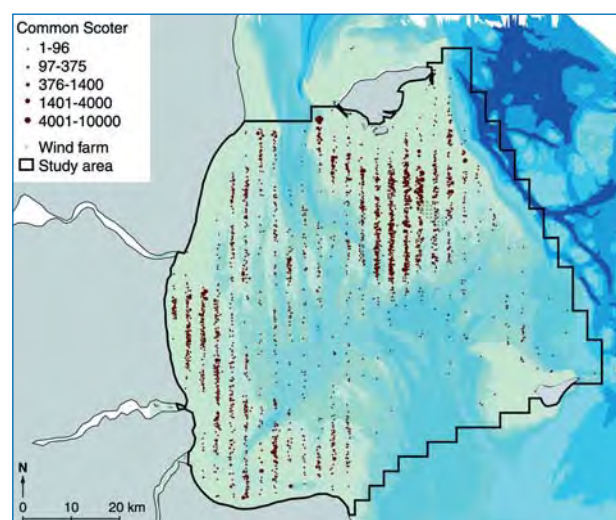

Fig. 2. Distribution of Common Scoter *Melanitta nigra* in the survey area during the moulting period (July to September).

During winter, Common Scoters were scattered over shallow areas of the study area, particularly in the vicinity of the proposed wind farm and in the western parts of the area. In the moulting period (July to September) the birds were concentrated

in the vicinity of the proposed wind farm, with lower concentrations in the western parts of the study area.

Thus the location of the proposed wind farm was close to concentrations of wintering and moulting Common Scoters, giving some cause for concern for their future favourable conservation status. Based on this new information it was decided to adjust the position of the proposed wind farm by 10 km, in order to avoid conflict with concentrations of Common Scoter. In addition it became clear that less than half of Common Scoters present in the study area were detected within boundaries of existing SPAs. This led to the enlargement of two SPAs and the designation of one new area so as to include 98% of the Common Scoters in the study area.

## Extending the boundaries of seabird breeding colony protected areas into the marine environment

Claire A. McSorley, Ben J. Dean, Andy Webb & James B. Reid

Joint Nature Conservation Committee Seabirds and Cetaceans Team, Dunnet House, 7 Thistle Place, Aberdeen, AB10 1UZ, UK.

McSorley, C.A., Dean, B.J., Webb, A. & Reid J.B. 2006. Extending the boundaries of seabird breeding colony protected areas into the marine environment. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 752-753.

During the breeding season, many seabird species engage in essential maintenance behaviours in the waters immediately adjacent to the colony and, therefore, should be accorded some protection within these marine areas. We investigated distribution patterns of Northern Gannet *Morus bassanus*, Common Guillemot *Uria aalge*, Razorbill *Alca torda* and Atlantic Puffin *Fratercula arctica* engaged in maintenance behaviours adjacent to their breeding colonies. We recommend a 2 km seaward boundary extension to existing Northern Gannet breeding colony Special Protection Areas (SPAs), and a 1 km extension for existing auk SPAs.

SPAs provide for the protection of the habitats of naturally occurring wild birds under the provisions of the EC Birds Directive. UK SPAs are mostly limited to terrestrial, freshwater and estuarine environments (Stroud *et al.* 2001). However, the Directive also applies to the geographical sea area. The Joint Nature Conservation Committee (JNCC) provides advice to government to support the classification of SPAs in the marine environment.

During the seabird breeding season, the inshore waters adjacent to colonies are used by many seabirds for essential preening, bathing and courtship behaviours (maintenance behav-

iours). The distribution patterns of seabirds engaged in maintenance behaviours are assumed to be independent of site characteristics and, therefore, generic to all colonies. In 2001, the JNCC conducted boat-based surveys around six UK seabird colonies. The aim was to determine appropriate generic seaward boundary extensions to existing seabird colony terrestrial SPAs that include the important marine areas used by seabirds engaged in maintenance behaviour.

A survey vessel navigated a series of transects extending up to 5 km from the coast of Skokholm and Skomer, Grassholm, the Farne Islands, the Bass Rock, the Isle of May, and Fowlsheugh. The species, number, location and behaviour of all seabirds observed on the water were recorded in one minute samples. Data analyses were performed separately for Northern Gannets, Common Guillemots, Razorbills and Atlantic Puffins.

Bird density data were interpolated using ordinary kriging, which makes use of the inherent spatial autocorrelation in the recorded densities modelled in a semivariogram. This generates a grid of predicted densities for each species. To investigate a possible generic solution for seabird colony SPA boundary extensions we plotted mean predicted density against distance from the colony shore for all sites.

Fig. 1. Distance band analysis showing relationship between mean predicted density (birds km<sup>-2</sup>; standard error bars) and distance from the colony shore for Northern Gannets *Morus bassanus* and Common Guillemots *Uria aalge*.

Predicted density of seabirds engaged in maintenance behaviour decreased with distance from the shore. This relationship was consistent within and between sites, but often at different density scales for each species and for each site. Northern Gannets engaged in maintenance behaviour formed significant aggregations within 2 km of the colony shore, and auks formed similar aggregations within 1 km of the colony shore (Fig. 1).

Based on these findings we recommend extending the boundary of existing terrestrial seabird colony SPAs into the marine environment by 2 km from mean low water mark (mean low water springs in Scotland) for Northern Gannet SPAs, and similarly, by 1 km for auk SPAs (McSorley *et al.* 2003).

## Assessing the numbers and distribution of waterbirds in UK inshore marine waters

Peter Cranswick, Colette Hall & Lucy Smith

The Wildfowl & Wetlands Trust, Slimbridge, Gloucestershire, GL2 7BT, UK. (email: [peter.cranswick@wwt.org.uk](mailto:peter.cranswick@wwt.org.uk))

Cranswick, P.A., Hall, C. & Smith, L. 2006. Assessing the numbers and distribution of waterbirds in UK inshore marine waters. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 754-755.

An assessment of waterbird numbers and distribution is essential for determining conservation priorities, for identifying and monitoring important sites, and for assessing the results of targeted conservation action. Long-term monitoring of waterbirds in the UK is well developed, covering a range of species and habitats, but systematic surveys of marine waters have historically been limited to offshore ship-based surveys, missing nearshore areas that are potentially important for divers and seabirds. In 2001/2002, a new aerial survey technique was adopted, enabling coverage of large areas in a short timescale and minimising disturbance to the target species (Common Scoters *Melanitta nigra* and Red-throated Divers *Gavia stellata*).

Distance-sampling methodology was adopted to provide a statistically robust means of determining numbers. The use of a Global Positioning System provided high spatial resolution data. A twin-engined plane followed transects separated at 2 km intervals and running perpendicular to the main environmental gradients. Between 2001/2002 and 2003/2004, surveys were undertaken by The Wildfowl & Wetlands Trust (WWT) in Liverpool Bay, the Thames Estuary, and parts of the Greater Wash, primarily in winter (e.g. WWT Wetlands Advisory Survey 2003, Cranswick *et al.* 2003, Cranswick *et al.* 2004).

Large numbers of Common Scoters were recorded at several sites in the Irish Sea, notably Carmarthen, Cardigan and Liverpool Bays. Distribution regularly extended up to 10 km from shore and, at one site – Shell Flat, a shallow sandbank off the Lancashire coast – up to 20 km from shore (Fig. 1). Most birds were found in waters less than 10 m deep. Distribution was broadly similar within and between winters, although there was some evidence of a gradual movement to deeper water during the course of a winter.

Analysis of survey data from February 2003 showed that 70 000 birds were present in Liverpool Bay alone. More than half of these were at Shell Flat, a site that before aerial surveys was not recognised as supporting any Common Scoter, but which at times is probably the most important site for this species in UK waters. In the early 1990s, fewer than 30 000 Common Scoters were estimated to winter in British waters.

Red-throated Divers were recorded during winter months, and although present at all sites, numbers and distribution were more variable than for scoters. Birds were distributed sparsely, up to 15 km from shore at many sites. Marked concentrations were, however, recorded on occasion in the Thames Estuary and provisional estimates suggest that at least 5 000, and perhaps as many as 10 000, were present in late winter. This compares with a current estimate of 4 850 for British waters as a whole. Distribution within the site, and the aggregation of birds into groups, varied between months, and marked movements were observed during the course of an individual aerial survey.

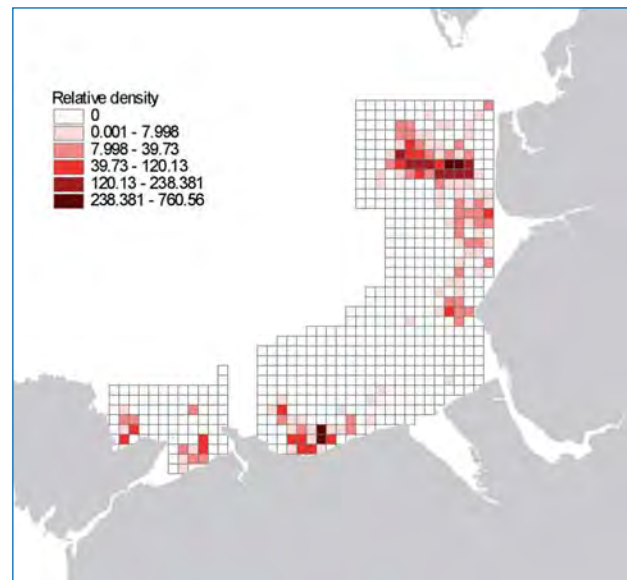

Fig. 1. Distribution of Common Scoter in Liverpool Bay, February 2003 (numbers are corrected for survey effort in 2x2 km cells).

Results from just a few winters' aerial survey have greatly increased the knowledge of numbers and distribution of waterbirds in UK waters: current estimates of wintering numbers are clearly considerable underestimates, and new sites of international importance have been identified, as have the offshore limits of distribution.

A strategy for monitoring waterbirds in UK inshore waters is currently under development. This advocates the use of aerial survey as the principal means of providing information for site monitoring and designation, complemented by boat-based and land-based surveys where conditions allow. Aerial data have already been used to underpin the designation of the UK's first marine Special Protection Area (Carmarthen Bay, SW Wales), for Common Scoter, and the precise spatial data enabled the site boundary to be defined.

Aerial survey will also be used increasingly by the expanding offshore wind industry, providing accurate information on waterbirds to inform Environmental Impact Assessments and to monitor the effects of windfarms. The ability to cover large areas near-synchronously will also enable assessment of the cumulative impacts of these developments. The aerial survey technique provides a robust and repeatable method for meeting these varied requirements for informing waterbird conservation in inshore waters.

WWT gratefully acknowledges funding from the Countryside Council for Wales, English Nature, and wind farm development companies, and the advice and encouragement of Tony Fox and Ib Petersen.

Milton, G.R., Illsley, P. & MacKinnon, F.M. 2006. An effective survey technique for large groups of moulting sea ducks. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 756-757.

### ABSTRACT

We report on a system that can be obtained at a reasonable cost for use in a standardized methodology to survey numbers within aggregations of sea ducks. Results are compared using digital analyses software and manual counts.

Common Eider *Somateria mollissima dresseri* gather in large moulting flocks in the Gulf of St. Lawrence and along the Atlantic coasts of Nova Scotia and Maine from July through August. Numbers of birds are often visually estimated from low flying aircraft, even though analyses of aerial photographs of these flocks have been shown to provide more accurate and repeatable results [see Bajzak & Piatt (1990) and review in Lavigne *et al.* (1977)]. This has been due in-part to costs associated with developing and printing large numbers of images, followed by hours of manual counting.

Low cost high-resolution digital cameras are now available, and advances in digital analyses software can be used to partially automate the counting process. Here we describe a system to record locations and acquire images of flocks of molting birds, and the use of commercially available software for digital image analyses.

### Image acquisition and preparation:

Flown at 300–400 feet (91–122 m), images were acquired (12 August 2002) using a Canon D60 digital camera equipped with a high resolution 2000 X 3000 pixel RGB CMOS image sensor, 1/500 sec shutter speed, and 24 mm wide-angle lens focused to infinity to provide a uniform pixel resolution of 3.1 cm. (at 328 ft/100 m) for vertical images. Aircraft drift can cause oblique images (more than 3 degrees from vertical) with pixel resolution varying across the image.

Waypoints of flocks were recorded on a scanned and geo-

**Fig. 1.** Eiders are recorded by placing a point on each individual within a point shape file created for each count area using ArcView.

**Fig. 2.** Objects are classified using eCognition as eider and grouped into memberships of one (red) or two (green) birds. The green area is one object representing two birds. \* compare with Fig. 1.

registered 1:50 000 topographic map entered into a moving map software package (Fugawi) linked to a Garmin 12XL GPS unit. The camera's time stamp was synchronized with GPS time as displayed on the moving map software. Overlapping images were required for large flocks.

Enhancement on some images using the 'One Step Photo Enhance' command in Jasc Paint Shop Pro 8 increased contrast between the water and ducks. Count breaklines were identified to avoid double counting of birds in flocks with overlapping images.

### Image analyses using ArcView

Images were imported to ArcView 3.2, and a line shapefile enclosing the count area was created. Individual eiders were recorded using a point shape file (Fig. 1) and the total number of records per point shape file was entered on a spreadsheet (Excel) with the time required for the count.

### Image analyses using eCognition

The eCognition software segments the image into similar objects. The size of the objects is dependent upon the scale parameter used. Objects can then be classified using membership functions, e.g. area of objects, image band values, and relation to other objects.

Images were imported into ArcView 3.2 and a shapefile was created around the entire image to form the image boundary. A second shapefile for the area of the image between the breaklines was created, and the two shapefiles were joined and the ID value for the area of interest set to 1. The image and the thematic shapefile were loaded into eCognition with the Protocol (see

below) and executed. Results (Fig. 2) were edited and identifiable errors in classification corrected. Processing and edit times were entered on the spreadsheet.

### eCognition Protocol

The Protocol is an executable program that separates the area of interest from the rest of the image, and then segments water from non-water. Objects are classified as water for values above a brightness threshold for channel 1, and non-water objects are further divided into ducks and non-ducks using a second brightness threshold value for channel 2. Multiple ducks were often grouped as an object because of minimal separation, and the number of birds in a group was determined using the area membership function. Thresholds can vary between images due to angle and height of acquisition. Once classified and results viewed, threshold values in the membership function can be changed and the image reclassified to improve accuracy. Run time for classification is minimal (c.10 seconds) once the segmentation process is complete.

### RESULTS

The ArcView approach recorded 36 981 Common Eider in 55 flocks (7-5 588 birds) distributed among 32 waypoints. Eleven flocks (each >1 000 birds) accounted for 63.4%, 8 flocks (500-1 000 birds) provide an additional 16.2% with the remaining 36 flocks contributing 20.4% of the total number. The analyses of the 145 images required 11:33:34 hr. Most images (87.6%) had fewer than 500 birds, 9.6% had 500-1 000 birds and 2.8% had more than 1 000 birds.

The true number is however greater than the 36 981 recorded. Several flocks had repeated passes and total counts varied from less than 1% to 4.4% and 6.1%. We speculate this variation is due to partially masked or hidden birds, and birds which may have surfaced or dove between acquisitions. A correction factor of 5% adjusts the estimate to 38 830 Common Eider, of which less than 1.5% are female (unpubl. data).

### Comparison of ArcView and eCognition approaches

A subset of the 145 images was selected for the eCognition approach. The number of eider in the count areas of 35 images (ArcView approach) varied from 13 to 2 556 birds and represents 45.7% of the total recorded. Between approaches, there was no difference in three count areas while an additional 16 varied between one and three birds, with count area totals ranging from 13 to 240 birds. Using a difference threshold of  $\pm 4\%$ , 10 count areas differed by 4-69 birds; in five instances the

ArcView approach had higher totals. The four images with the greatest number of birds are included within the  $\pm 4\%$  threshold, three had lower totals using eCognition. On the remaining six count areas, eCognition recorded 17 543 birds, an increase of 656 (3.9%) over ArcView, with individual counts varying from 6.8% to 15.0%.

Total time (processing and edit) to analyze an image is more for the eCognition approach, but does not require intervention once the protocol is executed. A more valid comparison is eCognition edit time versus ArcView time. In most cases, edit time is similar or significantly less than for ArcView time, particularly as the number of birds increase. Subjectively, images with separation between birds and less water reflectance required less edit time. The time required for the manual ArcView approach (4:48:53 hr) was approximately twice that of the alternate method (2:26:33 hr) for a 3.9% difference in total birds.

### DISCUSSION

Readily available and used by many natural resource management agencies, utilizing ArcView in this approach can provide accurate results and a permanent record but can also be time consuming and a potential health risk (repetitive motion syndrome). The object based eCognition software can provide the same or comparable accuracy with reduced expenditure of time and health risk.

The use of photography in low altitude aerial censuses of aggregations of animals has been repeatedly shown to provide more accurate numbers than visual estimates, and provide a permanent record. High-resolution digital cameras and moving map software linked to GPS provide increased flexibility and enhanced data acquisition and reporting capabilities. The system reported here can be readily obtained at a reasonable cost and be part of a standardized methodology for surveying aggregations of sea ducks. Ensuring images are vertical as opposed to oblique, a fast shutter speed ( $>1/500$ ) to reduce blurring, and undertaking surveys in conditions which reduce surface water reflectance glare will reduce the error associated with this approach.

## Ramsar site designation, marine sites and seaducks: a Scottish perspective

Chris M. Waltho

73 Stewart Street, Carlisle, Lanarkshire, ML8 5BY, UK. (email: Chris.waltho@eider.org.uk)

Waltho, C.M. 2006. Ramsar site designation, marine sites and seaducks: a Scottish perspective. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 758-759.

The Convention on Wetlands of International Importance especially as Waterfowl Habitat (Ramsar, Iran, 1971) defines wetlands as: “areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water the depth of which at low tide does not exceed six metres” (Article 1.1 of the Convention). However, concerning the designation of Wetlands of International Importance (Ramsar sites), Article 2.1 provides that wetlands: “may incorporate riparian and coastal zones adjacent to the wetlands, and islands or bodies of marine water deeper than six metres at low tide lying within the wetlands”. The intent of this provision is to permit flexibility in the boundary delineation of Ramsar sites so as to include connectivity within functional ecological units where appropriate.

This paper examines how well these provisions can be, and are being, applied to cover areas of coastal waters internationally important for seaducks – species which are included within the Convention’s definition of waterbirds. In marine waters, there is a continuum offshore in bird species distribution, from inshore waterbirds to pelagic seabirds. Seaducks form part of the inshore waterbirds guild occupying relatively shallow waters, but much of the marine area upon which they depend is deeper than the core six metre depth provision of the Convention.

The Ramsar Convention Manual (Ramsar Convention Secretariat 2003a) suggests that “The [6 metre] figure is thought to come from the maximum depth to which sea ducks can dive whilst feeding”. However, subsequent extensive research on seaducks (see e.g. Cramp & Simmons 1977) has shown that this depth is too shallow to capture many seaduck feeding sites (see also Petersen, this volume). Most seaduck species regularly feed

in deeper water, some considerably deeper. As extreme examples, King Eider *Somateria spectabilis* feed over offshore banks in water depths of 23–35 m in West Greenland (Mosbech *et al.* 2002) and Spectacled Eider *Somateria fischeri* feed in 40–70 m depths in the Bering Sea (Lovvorn *et al.* 2003).

Seaduck feeding sites are generally large in area (100s of km<sup>2</sup>). Coverage within Ramsar sites of the whole of nearshore marine areas important for seaducks could be achieved in two ways: either the inclusion of such large areas seawards of coastal systems such as estuaries, and/or the designation of offshore Ramsar sites where there are shallow offshore banks which are in water less than 6 m deep. However, sea areas such as those used by King Eider and Spectacled Eider in the above examples would still be excluded from this approach.

Using the example of Ramsar sites in Scotland, how effective is the existing Ramsar site network in covering the sea areas important for seaducks?

Most nearshore marine areas important for seaducks in Scotland are large (Table 1, mean 400 km<sup>2</sup>, n=6). Even at this scale, Scottish seaduck sites are well below the average for European Ramsar sites covering seaduck areas (mean 660 km<sup>2</sup>, n=16; source: Ramsar Sites Database). Where designated Ramsar sites in Scotland do include areas important for seaducks, coverage is at best only a small part of these areas: on average 27% of the area used by seaducks (n=6). In addition, four seaduck areas are wholly outside the suite of designated Ramsar sites (Table 1). Only the Solway Firth Ramsar site substantially covers the area important for seaducks (87% coverage), and three other Ramsar sites have less than 10% coverage of the seaduck area.

**Table 1. Scottish seaduck sites and current Ramsar coverage.**

Seaduck Site (see Fig. 1)	approx area (km <sup>2</sup> )*	Relevant coastal/marine Ramsar Site(s)	approx area (km <sup>2</sup> )**	Estimated % Ramsar coverage
1 Solway Firth	500	Upper Solway Flats and Marshes	436.4	87.3

\* Range estimated by author from aerial survey maps in Dean *et al.* (2003, 2004a, 2004b).

\*\* Estimated area of Ramsar site(s) relevant for seaduck distribution.

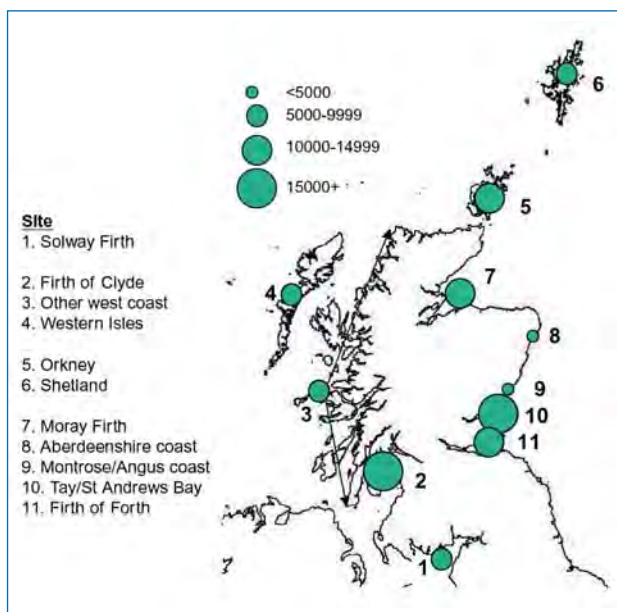

Fig. 1. Scottish seaduck sites.

Scottish seaduck sites and populations are well covered by areas included within Integrated Coastal Zone Management (ICZM) strategies (>70% of all seaduck numbers ( $n=111\,860$ ) and seaduck sites ( $n=11$ )). However, the significance of these areas for seaducks is poorly recognised by these ICZM strategies: seaducks are recognised in only two of the five published strategies, although all these strategies recognise designated Ramsar sites.

In the short to medium term, it is highly unlikely that the well-established definition of wetlands and 6 m depth scope of the Ramsar Convention text could be readily amended to widen coverage to deeper marine waters, since this would require amendments of major significance to the Convention text to be adopted and ratified by Contracting Parties. However, there are a number of practical steps which could be taken now to recognise all areas important for seaducks within protected areas networks. These include:

- i) improving the clarity of existing guidance for Ramsar site designation in relation to the acceptability of incorporating marine areas with a water depth of more than 6 m within Ramsar site boundaries, particularly in relation to ensuring improved coverage of areas important for off-shore seaduck concentrations, in a manner similar to the clarification on this matter provided for marine ecosystems such as coral reefs - see Ramsar's *Strategic Framework and guidelines for the future development of the List of Wetlands of International Importance* (Ramsar Convention Secretariat 2003b);
- ii. boundary extensions of existing designations of coastal Ramsar sites to fully cover the adjacent marine areas important for seaduck populations;

- ii. designation as Ramsar sites of marine areas important for seaducks where these include offshore banks in less than 6 m water depth;
- iii better recognition within ICZM strategies of areas important for seaducks, whether or not these areas are included within designated Ramsar sites; and
- iv. the application of other mechanisms, both national (e.g. Marine Protected Areas) and international (e.g. Special Protection Areas under the EU Birds Directive), for the designation of marine (deep sea) protected areas to fully cover the areas important for seaducks.

Implementing a combination of these approaches would enhance, for seaducks, the global and flyway-scale coherent and comprehensive networks of Ramsar sites called for by the Convention's *Strategic Framework* (Ramsar Convention Secretariat 2003b).

Cooper, J. 2006. Potential impacts of marine fisheries on migratory waterbirds of the Afrotropical Region: a study in progress. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 760-764.

### ABSTRACT

A study of the potential impacts of marine fisheries on AEWA-listed waterbirds of the Afrotropical Region is described. A total of 43 waterbirds of eight families forage in marine waters in the region. Nearly one-third are gulls and terns, the rest of the assemblage being made up of a penguin, cormorants, a gannet, pelicans, phalaropes and a grebe. Only four of the species are considered to be globally threatened, and three of these are southern African endemics. Nearly half the species considered are breeding residents. Palearctic migrants make up the next largest category. The listed species are affected by a broad range of fisheries, both directly by mortality and indirectly by competition for resources. The fisheries of most concern are longlining, demersal trawling and purse-seining. The species most affected are the African Penguin *Spheniscus demersus*, Cape Gannet *Sula (Morus) capensis*, Cape Cormorant *Phalacrocorax capensis* and Great Crested Tern *Sterna bergii* in southern Africa, and probably Palearctic gulls and terns further north on the Continent. These species are recommended for future study and monitoring.

### INTRODUCTION

The First Session of the Meeting of the Parties to the African-Eurasian Migratory Waterbird Agreement (AEWA), held in Somerset West, South Africa, in November 1999, adopted Resolution 1.4 "International Implementation Priorities for AEWA 2000-2004" that listed a number of projects considered to be of international importance and for which international cooperation was needed (AEWA 1999, 2000). Funding to undertake Project 24 "Study of the potential impacts of marine fisheries on migratory waterbirds" was not attained by the AEWA Secretariat until the end of 2001. For a number of years, there has been significant concern about the potential impacts of commercial marine fisheries on bird populations. Whereas research has been conducted on seabird species (e.g. Tasker *et al.* 2000), there has been no overview on the potential impacts on waterbirds listed within Annex 2 of AEWA, a number of which are known to feed on marine prey. Such a review would identify candidate species and areas for more detailed study or monitoring.

In May 2002, a contract was awarded by the AEWA Secretariat to the Avian Demography Unit, University of Cape Town, to undertake the study. Following discussion, it was agreed that the study would be a "desk study", reviewing published and unpublished ("grey literature") sources, and would be largely restricted to the Afrotropical Region (Africa south of the Sahara). A first consideration of the species then listed within AEWA revealed that 33 species foraged to a greater or lesser extent in marine Afrotropical waters (here defined as

commencing below low-water mark, and thus excluding birds that forage in the inter-tidal zone, such as most waders (shorebirds) and the large wading birds (Ciconiiformes).

A CAMP (Conservation Assessment and Management Plan) workshop held jointly by the Avian Demography Unit, University of Cape Town, and the IUCN/SSC Conservation Breeding Specialist Group in Cape Town, South Africa, in February 2002 recommended that 10 species of southern African breeding coastal seabirds should be nominated by South Africa for inclusion within Annex 2 of AEWA (du Toit *et al.* 2003). The workshop report included draft nomination texts which were then submitted by South Africa to the AEWA Secretariat. These nominations were accepted by the Second Session of the AEWA Meeting of the Parties, held in Bonn, Germany, in September 2002 (AEWA 2002), and were added to those birds to be included within the review of marine fisheries impacts, giving a total of 43 species spread over eight families (Table 1).

### METHODS

For each species, a literature review has been conducted and a species account has been drafted under the headings: description and taxonomy, distribution, migration and movements, habitat, breeding, population size and trends, foraging behaviour and diet, potential and actual impacts of marine fisheries, other related conservation concerns, and recommendations. The text of each species account is to be accompanied by a distribution map and a selected bibliography. An example of a species text, that for Great Crested Tern *Sterna bergii*, is given as Appendix 1.

Regional reviews of Afrotropical commercial marine fisheries in relation to potential impacts on waterbirds are to be undertaken separately for three regions: western (Mauritania to Congo), southern (Angola to Mozambique) and eastern (Tanzania to Sudan).

### A PRELIMINARY ANALYSIS

#### Taxonomic and threatened status

Most (31; 72%) of the 43 marine-foraging species are gulls and terns. Cormorants (five species) form the next largest grouping. The pelecaniform order is also represented by one gannet and two pelicans. There are single species of grebes and penguins and two phalaropes (Table 1).

Only four of the 43 species have been accorded globally threatened status by the World Conservation Union (BirdLife International 2004). Three are southern African endemic species (African Penguin *Spheniscus demersus*, Vulnerable; Cape Gannet *Sula (Morus) capensis*, Vulnerable; and Bank Cormorant *Phalacrocorax neglectus*, Endangered). The fourth is the Vulnerable Socotra Cormorant *P. nigrogularis*, which is a non-breeding visitor to the Afrotropical Region (Gulf of Aden and southern Red Sea). No species has been categorized as

\*Species added to Annex 2 of AEWa in 2002 following nomination by South Africa.  
 Note: Taxonomy, nomenclature and sequence after AEWa (2002).

Critically Endangered. Five species have been categorized as Near Threatened, including an additional three southern African endemics: the Crowned Cormorant *P. coronatus*, Cape Cormorant *P. capensis* and Damara Tern *Sterna balaenarum*, and two gulls, White-eyed *Larus leucophthalmus* and Audouin's *L. audouinii*. The White-eyed Gull is endemic to the Red Sea; Audouin's Gull is a non-breeding visitor to the western Afrotropics (Mauritania and Senegal) from the Mediterranean.

When considered on a regional basis, it is noteworthy that six of the nine threatened and near threatened species are endemic to southern Africa. The absence from the Afrotropics of threatened gulls and terns is also noticeable, with only two of the 31 species being considered as near threatened.

**Migratory and regional status**

Nearly half (19; 44%) of the 43 AEWa species under consideration are breeding residents of the Afrotropical Region (although some of these may also be regarded as intra-African migrants). Twenty-three (53%) are Palearctic migrants, of which eight species also have breeding populations within the Afrotropical Region. A single species, the Antarctic Tern *S. vittata*, is a non-breeding visitor from the Southern Ocean to southern Africa.

The regional distribution of AEWa marine-foraging Afrotropical species shows some intriguing patterns (Table 2). Not surprisingly, there are more Palearctic visitors to western and eastern Africa than to southern Africa. Perhaps most significant is that southern Africa supports more breeding species than do the other two regions. On a taxonomic basis, southern Africa supports the largest numbers of pelecaniform species (due to the presence of four species of marine cormorants, three of which are

**Table 2.** Regional distribution and origins of marine-foraging AEWa-listed species within the Afrotropical Region.

Category	Region		
	Western	Southern	Eastern
Breeders	4	14	8

Grebes	1	1	1
Pelicans and allies	3	6	4
Phalaropes	1	1	1
Gulls	9	4	9
Terns	11	12	10
<b>Totals</b>	<b>25</b>	<b>25</b>	<b>25</b>

endemic to the region), but supports less than half the number of gulls that occur in the other two regions, since a number of Palearctic migrant gulls do not venture that far south (Table 3).

### Impacts of marine fisheries

Southern African fisheries are mainly by trawl, purse-seine and longline, whereas western African fisheries are more diverse, with a significant artisanal component (as is the case for eastern Africa). Each of these fisheries impacts upon seabirds in negative and in positive ways, as summarized below.

### Longline fisheries

Longline fisheries are well known for their injurious effects on many seabird populations, mainly members of the Procellariiformes (albatrosses and petrels). However, there is little evidence that AEWA species are significantly affected within the Afrotropics. The exception may be the Cape Gannet, which has been recorded caught on longlines off South Africa and Namibia (Cooper & Ryan 2003). Although evidence is lacking, gulls may be at risk in western Africa, since the migrant visitors Audouin's Gull and Yellow-legged Gull *L. cachinnans* are killed by longlines set in the Mediterranean Sea (Cooper *et al.* 2003). Longlining does offer some advantages to seabirds, in the form of discarded offal and non-target species, but this has not been assessed within the Afrotropics.

### Trawling

Demersal trawling off southern Africa is an important source of food (discards and offal) for several AEWA species, most especially the Cape Gannet, and to a lesser extent the Kelp Gull *L. dominicanus* (Abrams 1983, Ryan & Moloney 1988). However, birds may become trapped in trawls, and be killed or injured by collisions with trawl warps (S.L. Petersen pers. com., pers. obs). Published information is lacking from elsewhere within the Afrotropics.

### Purse-seining

This type of fishery acts indirectly by reducing the food supply of several AEWA species. Significant examples are a suite of species that prey upon small shoaling fish in southern African waters (African Penguin, Cape Gannet, Cape Cormorant and Great Crested Tern; see, for example, Crawford & Dyer 1995 and Crawford 2003). Quantitative information from the western Afrotropical Region is largely absent, but several species of terns are known to consume fish prey also taken by purse-seine and beach-seine fisheries (Brenninkmeijer *et al.* 2002, Veen *et al.* 2003).

### Traps

Traps set for Cape Rock Lobster *Jasus lalandii* have been known occasionally to entrap and drown Bank Cormorants in southern African waters, but this is not thought to be a significant cause of mortality (Cooper 1981, 1985). However, over-fishing of rock lobster may be adversely affecting this Endangered and decreasing species indirectly, since the lobster forms an important part of its prey in most of its breeding range (unpubl. data)

### Gill nets

Gill and set nets have occasionally drowned African Penguins in South African waters (pers. obs). However, as these nets are

Great Crested Terns *Sterna bergii* breeding on Robben Island, South Africa. Photo: Dieter Oschadleus.

mainly used within sheltered bays and estuaries, the drownings that they cause are not thought to be a significant cause of mortality to the species.

### Indirect fishery impacts

Discarded gear can lead to entanglements and ingestion, as has been reported for Great Crested Terns in southern Africa (Cooper *et al.* 1990). All of the species under consideration are potentially at risk, but information on species and regional differences is essentially lacking. The catching of birds, such as gannets and terns, by fishers for food nowadays is largely restricted to artisanal fisheries, although hard evidence is generally lacking.

### CANDIDATE SPECIES FOR MONITORING

The following species are suggested for further study and monitoring to assess the effects of marine fisheries on their populations within the Afrotropical Region. Within the southern African region, continued demographic and dietary studies of the African Penguin, Cape Gannet, Cape Cormorant, Bank Cormorant and Great Crested Tern are warranted, following on from the large body of work undertaken over the last 50 years (e.g. Crawford 2003 and references therein). In the western and eastern regions, far less is currently known, and new studies should continue to concentrate on those migrant and resident gulls and terns which are known or are thought to overlap in their prey with commercial fisheries (e.g. Brenninkmeijer *et al.* 2002, Veen *et al.* 2003).

### ACKNOWLEDGEMENTS

The study reported here has been funded by the African-Eurasian Migratory Waterbird Agreement. The author thanks the Organizing Committee of the Waterbirds around the world Conference for funding his attendance. Gerard Boere is acknowledged for his extraordinary editorial patience and perseverance. Samantha Petersen and Genevieve Jones contributed to the species and regional reviews, respectively.

## APPENDIX 1

### GREAT CRESTED TERN *STERNA BERGII*

Family: Laridae

Other names: Swift, Crested, Greater Crested Tern

#### Description

The Great Crested Tern is a large, slender marine tern with long, narrow, strongly angled wings, a long deeply forked tail, a yellow bill and black legs and feet. It is grey above and white below with a black cap and a shaggy crest. Breeding adults have a black cap covering the upper forehead, crown and nape. The cap covers the eye and is separated from the bill by a narrow white forehead. Non-breeding adults differ from breeding birds in that the forehead is white, merging into a black-spotted or streaked crown. The hind crown and crest are matt black and may have faint white grizzling. The crest feathers are shorter and more rounded than those of adults in breeding plumage. The juvenile has a brownish black head and the crown is more mottled forming a paler cap. Juvenile upperparts are grey with brown and white mottling and barring.

#### Distribution

Five subspecies have been recognized, four of which occur within the Afrotropical Region:

- *S. b. bergii* (smallest and palest subspecies) is endemic to southern Africa, with records extending from Luanda, Angola, in the west to Maputo, Mozambique, in the east. Breeding by *bergii* has been recorded at 27 localities, from Swakopmund, Namibia, to Stag Island, Algoa Bay, Eastern Province, South Africa.
- *S. b. enigma* occurs from the Zambezi Delta, Mozambique, south to Durban, KwaZulu-Natal, South Africa, and is believed to breed on islands off Mozambique and Madagascar.
- *S. b. thalassina* (largest and darkest race) breeds in East Africa and the central Indian Ocean.
- *S. b. velox* breeds in the Red Sea, East Africa, Arabian Sea, Persian Gulf and the northern Indian Ocean.

Note: only the African and south-western Asian populations are included in Appendix II of the Bonn Convention on Migratory Species.

#### Movements

The southern African population is mobile. Adults leave breeding sites at the end of the breeding season and most move east to the Indian Ocean coastline of the Eastern Cape and KwaZulu-Natal, South Africa. Many fledglings move east from colonies in Namibia and Western Cape as shown by band recoveries. For example, a nestling banded at Lüderitz, Namibia, was recovered

at Umzumbe, KwaZulu-Natal (2 169 km), and a bird banded at Robben Island, Western Cape, was recovered at Sodwana Bay, KwaZulu-Natal (1 716 km). Other fledglings move substantial distances north, e.g. from Marcus Island, Western Cape, to Swakopmund, Namibia. Areas used by post-breeding adults and immatures overlap. Birds frequently change breeding sites between years, both changing sites of colonies at islands and moving between islands or mainland breeding localities.

The *thalassina* subspecies winters along the east African coast north to Kenya and Somalia and may move as far south as Durban, South Africa. Populations of *velox* breeding from the Persian Gulf eastwards appear to be sedentary or dispersive rather than migratory, but the population breeding in the Red Sea is partly migratory, wintering south along the east African coast to Kenya.

### Habitat

Great Crested Terns breed colonially on offshore islands, lagoons and salt pans. They may roost or loaf on sandy or rocky shores and less often on artificial structures such as boats, pilings and harbour buildings. In Namibia, they favour poles in cultivated oyster beds or raised salt encrustations in lagoons. They occur on their own or in flocks of up to several hundred birds, sometimes with gulls or other species of terns.

The species does not occur far out to sea, being restricted to the continental shelf usually within sight of land. It ventures

inland at only a few localities when birds may forage at water bodies up to 3 km from the sea and cross narrow strips of land that separate water bodies, such as between Table and False Bays near Cape Town, South Africa.

### Breeding

Great Crested Terns breed in colonies, often in association with other seabirds. They are monogamous and the pair bond is maintained during the year and sometimes lasts from year to year. Mean colony size is significantly related to the abundance of pelagic fish prey. The nest consists of a shallow scrape in the sand on open flat or occasionally sloping ground. It is often unlined, but sometimes includes stones or the bones of cuttlefish *Sepia* spp. One, occasionally two, eggs are laid and incubated for 25-30 days during the months of January to early July in the Western Cape. Newly hatched chicks are very pale, with sparse black speckling. They are brooded and fed by both parents. Older chicks form crèches or loose groups. Young fledge at 38-40 days. Some fledged young accompany their parents after leaving colonies and most remain dependent until at least four months of age.

### Population size and trends

The species' total population within the Afrotropical Region is unknown. Best estimates follow:

Madagascar and Mozambique	<i>enigma</i>	8 000-10 000 individuals
Eastern Africa & Seychelles	<i>thalassina</i>	2 550-4 500 individuals
Red Sea & north-eastern Africa	<i>velox</i>	numbers unknown
Southern Africa	<i>bergii</i>	20 000 individuals

Note: The breeding population of *bergii* was 4 835 pairs in 1984 and 6 336 pairs in 2000 in South Africa, and up to 1 682 pairs have nested in Namibia.

### Food and feeding

In the Western Cape (1977-1986), fish formed 86% of all prey items consumed. The remainder was made up of cephalopods, crustaceans and insects. Prey size ranged from 7-138 mm in length and 0.1-30.0 g in mass. Shoaling pelagic fish, notably Anchovy *Engraulis capensis* and Sardine *Sardinops sagax*, are especially important in the diet. In Namibia, Great Crested Terns feed mainly on Pelagic Goby *Sufflogobius bibarbat* and hakes *Merluccius* spp. Immature birds are often kleptoparasitized by Kelp Gulls *Larus dominicanus* in Namibia. On Stag/Seal Island in the Eastern Cape, young were mainly fed on *Petalichthys capensis*. Fiddler Crabs *Uca stenodactyla* have been reported as prey in Tanzania.

Great Crested Terns feed mostly at sea by plunge diving or by dipping and food is usually swallowed in mid air. They are restricted to the top one metre of the ocean and birds may forage up to 10 km from land in the breeding season.

### Impacts of marine fisheries

Although this species is not threatened in southern Africa, large fluctuations in numbers of Great Crested Terns breeding in the Western Cape of South Africa are significantly related to fluctuations in the abundance of pelagic fish on which they prey. These are intensively exploited by a purse-seine fishery, which could thus have deleterious indirect effects on prey availability.

Mitchell, P.I., Newton, S.F., Ratcliffe, N.R. & Dunn, T.E. 2006. Seabird populations of Britain and Ireland: the last 30 years. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 765-766.

This note summarises the results of *Seabird 2000*, a census of all 25 species of seabird breeding in Britain and Ireland. Comparisons with two previous censuses enable trends over the last 15-30 years to be assessed.

The British Isles are one of the most important areas in the world for breeding seabirds. The coastal population of Britain and Ireland has been censused three times: in 1969-70, 1985-88 and most recently during *Seabird 2000* in 1998-2002. *Seabird 2000* also surveyed inland colonies of terns, gulls and Great Cormorants *Phalacrocorax carbo* and provided the first accurate estimates of shearwater and petrel numbers.

Standardised recording methods were employed by over 1 000 surveyors (Mitchell *et al.* 2004). Population estimates were obtained from complete counts or from sample surveys of large colonies of ground-nesters.

Numbers of seabirds breeding in Britain and Ireland have increased from approximately five million in 1969-70, to over six million in 1985-88, then to almost eight million in 1998-2002. However, since 1985-88, populations of only seven species have increased in size by more than 10%; while five have changed by less than 10% and eight have declined by more than 10% (Table 1).

**Table 1.** Numbers of seabirds breeding in Britain & Ireland 1969-2002. All counts are of pairs unless otherwise stated.

Species	Coastal colonies only <sup>1</sup>			% change		Inland & coastal
	1969-70	1985-88	1998-2002	since 1969-70	since 1985-88	
Northern Fulmar <i>Fulmarus glacialis</i>	308 960	536 577	537 991	74%	0%	537 991
Manx Shearwater <i>Puffinus puffinus</i> <sup>2</sup>			332 267			332 267

<sup>1</sup> inland colonies were not surveyed during 1969-70 and 1985-88.

<sup>2</sup> not surveyed during 1969-70 and 1985-88.

<sup>3</sup> counts of individuals.

<sup>4</sup> counts of pre-breeding adults; pre-breeding surveys were not conducted during 1969-70 and were not conducted in the Republic of Ireland during 1985-88.

Over 50% of Britain and Ireland's seabirds are comprised of four species, whose abundance increased considerably between 1960-70 and 1985-88. Subsequently, numbers of Common Guillemot *Uria aalge* and Atlantic Puffin *Fratercula arctica* have continued to increase, but numbers of Northern Fulmars *Fulmarus glacialis* are stable and Black-legged Kittiwakes *Rissa tridactyla* have declined by 23% (Table 1). Herring Gulls *Larus argentatus* are the only species that have decreased in number between all three censuses.

Food supply and habitat availability have been the major factors affecting breeding seabird numbers in Britain and Ireland over the last 30 years. All species that have declined by more than 10% since 1985-88 (Table 1), with the exception of Herring Gull, are reliant on small fish, mainly sandeels *Ammodytes marinus*, to feed themselves and their chicks. Since the late 1980s, colonies of these species in the Northern Isles and along the North Sea coast of Britain have experienced successive years of poor breeding success due to sandeel shortages (Mavor *et al.* 2004). This period coincided with increased sea-surface temperature in the North Sea and consequent changes to the plankton community (Beaugrand *et al.* 2003) that may have reduced sandeel recruitment (Arnott & Ruxton 2002). If sea-surface temperatures continue to increase, sandeel-dependent seabird populations will decline further. Climate change may also have direct effects on breeding seabirds: rising sea levels may reduce the amount of breeding habitat available for shoreline nesting species such as terns; winter storms can cause large-scale 'wrecks' of seabirds; and summer storms can cause wide scale breeding failure.

Another major source of food — discards and offal produced by commercial fishing — is set to decline in the future following the recent reductions of white fish stocks in the North Sea. This will probably impact on large gulls, skuas and Northern Fulmars that rely on such sources.

Predation by mammals has had a significant impact on the size of seabird populations, particularly on ground-nesters, by limiting availability of safe nesting habitat. For instance, the distribution of Storm-petrels is limited to offshore islands free of rats. American Mink *Mustela vison* can swim to offshore islands and their habit of surplus taking of eggs and killing chicks and adult seabirds has significantly impacted on gulls and terns in NW Scotland and throughout Ireland. Eradication of Rats *Rattus norvegicus* and Mink from some islands has led to recolonisation by breeding seabirds.

*Seabird 2000* was a partnership between JNCC, RSPB, Scottish Natural Heritage, English Nature, Countryside Council for Wales, Environment & Heritage Service Northern Ireland, the Seabird Group, Shetland Oil Terminal Environmental Advisory Group, BirdWatch Ireland and the National Parks & Wildlife Service – Republic of Ireland. Many other organisations and individuals contributed time and funds to the census.

Marwick Head on the west coast of Orkney is classified as a Special Protection Area for its internationally important populations of seabirds. It holds about 75 000 seabirds in the breeding season, including Kittiwakes *Rissa tridactyla* and Guillemots *Uria aalge*. Photo: David Stroud.

## The UK Seabird Monitoring Programme

Matthew Parsons, Roderick A. Mavor & P. Ian Mitchell

Joint Nature Conservation Committee Seabirds and Cetaceans Team, Dunnet House, 7 Thistle Place, Aberdeen, AB10 1UZ, UK.  
(email: matt.parsons@jncc.gov.uk)

Parsons, M., Mavor, R.A. & Mitchell, P.I. 2006. The UK Seabird Monitoring Programme. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 767-768.

The UK Seabird Monitoring Programme (SMP) facilitates the co-ordination of breeding seabird monitoring on a UK-wide basis and is one of the most extensive and detailed of its kind, collecting annual demographic data on 26 species. Population trends of three abundant and widespread species with different feeding strategies are presented, and likely causative factors discussed.

The Joint Nature Conservation Committee's (JNCC) Seabird Monitoring Programme has, since 1986, co-ordinated the monitoring of breeding seabirds on a UK-wide basis (Mavor *et al.* 2004). The aim of the SMP is to ensure sufficient data on seabird numbers and breeding success are collected to enable their conservation status to be assessed. The programme assists JNCC and partner organisations in providing advice relevant to government and others on the conservation needs of breeding seabirds.

Standardised methods of collecting field data on breeding numbers and breeding success were used (Walsh *et al.* 1995) and promoted nationwide to ensure comparability of results. UK-wide breeding numbers are presented as indices, whereby the number of birds counted in a sample of colonies in a particular year is expressed as a percentage of the number present in the same colonies when the SMP was initiated in 1986.

Fig. 1 shows the annual UK breeding population indices of three abundant and widespread seabird species from 1986 to 2003. Black-legged Kittiwakes *Rissa tridactyla* have declined significantly since 1995, at a mean rate of -5.8% per annum

Fig. 1. UK population indices of Black-legged Kittiwake *Rissa tridactyla*, Northern Fulmar *Fulmarus glacialis* and Common Guillemot *Uria aalge*, 1986-2003.

( $t=5.04$ ,  $P<0.001$ ), in contrast to increases in the population of Common Guillemots *Uria aalge* (though the latter has declined since 2000). These trends are thought to be related to the feeding strategies of each species: the former restricted to feeding near the sea surface (mostly taking small sandeels *Ammodytes* spp.) while the latter can dive to reach a wider range of fish. Sandeel recruitment in the North Sea has been negatively affected by sea temperature increases in recent decades (Arnott & Ruxton 2002)

Fig. 2. Breeding success of Black-legged Kittiwake *Rissa tridactyla* on Orkney and Shetland, 1986-2003.

and it is likely that their availability to surface-feeders such as Kittiwakes also declined, at least locally. For example, in Shetland in 1988-90, 1997-98 and 2001-2003, the breeding success of Black-legged Kittiwakes was extremely low (Fig. 2), a phenomenon that has been correlated with low local availability of sandeels in that region (Oro & Furness 2002). In contrast, in adjacent Orkney the species was much more successful in each year and, presumably, sandeels more available.

The Northern Fulmar *Fulmarus glacialis* feeds on fish, zooplankton and discards and offal from fishing boats. The increase in numbers (up to c. 1996; Fig. 1.) may be attributed to moderate levels of fishing activity (and associated feeding opportunities); recent declines are perhaps due to decreased fishing effort and to declines in zooplankton and sandeels (Tasker 2004).

JNCC is funded by Scottish Natural Heritage, English Nature and the Countryside Council for Wales. Lead partners in the SMP are RSPB and Shetland Oil Terminal Environmental Advisory Group. Many others have contributed data, including volunteers funded via the Seabird Group.

The Stationery Office, Edinburgh, UK. pp. 769-776.

### ABSTRACT

Satellite transmitters were implanted in King Eiders *Somateria spectabilis* at three moulting sites in West Greenland (26 birds) and a breeding site in Arctic Canada (10 birds). The tracked birds showed a diversity of migration routes and staging areas. However, regardless of the implantation locality, almost half of the tracked birds wintered at the Store Hellefiskebanke and adjacent coast in West Greenland (68°N) at some point in November, December and January. Locations on Store Hellefiskebanke were centred in areas with a water depth of 23-35 m and up to 70 km from the coast. A bird with a depth transducer showed a diurnal diving pattern, preferentially diving during daylight. The maximum depth of dive recorded was 43 m. Satellite telemetry has proven to be an important supplementary tool to locate key habitats for marine birds in remote areas.

### INTRODUCTION

There is increasing human use of marine areas for fishing, recreation and mineral extraction in polar environments. Consequently, it is important to identify key habitats used by wildlife to minimize unforeseen environmental impacts from anthropogenic activities. For example, surveys by plane or ship have provided important data on bird distribution and population estimates of several marine bird species in West Greenland (Mosbech & Johnson 1999, Merkel *et al.* 2002). However, the results generated by surveys are often restricted to short time periods. In the Arctic, offshore surveys whether by plane or ship are costly and are limited by light and bad weather, and during the Arctic winter, also by ice.

Satellite telemetry can provide supplementary data to identify key habitats by showing bird locations daily or several times a week for up to a year. However, to give reliable information, transmitters have to be small and attached to the birds in ways that do not alter their behaviour. Among seabirds, implantable transmitters with protruding external antenna have proven to function well; for example with Spectacled Eiders *Somateria fischeri* (Petersen & Douglas 1995, Petersen *et al.* 1999). Satellite transmitter data also have the potential to provide information on behaviour if the transmitters contain appropriate sensors on board. Depth transducers have often been used in satellite telemetry in marine mammals. Here we test a satellite transmitter prototype with a depth transducer in a seabird to obtain information on diving behaviour which can elucidate how much and when birds actually forage in a remote staging area.

Fig. 1. Distribution of breeding and wintering King Eiders *Somateria spectabilis* with the study area indicated. (Distribution based on Pearce *et al.* 2004, Cramp & Simmons 1977, and this study).

West Greenland is an important moulting, staging and wintering area for the King Eider *Somateria spectabilis* (Salomonsen 1968, Frimer 1995, Lyngs 2003, Mosbech & Boertmann 1999; Fig. 1). Based on surveys covering different parts of West Greenland in different years, about 300 000 King Eiders have been estimated to winter there (Mosbech & Johnson 1999). Most of these breed in the eastern Canadian Arctic and some in north-western Greenland, while King Eiders do not breed in West Greenland. Surveys of moulting areas in West Greenland (Mosbech & Boertmann 1999) and a breeding area in Canada (the Rasmussen Lowlands, Gratto-Trevor *et al.* 1998) indicate a decreasing population size. Because of the large flock sizes of King Eiders (up to 25 000 individuals) and very uneven distribution of flocks in West Greenland, knowledge of habitat use and movements are needed to plan a dedicated survey that can cover the key areas, both on the offshore banks and in the coastal zone.

In this study, we present an initial analysis of location data from King Eiders tracked through the autumn and winter of 2003/04, together with tracking data from the autumn and winter of 1999/2000 (Mosbech *et al.* 2001). King Eiders were tracked

from three moulting sites in West Greenland and a breeding site in Arctic Canada to locate key autumn and winter habitats. We also examine diving data from a satellite transmitter with pressure transducer from a King Eider staging in West Greenland.

## STUDY AREA

During winter, Baffin Bay and the western part of the Davis Strait between Canada and Greenland are covered with ice (90-100%), except for a few polynyas (i.e. spaces of open water in the midst of ice in the Arctic seas). However, along the south-west coast of Greenland in the eastern Davis Strait (62-67°N), there are large areas with open water and open drift ice all year round. The area is called the South-west Greenland Open Water Area, and is a very important wintering area for auks (Alcidae) and eiders (Boertmann *et al.* 2004). The south-west Greenland continental shelf is up to 120 km wide north of the open water area, and narrows down to 50 km in the south. The shelf includes several shoals or banks which range in depth from 20 m to 100 m. The largest continuous offshore area with depths less than 50 m in West Greenland is on the northern part of Store Hellefiskebanke (about 5 000 sq. km) in the marginal ice zone north of the Open Water Area. During winter, there are usually drifting ice floes with at-sea ice coverage of 10-80%. Within the West Greenland area, fishing and hunting are intensive, and oil exploration activities are increasing. Consequently, there is a need for careful assessment of potential environmental impacts on eider populations (CAFF 1997).

## METHODS

In 2003, a total of 26 King Eiders were tracked during autumn and winter using intra-abdominally implanted satellite transmitters. In July 2003, 10 King Eiders (seven females and three males) were tracked from a breeding site at East Bay, Southampton Island, Nunavut, in Arctic Canada. In September 2003, 16 King Eiders (six females and 10 males) were tracked from the moulting sites in Mellemfjord and Nordfjord at Disko Island, Greenland. In addition, in August 1999, 10 King Eiders (three females and seven males) were tracked from the moulting site at Umiarfik, in the Upernavik region of West Greenland (Mosbech *et al.* 2001), and these location data are included in the analysis.

At moulting sites, birds were captured in mist nets set between floating platforms (Mosbech *et al.* 2001) or in modified fishing nets. In the fish gillnets, birds were captured one at a time while escape-diving. Specially designed surface-floating fishing nets (Daconetmonofil cod nets 3.3 m deep, 41 m long, equipped with floats and a light lead line, and with a mesh size of 55 mm) were set from fast boats moving in front of a diving bird. The nets had very little weight at the bottom so a bird caught in the net could surface and breathe.

At the breeding site, birds were caught in large mist nets as they flew around an island colony, or in wire funnel traps placed over nests (Gilchrist 2003). After capture, the birds were immediately freed from the net and held in a box of plywood or cardboard lined with puppy nappies prior to and after surgery. Birds were released close to the capture site 2-16 hours after surgery.

The satellite transmitters (PTTs - Platform Transmitter Terminals) were pressure-proof implantable PTT-100 from Microwave Telemetry Inc. weighing about 50 g. The PTTs have expected battery life for 700 transmission hours. To obtain as detailed information as possible, some PTTs were programmed

with fast duty cycles (i.e. four hours transmission and 30 hours off) giving detailed information on local movements, while others were programmed with slow duty cycles (e.g. four hours transmission and 60 hours off). In some cases, the latter provided locations for more than a year. Some of the PTTs were fitted with pressure transducers, which reduced expected battery life to 400-500 transmission hours.

The surgical implantation procedure was performed according to Korschgen *et al.* (1996) with a few modifications (Mosbech *et al.* in prep.).

Location data were received through the Argos Location Service Plus system in DIAG format. Locations are classified according to accuracy by Argos. Location Class (LC) 3, 2 and 1 locations have an estimated accuracy (within one SD) of <150 m, 150-350 m, and 350-1 000 m, respectively, whereas the accuracy of non-standard locations (LC 0, A and B) are >1 000 m or unknown (Argos User's Manual: <http://www.cls.fr/manuel>). However, most of the LC 0 and A locations are within 9 km of the true location (Britten *et al.* 1999). For the general analysis of staging areas, location class 3, 2, 1 and 0 locations were included in this analysis. For one bird, a more detailed analysis of home range combined with dive behaviour has been performed, including non-standard locations when there was positional redundancy within 5 km (using the PC-SAS ARGOS filter by Douglas 2003). For home range calculations, we used the ArcView GIS extension "Animal Movements" (Hooge *et al.* 1999). We used the fixed-kernel home range estimator (Worton 1989) to estimate the 50% and 95% utilization distribution, and to determine the smoothing parameters, we applied least squares cross-validation (Seaman & Powell 1996, Hooge *et al.* 2004). The information on diving behaviour from the pressure transducer was processed in the PTT in 4-hour time frames, and the compressed data transmitted as number of dives, average dive duration, and time spent at different depth intervals for each 4 hour time frame. The depth intervals used were the intervals 0-1 m (surface), 1-10 m, 10-20 m, 20-30 m, 30-40 m and >40 m.

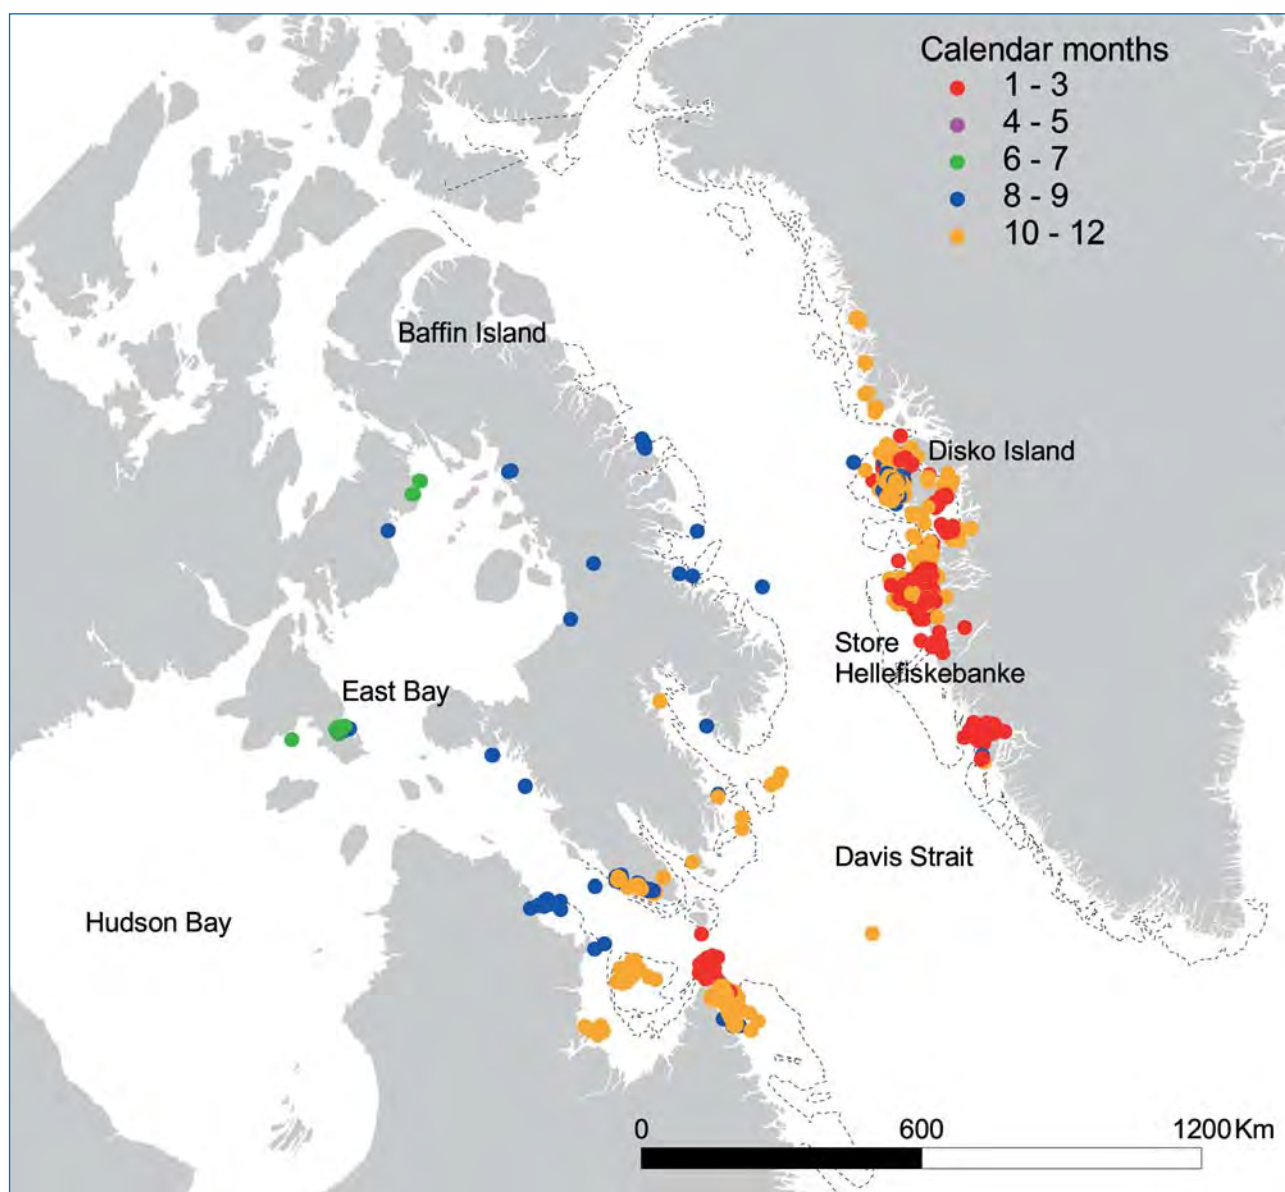

## RESULTS

This analysis includes location data received until March 2004, at which time there were still 16 active transmitters of the 26 PTTs deployed in 2003 (Table 1).

**Table 1.** Number of locations received from King Eiders *Somateria spectabilis* tracked from East Bay (Canada) and Disko (Greenland) in 2003-2004, and the relative abundance of the tracked King Eiders at Store Hellefiskebanke. (Based on Argos location classes 3, 2, 1 and 0).

Month	Total		Store Hellefiskebanke	
	No. of locations	No. of birds	No. of birds	% birds
September	337	26	0	0
October	567	26	5	19
November	519	22	10	45
December	476	22	11	50
January	384	22	10	45
February	203	16	6	38

**Fig. 2.** PTT locations received until 29 March 2004 from 10 King Eiders *Somateria spectabilis* tracked from June 2003 from East Bay, and 16 King Eiders tracked from September 2003 from Disko Island (Argos Standard Locations). The location colour code refers to the calendar month.

For the 10 King Eiders with transmitters implanted at the breeding site in East Bay, nine transmitted throughout the autumn (past 15 November), and these nine birds showed a diversity of migration routes and staging areas (Fig. 2). Six of the nine King Eiders migrated to Greenland (four of the six females; two of the three males) and arrived in Greenland between the end of August and the beginning of December. Three birds crossed Baffin Island during the autumn migration. Moulting areas have been identified for six birds based on the fact that during the flightless wing moult period the birds have restricted movements during a period of over three weeks. Three of the six birds performed wing moult in Greenland (one of the two males and two of the four females). The three birds from East Bay which moulted in Greenland moulted at three different sites; two of these are outside the localities where high concentrations of moulting birds have previously been identified (Mosbech & Boertmann 1999).

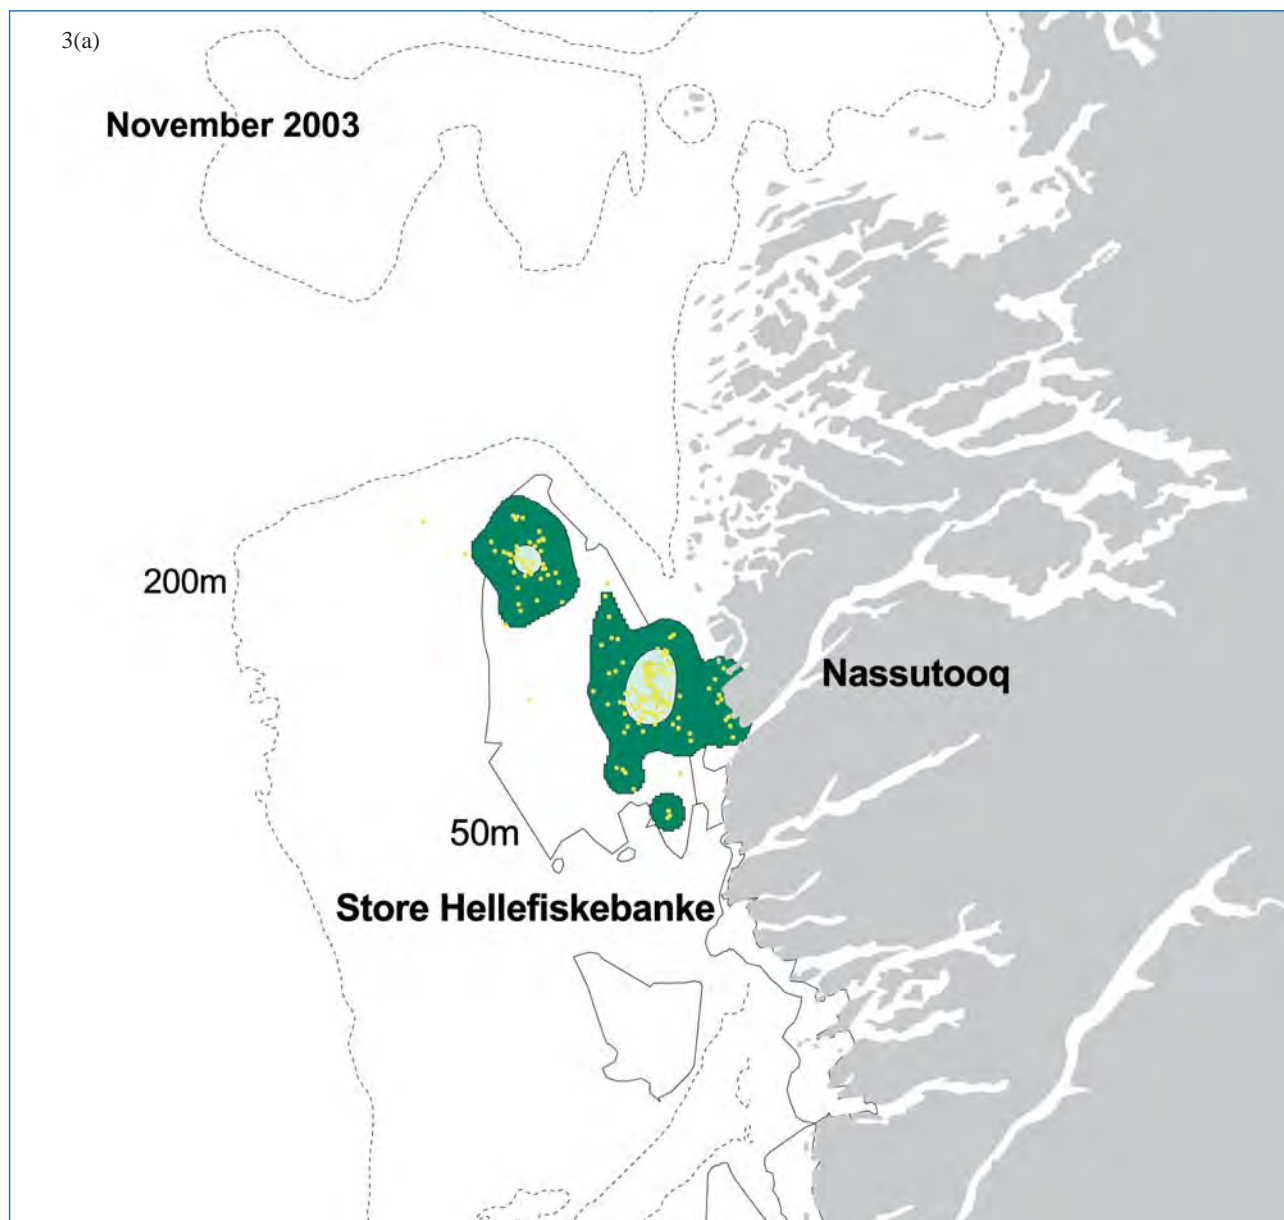

Satellite tracking of 16 King Eiders from moulting areas in two fjords (Mellemfjord and Nordfjord) at western Disko Island, Greenland, showed that in the period from the start of tracking

on 7 September to 10 October 2003 the birds stayed close to their moulting areas with small daily movements. Soon after 10 October, most of the birds initiated their migration southward to Store Hellefiskebanke (an offshore bank) and the nearby coast off the mouth of Nassuttooq fjord (Nordre Strømfjord).

In 1999, the birds were tracked from just before wing moult (the end of July) in a moulting area in southern Upernavik. The birds moulted in the area and stayed in the vicinity of southern Upernavik until October. Six birds were tracked beyond October 1. Five of these birds went to Store Hellefiskebanke about 450 km further south, while one male stayed in southern Upernavik until the end of transmissions in February 2000.

#### Store Hellefiskebanke

Store Hellefiskebanke and the adjacent coast off Nassuttooq were a very important winter staging area for birds tracked in 2003/04 (Figs. 2 & 3). In the winter, Store Hellefiskebanke occurs in the marginal drift ice zone just north of the West Greenland Open Water Area. Birds arrived in the area from 13

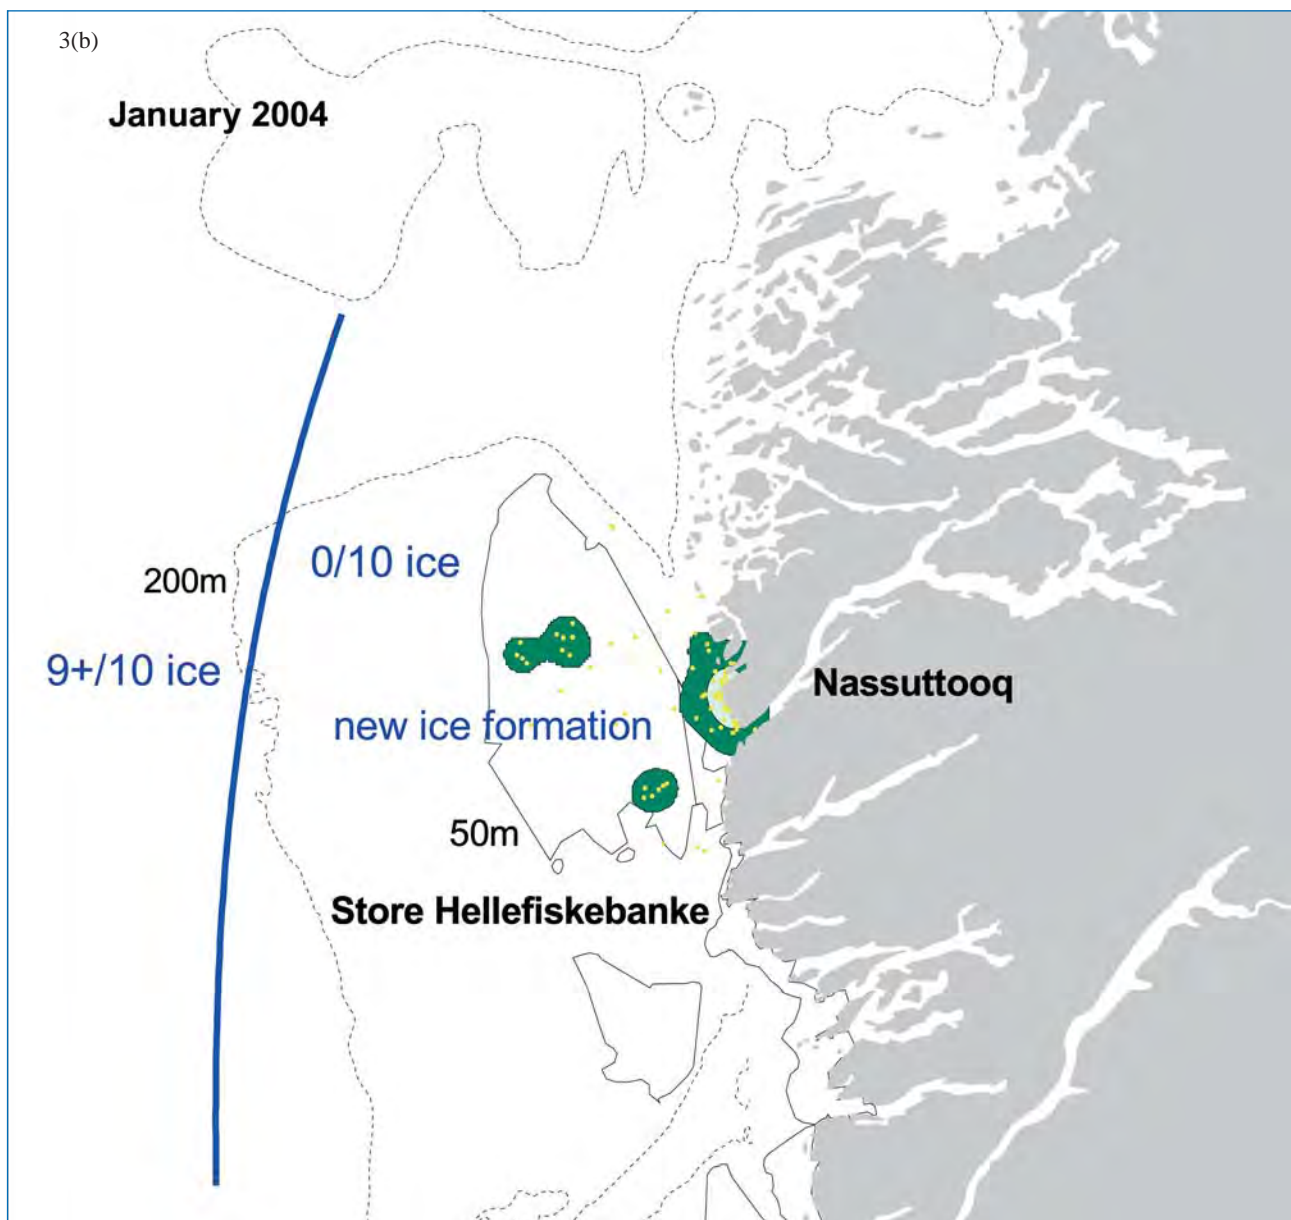

**Fig. 3.** PTT locations (yellow dots) and kernel home range contours, 50% (green shading) and 95% (light green shading), for tracked King Eiders *Somateria spectabilis* on Store Hellefiskebanke in November 2003 and January 2004. The solid black line is the 50m depth contour; the dotted line is the 200 m depth contour. The thick blue line in 3b is the edge of the drift ice when new ice formation began on the Bank between the drift ice and the coast in January 2004.

October with a median arrival date of 15 November. From October to March, 16 out of a total of 25 birds staged for some period in this area: five of the nine birds tracked from the East Bay breeding site in Canada (five of the six birds which migrated from Canada to Greenland), and 11 of the 16 birds tracked from the Disko moulting areas (Nordfjord and Mellemfjord).

In the period November to March, 31–38% of the total number of PTT locations received each month came from Store Hellefiskebanke, and in the period November to January, about half of the birds with active PTTs staged in this area (Table 1). Four out of seven males stayed for less than a week (range 1–6 days between first and last PTT location in the area), while the remaining three males and nine females spent between 33 days and 164 days (median 78 days between first and last PTT location in the area). In 1999, six birds from the moulting area in Upernavik were tracked during autumn. Five of the six birds

went to Store Hellefiskebanke (median arrival date 30 October), and stayed until the last transmitted locations in January 2000. Combining PTT location data from the two winters 1999/2000 and 2003/04, a total of 21 out of 31 King Eiders tracked during winter staged at Store Hellefiskebanke.

The locations from King Eiders at Store Hellefiskebanke in 1999 were centred on areas with a water depth of 23–35 m, which typically occurred about 50 km from the coast. The daily movements of the birds within Store Hellefiskebanke were relatively small. Ice cover on Store Hellefiskebanke from November 1999 to February 2000 was variable but never exceeded 90% (Danish Meteorological Institute ice charts based on Radarsat and NOAA satellite data), and no clear relationship between the movements of the birds and changes in ice cover could be detected. In November 2003, King Eider locations were centred on the same shallow areas of this offshore bank as in 1999 (Fig. 3), and there

were ice-free conditions on the bank from November to January. However, by January, the Danish Meteorological Institute ice charts showed formation of new ice on the bank potentially covering the sea surface completely for a period. At this time, we detected a significant movement of the kernel home range towards the coast just north of Nassuttooq (Fig. 3). The area of the more coastal home range in January was only about half the size of the home range in November (95% contour: 986 sq. km and 2 195 sq. km, respectively; 50% contour: 145 sq. km and 277 sq. km, respectively). Along the coast north of Nassuttooq, the tidal amplitude is 4 m, and strong tidal currents typically ensure that there is always some open water. In February and March, the kernel home range moved slowly away from the coast again.

#### Combined location and dive data

One female King Eider was tracked between 7 September 2003 and 11 January 2004 (127 days) using a satellite transmitter with a depth recorder installed. During this period, the bird used three distinct home range areas (Table 2, Fig. 4). At the Store Hellefiskebanke staging area, the minimum water depth is about 20 m. The bird spent about 5% of the time at the depth interval

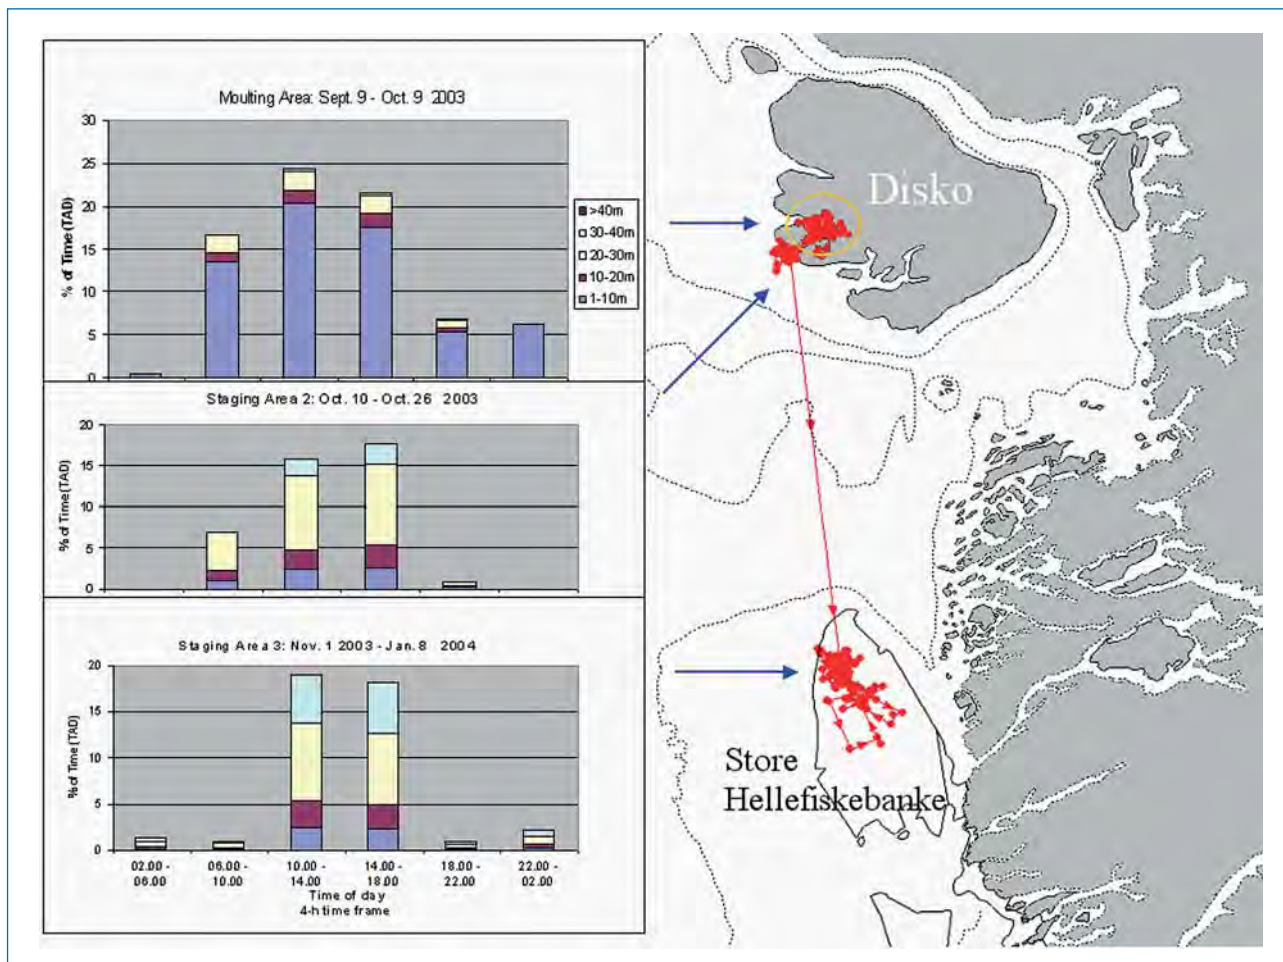

1-20 m in the time frames 10:00 to 14:00 and 14:00 to 18:00. For this bottom-feeder, this is time spent swimming between the surface and the bottom. The overall maximum diving depth of 43 m was recorded at Store Hellefiskebanke. The total daily diving activity (time spent below 1 m  $\pm$ SD) was  $138 \pm 45$  min,  $99 \pm 16$  min and  $102 \pm 22$  min for the moulting area and the two subsequent staging areas, respectively, and thus tended to be highest in the moulting area. This King Eider showed a clear diurnal dive rhythm in all areas ( $p < 0.001$ ), preferring to dive during daylight. This pattern resulted in a short diving peak

**Table 2.** Fixed-kernel home range in three staging areas for a female King Eider *Somateria spectabilis*.

Locality	No. of days	No. of locations	Kernel home range (km <sup>2</sup> )*	
			95% area	50% area
Moulting area	29	44	256	50
Staging A.2	17	40	97	15
Staging A.3	72	90	621	54

\* Calculations of area of fixed-kernel home range with LSCV.

**Fig. 4.** PTT locations and track-line for a female King Eider *Somateria spectabilis* using three distinct staging areas from 7 September to 8 January, and diurnal diving behaviour in these three areas. The columns show the time spent in different depth intervals (Time At Depth, TAD) as a percentage of the time in each four-hour time frame and averaged for the staging period. The diving data covered 75%, 79% and 54% of the time spent in the three staging areas, respectively.

during the winter at Store Hellefiskebanke, when there is only a short period of twilight at this latitude (68°N).

## DISCUSSION

This satellite telemetry study has provided valuable information on migration routes and staging areas, and has clearly shown that the offshore area at Store Hellefiskebanke and adjacent coast are very important wintering habitat for King Eiders breeding in the eastern Canadian Arctic.

Although the sample size is small, it is striking how diverse the migration routes and moulting and staging areas are for the birds tracked from the East Bay breeding area. This diverse dispersal accords well with the lack of spatial genetic structure found among nesting and wintering King Eiders (Pearce *et al.* 2004). Based on stable isotope signatures, Mehl *et al.* (2004) found that female King Eiders breeding at the migratory divide in the central Arctic of the American continent are not strongly philopatric to wintering areas in eastern or western North America. Some females have been found to use completely different migration routes in different years.

While large flocks of King Eiders had previously been observed in the drift ice over Store Hellefiskebanke in March and April (Mosbech & Johnson 1999), this satellite telemetry study has shown that the first birds arrive in this offshore area in

October. Satellite tracking from the major moulting areas in West Greenland and a breeding area in central Canada indicates that about 50% of the King Eiders from these areas choose to stage for a period on Store Hellefiskebanke. Why do the birds choose this area in the drift ice north of the Open Water Area? Firstly, it is the largest continuous area of shallow water in West Greenland that provides appropriate foraging areas. Secondly, the dynamic drift-ice environment that is the usual condition on Store Hellefiskebanke from midwinter (January) may actually reduce energetic costs because the birds can roost on the ice and the ice dampens the waves and the wind. Mosbech & Johnson (1999) found that in March and April, the distribution of King Eiders during aerial surveys of the bank was not negatively correlated with heavy ice (up to 90%). However, new ice formation in calm weather, as seen in January 2004, may close the water surface and force the birds to move away. Ice conditions on the bank are dynamic, and usually the water surface will only be completely closed for a few days. The offshore drift-ice habitat seems to resemble the wintering habitat of Spectacled Eiders described by Petersen & Douglas (2004).

In 2004, most birds shifted to the coast in January and stayed there for several weeks, indicating the importance of the coastal part of the area as well. Satellite telemetry showed that the birds were not commuting between the coast and the offshore area.

Such information is important for planning and interpretation of surveys.

The diurnal diving activity that we found for a female is in accordance with earlier reports that King Eiders feed mainly by day (Cramp & Simmons 1977). We found less feeding activity at the moulting locality (138 min or 10% of a 24-hour period) than Frimer (1994) found during his land-based observations in the Disko moulting area in September. He found that King Eiders allocated 12% of the 24 hours to diving. Frimer found that most feeding took place at depths of between 10 and 25 m, while our bird spent most of its diving time at depths of between 1 and 10 m. At the two subsequent staging areas, this King Eider allocated less time to diving (99 min and 102 min, respectively, or about 7% of the 24 hours), and dived considerably deeper. This is very much like the King Eiders wintering in a fjord in northern Norway (70°N). Here, land-based observations have shown that flocks of King Eiders usually dived deeper than 20 m and were diving down to depths of 40 m (Bustnes & Lønne 1997, Systad *et al.* 2000). These birds allocated 102 min per day (November–April) to diving; a similar time to that spent by the female King Eider from this study in West Greenland. However, the Norwegian birds increased their diving time from 57 min on the shortest days in December to 161 min on the longest day in April. The reduced diving activity in December in northern Norway compared with our bird is probably due to there being less daylight in northern Norway, which lies at two degrees latitude further north.

One important point to be taken into account in the management of staging areas for King Eiders is that nearly all foraging takes place during daylight hours. Thus, disturbance during the few hours of daylight in midwinter could have a significant impact on foraging. Further analysis of location and diving data combined with data on body condition, stomach samples and benthos will provide precise descriptions of habitat quality, and has the potential to identify population bottlenecks.

## ACKNOWLEDGEMENTS

We thank the field teams at East Bay and Disko Island for their invaluable support in catching the birds. We thank Ebbe Bøgebjerg, NERI, for generously sharing his experience with net designs, Margaret R. Petersen and Daniel M. Mulcahy, Alaska Science Center, for helping us with implantation expertise, and Paul Howey, Microwave Telemetry, for solving all the technical problems and collaborating with us on the development of the PTTs with depth recorder. We were supported by Dancea (Danish Co-operation for Environment in the Arctic) and the North American Sea Duck Joint Venture. Avatangiisut Pinngortitamullu Pisortaqarfik, The Nature Directorate, Greenland, granted us the necessary permits for the work in Greenland.

## Cape Gannet *Morus capensis* movements in Africa

H. Dieter Oschadleus<sup>1</sup> & Michael Brooks<sup>2</sup>

Avian Demography Unit, Department of Statistical Sciences, University of Cape Town, Rondebosch, 7701, South Africa.  
(email: <sup>1</sup>dieter@adu.uct.ac.za, <sup>2</sup>mbrooks@adu.uct.ac.za)

Oschadleus, H.D. & Brooks, M. 2006. Cape Gannet *Morus capensis* movements in Africa. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 777-778.

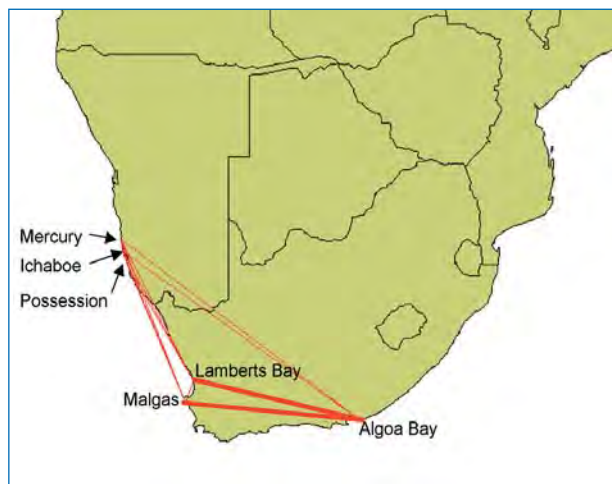

Cape Gannets *Morus capensis* breed at only six coastal islands off Namibia and South Africa (Table 1, Fig. 1). They are the third most-ringed birds in southern Africa, with some 140 000 ringed since 1950 (Oschadleus & Underhill 1999). Most ringing records since 1975 have been captured electronically.

After breeding, gannets disperse around the African coast, to West Africa on the west coast and to the Gulf of Guinea and Mozambique on the east coast. However, there have been some unusual recoveries. On 18 October 1986, a ringed Cape Gannet was entangled with fishing line in Western Australia, and was released unharmed. It had been ringed on Bird Island, Algoa Bay, 7 860 km away. In October 1989 this individual was seen on an unoccupied Yellow-nosed Albatross *Diomedea chlorohynchus* nest on Amsterdam Island, in the southern Indian Ocean halfway between South Africa and Australia. It was seen again on several dates in the same season, and in the following season, on Amsterdam Island.

Two other unusual Cape Gannet recoveries have been reported to SAFRING. One was found in a rubbish dump in Murmansk, NW Russia, but the gannet was probably caught on a Russian trawler and the ring and leg later discarded. Similarly, a South African ringed bird was reported from the Philippine Islands, without further details, but presumably this ring was also dropped off by a trawler. Cape Gannets often forage around trawlers and may become entangled in their nets.

A total of 2 516 gannets have been recovered sick or dead (0.6%), and 21 700 have been recaptured (5.4%). Adults usually remain within 540 km of their breeding site but may move up to 3 300 km, while immature birds of under two years old migrate as far as 6 800 km (Table 2).

The Cape Gannet is a regular winter visitor as far as the Gulf of Guinea. Outside of South Africa and Namibia, there have been 103 recoveries from Angola, 14 from Congo, 11 from Gabon, 17 from Equatorial Guinea, 10 from Cameroon, two from Nigeria, and one from Western Sahara. The last record is of a fledgling ringed at Lambert's Bay in 1966 that had moved to Western (former Spanish) Sahara after only 51 days. On the east coast of Africa, it is a regular winter visitor to Kwazulu-Natal

**Fig. 1.** The six breeding colonies of Cape Gannets *Morus capensis* in South Africa and Namibia, and known movements between the colonies.

**Table 2.** Number of Cape Gannet *Morus capensis* recoveries by ringing age.

Area of recovery	Juv	Adult	Total
Angola	33	68	103
Gulf of Guinea	12	44	56
Mozambique	20	17	37

**Table 3.** Number of Cape Gannet *Morus capensis* recoveries by decade and area of recovery.

	1950s	1960s	1970s	1980s	1990s
Angola	64	19	0	6	14
Gulf of Guinea	50	4	0	0	2
Mozambique	13	7	0	9	8
Totals	127	30	0	15	24

**Table 1.** Numbers of pulli and adult Cape Gannets *Morus capensis* ringed at breeding colonies 1975-2002, and all recoveries 1950-2004. Colonies are sorted in decreasing size (no. of pairs in 1995 from Rob Crawford *in litt.*).

Breeding site	Pulli	Adults	Recovered	No. of pairs in 1995
Algoa Bay, Eastern Cape	29 317	1 847	2 441	68 000
Malgas, Western Cape	21 480	3 827	5 483	58 000
Ichaboe, Namibia	7 621	742	471	28 000
Lamberts Bay, Western Cape	11 838	1 586	3 766	10 000
Mercury, Namibia	4 012	135	367	2 100
Possession, Namibia	2 300	215	186	800
Total	76 568	8 352	12 714	166 900

**Table 4.** Number of Cape Gannet *Morus capensis* resighted or retrapped between breeding colonies.

Ringed at:	Colony moved to:						
	Mercury	Ichaboe	Possession	Lamberts	Malgas	Algoa	Other*
Mercury		10		8	11		
Ichaboe	7		3	31	22		
Possession	3	18		16	16		
Lamberts Bay	1	6			291	5	6
Malgas	2	2	1	260		3	6
Algoa	1	1		34	56		1

\* birds resighted or retrapped at non-breeding locations

and Delagoa Bay, Mozambique. Recoveries along the east coast of Africa include 37 from Mozambique and one from Madagascar.

The number of recoveries reported declined after the 1950s (Table 3), indicating a possibly altered pattern of dispersal (Oatley 1988, Klages 1994). This cannot be explained by a decrease in ringing effort.

Most inter-colony movement occurred between the closest colonies: Malgas and Lambert's Bay (Table 4, Fig. 1). Some movement occurred between South African and Namibian colonies. The most isolated colony seems to be at Algoa Bay.

“Farmer - what have you done with my grain?”

There are a growing number of examples from many countries, where there has been successful resolution of conflicts between goose populations and farmers. Protest banner (from 1989) in Nordrhein Westfalen, Germany, where goose shooting had been prohibited. Photo: David Stroud.

The conservation of waterbirds often comes into conflict with the advancement of economic, recreational, transportation and agricultural development both at broad landscape scales and at specific sites. This workshop covered several examples of the kinds of issues that are emerging as society advances.

Among the key points emerging from the papers were:

- Waterbird specialists must play key roles in the development of practical and sustainable solutions to most problems. It is critical to waterbird conservation that the best science available is applied to each situation.
- Problems can emerge unexpectedly in areas that may, even recently, have been thought to be of low threat to conservation interests. It is highly desirable to monitor all waterbird species, even the most common, to help ensure sensitivity to environmental changes when they occur in the future.
- After management actions have been implemented, it is important to follow through with adequate evaluation programs to encourage the continuation of satisfactory practices or to offer feed-back that provides guidance for improvements of future management programs. The case of the permanent inundation of the estuarine Cardiff Bay in the UK was reported by Burton.
- Competing alternative uses for limited habitats remain at the centre of most conflicts. With the habitats available to most species already generally much limited over what was historically available, it is critical that waterbird interests engage in these problems before significant investments have been made by economic interests.
- It is usually preferable to define mutually compatible uses of areas for both their natural values and for economic development, but these cases are often illusive to discover.
- It is critical to get all stakeholders involved in the resolution of most conflicts as mutual ownership of action plans is a highly desirable element that can lead to the successful results.
- The unusual problem of overabundant species has begun to emerge among a few species of waterbirds as described by Batt *et al.*. Management experience of the current cases

will provide important guidance for similar issues when they arise in the future with other species, or in other regions.

- Non-native waterbirds introduced beyond natural ranges, especially Anatidae, may have closely related species that might be subject to genetic swamping and excessive competition to the detriment of indigenous species (as described by Henderson in relation to the genetic impacts of Ruddy Duck *Oxyura jamaicensis* on White-headed Ducks *O. leucocephala* in Europe). Introductions of non-native waterbirds should be prevented at the outset, but if - despite this - ecologically damaging species have become established, it is preferable to move quickly to remove or contain them before the problem grows to the point where little can be done.
- New industrial uses of intertidal and supratidal habitats are especially threatening as these areas are critical to many species

of waterbird. Conflicts raised by intensive shellfisheries in the Dutch Wadden Sea are described by Ens, and as a consequence of intensive shrimp aquaculture by Schaeffer-Novelli *et al.* (See also papers within the section on 'Declining waterbirds: problems, processes and sites'). These problems are emerging in both developed and developing countries.

- Two examples of apparently successful resolution of conflicts between hunting and the local protection of waterfowl populations are described by Stroud *et al.* and by Cope *et al.*
- The growth of wind farms is a broadly important issue for bird conservation and has recently emerged in offshore environments. As stressed by Fox & Petersen, it is highly desirable to implement extensive monitoring of the impacts on waterbirds as better knowledge is critical for the location and management of this industry in the future.

The severe physical disturbance of inter-tidal sediments following mechanised dredging for cockles in the Dutch Waddensea is clearly visible from the air. Ens (this volume, p. 806) summarises the consequences of this fishery for waterbirds. Following intervention by the European Court of Justice, these damaging practices have now ceased. ### ABSTRACT

In periods of severe or particularly harsh winter weather in Britain, wildlife legislation enables the suspension of waterbird shooting so as to help reduce mortality from both direct and indirect causes. Following controversy over the imposition of shooting suspension in the severe weather of January 1979, a formal system of criteria to be operated under similar future circumstances was jointly agreed by the British government's nature conservation advisory body and non-governmental organizations representing shooting and conservation interests. These criteria have been progressively developed in the years since, with formal reviews following those winters when suspensions occurred so as to learn lessons and further refine good practice. We outline the evolution of the current system and summarize the last 25 winters, in particular focussing on those elements that have led to the effective operation of the system and lessons learnt in reducing unnecessary conflicts. There are some aspects of the British system that would be of wider applicability to other countries interested in developing a similar system. Finally, we review the recent pattern of severe midwinter weather and note the decreasing frequency of prolonged severe weather events consequent on currently changing climate.

### INTRODUCTION

For many species of bird, and especially for waterbirds, midwinter can be an ecological "bottle-neck" when they have particular difficulty obtaining enough food. They face reduced prospects for survival during winter (Goss-Custard *et al.* 1977, Clark 2002) and especially in periods of harsh weather (Dobinson & Richards 1964, Davidson & Evans 1982, Mitchell *et al.* 2000). In addition, there can be significant movements within Europe of waterbirds seeking milder conditions, and many move to Britain to escape from even colder conditions in continental Europe (Lack 1986, Ridgill & Fox 1990, Kirby 1995).

Lengthy spells of severe weather can result in changed behaviour, with birds becoming "tame" and reluctant to fly when approached in order to avoid using up remaining energy reserves. Under such circumstances, the conservation response should be to limit unnecessary disturbance to enable the conservation of remaining energetic reserves, and thus reduce mortality.

### EVOLUTION OF CRITERIA FOR SUSPENDING WATERBIRD SHOOTING

In Great Britain, the open season for waterbird shooting on inland sites finishes on 1 February, although shooting on the

**Fig. 1.** The British network of meteorological stations currently used to provide ground condition data for severe weather alerting (since 2001/02).

foreshore continues until 21 February (Section 2 (4) of the Wildlife and Countryside Act 1981). In periods of prolonged severe winter weather (usually when freezing is persistent), the relevant Secretary of State(s) have the power under Section 2 (6) of the Wildlife and Countryside Act to make a Protection Order temporarily suspending the shooting of waterbirds.

In January 1979, a ban on wildfowling (waterbird shooting) was imposed as a result of prolonged severe weather. There was considerable disagreement and confusion between interested parties over the calling of this ban due to the lack of universally accepted criteria and procedures. As a result, a government Working Group was established to devise criteria for future use, and proposals focused on the recording of frozen ground states at a network of coastal meteorological stations (Batten & Swift 1982). Since then, there have been progressive modifications to the system, as detailed by Stroud (1992).

The current guidelines, given below, have been agreed between the statutory conservation agencies (Joint Nature

Conservation Committee (JNCC), English Nature, Countryside Council for Wales, and Scottish Natural Heritage), the Department of the Environment, Food and Rural Affairs (DEFRA), the Scottish Executive Environment and Rural Affairs Department (SEERAD), the National Assembly of Wales, and the principal non-governmental organizations involved in the monitoring and management of severe-weather suspensions: the Royal Society for the Protection of Birds (RSPB), Wildfowl & Wetlands Trust (WWT), British Trust for Ornithology (BTO), and British Association for Shooting and Conservation (BASC). A similar but separately organized system operates in Northern Ireland.

#### Current criteria for suspending waterbird shooting

Under contract to JNCC, the UK Meteorological Office summarizes daily data on ground conditions at 23 meteorological stations throughout England, Scotland and Wales (Fig. 1). These stations are chosen to reflect the winter weather conditions around the whole British coast and because they are close to major estuaries and other centres of foreshore shooting, since waterbirds typically concentrate at the coast during severe weather.

Suspensions can occur either throughout Great Britain, in Scotland alone, or in England and Wales only. However, since the advent of devolved government in Britain in the mid-1990s, the system has operated effectively at only two scales, Scotland, and England and Wales. Although, in principle, simultaneous suspensions in these two areas would give a shooting suspension at the scale of Great Britain, this has not occurred since 1986/87.

#### Current procedures in the event of a severe cold period

- When more than half of these stations (either throughout Great Britain, in Scotland alone, or in England and Wales) have recorded frozen conditions for five consecutive days, JNCC is alerted. Weather conditions are then monitored more closely during a “countdown period” prior to a statutory suspension being invoked.
- After seven days of frozen conditions, JNCC informs BASC who initiate a comparable information-gathering and condition-monitoring exercise of birds and habitat through regional staff and local contacts if severe weather looks likely to continue. Once alerted, BASC contacts all its member wildfowling clubs and shooting syndicates, calling for voluntary restraint in waterbird shooting in those parts of the country where appropriate (and warning of the possibility of a statutory suspension if conditions persist). Such voluntary measures continue up to the point of any statutory suspension or as considered necessary in the light of prevailing conditions and information, especially on the condition of birds and their habitats. When several periods of severe weather occur within a short time scale, voluntary restraints play a particularly important role because they allow populations to recover from stress. At this stage, waterbird shooters and others provide invaluable information on local conditions.
- With respect to the criteria applying to the “count-down period”, short periods of thaw (one or two days with less than half the stations frozen) have no effect on the process that will trigger a statutory suspension, but three or more days of thaw have the effect of terminating the process. Such short periods of thaw are “neutral” in terms of counting

a) Stations used from 1980/1 - 1984/5

b) Stations used from 1985/6 - 2000/1

**Fig. 2.** Progressive development in numbers and range of the network of meteorological stations used to provide the initial alert for statutory shooting suspensions (after Stroud 1992).

days towards a suspension – that is they neither count towards, nor terminate, the process.

- During the alert stage (Day 7 onwards), regional representatives from relevant country agencies, RSPB and BASC liaise with one another to exchange information and pass this to JNCC for national collation. The BTO supplies JNCC with information from their observer networks. Particular attention is paid not only to the foreshore and the freezing of inland waters and feeding grounds, but also to the condition of birds, bird numbers, movements and behaviour, appearance of unusual species, significance of wind chill and snow cover, the last especially in Scotland. To aid review, information is encouraged to be reported on a standard proforma available on JNCC's web-site.
- On the thirteenth day after the start of the severe weather, if more than half the relevant meteorological stations are still frozen, a case is presented to the relevant Secretary of State(s) requesting a suspension of waterbird shooting due to the severe weather. Such suspensions can be instituted throughout Great Britain, or in Scotland alone, or in England and Wales, dependent on the extent of the severe weather.
- Once this Statutory Instrument has been signed, it comes into force at 09:00 hrs on the fifteenth day of severe weather.
- The two intervening days are used to publicize the impending suspension as widely as possible. BASC

contacts all its wildfowling clubs and game shooting syndicates, issues press releases to newspaper, sporting magazine, radio and television editors, and institutes a 24-hour telephone information service in all regions of the country. Similarly DEFRA and SEERAD, as appropriate, issue press releases and place public notices of the suspension in an agreed selection of national and regional newspapers. Efforts are made to have such notices included on national and regional television and radio news, and weather programmes. A general call is made for other recreational users of the coasts to avoid disturbing waterbirds.

- Once the suspension comes into force, it prohibits the shooting of any bird on Schedule 2 Part 1 of the Wildlife and Countryside Act 1981<sup>1</sup>; in effect it introduces a temporary close season for shootable ducks, geese, waders, Common Coot *Fulica atra* and Common Moorhen *Gallinula chloropus*, for an initial period of 14 days. This applies throughout the specified country, affecting all inland and coastal waterfowl shooting. The species affected include the Eurasian Woodcock *Scolopax rusticola* and Common Snipe *Gallinago gallinago*, often encountered in non-wetland habitats, and so affects all those who shoot waterbirds, whether on the coast or inland.
- The suspension is examined after seven days: if the weather conditions have improved and the forecast is for a continua-

<sup>1</sup> Pink-footed Goose *Anser brachyrhynchus*, Greater White-fronted Goose *A. albifrons* (England and Wales only), Greylag Goose *A. anser*, Canada Goose *Branta canadensis*, Eurasian Wigeon *Anas penelope*, Gadwall *A. strepera*, Common Teal *A. crecca*, Mallard *A. platyrhynchos*, Northern Pintail *A. acuta*, Northern Shoveler *A. clypeata*, Common Pochard *Aythya ferina*, Tufted Duck *A. fuligula*, Greater Scaup *A. marila*, Common Goldeneye *Bucephala clangula*, Common Moorhen *Gallinula chloropus*, Common Coot *Fulica atra*, Eurasian Golden Plover *Pluvialis apricaria*, Common Snipe *Gallinago gallinago* and Eurasian Woodcock *Scolopax rusticola*.

tion of this improvement, then, in consideration with other factors, the lifting of the suspension can be recommended. However, if there has been no thaw and the weather is still severe, then the suspension continues for the full 14 days.

- Any lifting of the suspension before the full 14 days takes into consideration the need for a period of recovery for waterbirds after the end of the severe weather itself. In this event, DEFRA or SEERAD, and BASC undertake publicity campaigns as extensively as possible to provide information to the shooting community.
- There can be an extension of the suspension beyond 14 days, through a second Statutory Instrument, if weather is still severe and no improvement in conditions is forecast. The management of the second period of suspension is undertaken in the same manner as the first.

## 25 YEARS OF IMPLEMENTATION

Table 1 summarizes episodes of severe winter weather from 1980/81 to 2004/05, and the policy responses under this system. Overall the system has worked well, especially so in more recent years as there has been increasing familiarization of the criteria and their operation by all concerned.

### Lessons learnt

When the system was established in the early 1980s, the Secretary of State requested that there be a review of the operation of the system following each year when it came into effect, in order to learn lessons and further refine its operation. A number of important themes have emerged over the years, which we summarize below.

#### 1. The importance of good communication

The need for good (clear and regular) communication has been repeatedly stressed, not only at a national scale between the staff in headquarters of collaborating government departments, agencies and non-governmental organizations, but also regionally and locally between the various interested parties. In particular, the need for clear communication with the shooting community – whose recreational activities are directly affected – is crucial, particularly through their representative body (BASC), but also via the media.

#### 2. Value of data and information on condition of waterbirds

The interpretation of meteorological data is greatly aided by information on the physiological condition of waterbirds, and this is a very valuable adjunct to decision making. To this end, a standard form was developed in 1995 for field reporting of bird condition and ground conditions, and this has been disseminated especially to BASC regional contacts, nature reserve wardens and other networks, as well as being made available via JNCC's web-site ([www.jncc.gov.uk](http://www.jncc.gov.uk)).

#### 3. Importance of review after implementation of a severe weather suspension to improve future planning

The establishment of consultative arrangements after each severe weather event has allowed progressive fine-tuning of the system. For example, the need for a greater number and spread of meteorological stations was highlighted in the 1980s (Fig. 2). However, not least from the perspective of clear communication

with the shooting community, the need for consistency of criteria and approaches has also been recognized. There are no doubt sophisticated elaborations of criteria that might be possible, but there is merit in having criteria that are intuitively and easily understood, and which remain constant from year to year.

#### 4. The scale of shooting suspensions

The possibility of regional<sup>2</sup> suspensions of shooting has been discussed several times and always rejected, for two principal reasons. Firstly, problems of clearly communicating to shooters and police in which areas shooting is suspended and in which it is not would give considerable enforcement problems. Secondly, in a severe weather period, although ground conditions in some parts of the country may not be equally frozen, birds in areas with milder weather may have moved from colder regions and so be recovering their condition. From a waterbird management perspective, it makes conservation sense to consider policies towards severe-weather suspensions over as large an area as possible – at least at the scale of a whole country.

#### 5. Importance of a full complement of sites to avoid ambiguity

Although the alerting system operated by the Meteorological Office operated well in the 1980s, by the mid-1990s, there were growing problems caused by the progressive automation of meteorological stations resulting in an abandonment of the visual observations of ground state needed to operate the alerting system. This resulted in the network in some years operating with less than a full complement of sites, and data being needed from regions without appropriate stations. Accordingly, in 2001, JNCC commissioned the Meteorological Office to undertake a modelling exercise so as to assess the potential for use of automatically collected data. The results (Ashcroft 2001) indicated that automatically collected data could be used, and such data were included from the winter of 2001/02 to supplement observations made at the remaining manned stations. The ability to operate an alert system based on a geographically balanced, full network of stations has removed an element of ambiguity that gave problems with decision making.

#### 6. Reaching other sectors

Clearly, shooting is not the only source of potentially damaging disturbance for waterbirds in prolonged severe weather, although owing to the statutory basis under which it occurs, it is one of the most feasible to regulate in a responsive manner. A number of recreational and other activities can also significantly disturb waterbirds, notably dog-walking, horse-riding, anglers, water-based sports, low-flying aircraft and others (Davidson & Rothwell 1993, Madsen 1998). In publicity related to the operation of this system, it has been important to get clear messages to these other interests, so as to try and more widely reduce disturbance to waterbirds in poor energetic condition. Thus, for example, the BTO bans the capture and ringing of waterbirds except by individuals studying the effect of weather, who have to apply for a specific exemption.

## CONCLUSIONS AND FUTURE PROSPECTS

Overall, the system developed in the early 1980s has worked well. The criteria developed have been robust in identifying periods that most of those concerned would intuitively consider

<sup>2</sup> meaning a scale smaller than that of a single country.

**Fig. 3.** Frost days at an example meteorological station on the English east coast at the Wash (Terrington St Clement). Frost days are the total days when the temperature was below 0°C multiplied by the difference from zero on each day (from Clark 2002).

to be weather that is prolonged and severe. In no small measure, the success of the system has been due to the co-operation of the shooting community and the partnership approach adopted from the outset by involved organizations – itself a result of a long history of collaborative working between non-statutory and statutory bodies concerned with British waterbird conservation (Harrison 1973). The need to review the alerting system after each use has provided a formal means for exchanging differing perspectives and a trigger for developing enhancements (such as the increased size of the network of meteorological stations from 1985/86, and the consideration of proposals to use some different types of data from 2002/03). The close working

together of nature conservation and shooting organizations in the joint exchange of information has avoided a return to the damaging public conflicts of January 1979.

It is somewhat ironic then, that having developed a widely accepted alert system, current changes in climate seem set – in the medium term – to render this system redundant. The trend through the 1990s has been for progressively milder winters, with few extended periods of severe, cold weather. This is apparent both from local temperature records (Fig. 3) as well as nationally (Fig. 4). Projections undertaken by the UK Climate Impacts Programme suggest that Britain will experience very few periods of prolonged severe weather after 2030 (Fig. 4; Hulme & Jenkins 1998, Watkinson *et al.* 2004). Although reducing risks to wintering waterbirds associated with severe weather, the ecological consequences of such climate change will be highly uncertain, affecting as they will Arctic breeding areas, migratory flyways and over-wintering areas.

However, at least for the next decades, climate models predict occasional periods of severe weather. These have potential to have significant effects on waterbird populations as many of the birds will be naive, through not having experienced severe weather previously, and may therefore be less able to cope. Further, with a current change of winter distributions within Britain (with increasing concentrations now occurring on east coasts; Austin & Rehfish 2005), a higher proportion of total populations will be likely to occur on those eastern coasts typically most severely affected by periods of prolonged severe weather. There is thus merit in maintaining the current system for the foreseeable future.

#### ACKNOWLEDGEMENTS

The British system of suspending shooting in severe weather has evolved over the last 25 years. We are grateful to all those who have given inputs to the development of criteria and provided subsequent advice leading to the progressive “fine-tuning” of the

**Fig. 4.** The past, and projected future, seasonal pattern of periods of severe cold (and hot) weather in the UK. Data drawn from Hulme & Jenkins (1998).

current system, in particular to Leo Batten and John Swift for their initial work, and to the many individuals who have contributed to the Working Group since the 1970s.

## ABSTRACT

This paper is a summary of: Cope, D.R., Vickery, J.A. & Rowcliffe, J.M. In press. From conflict to coexistence: a case study with geese and agriculture in Scotland. In: S.M. Thirgood, A. Rabinowitz & R. Woodroffe (eds) *People and Wildlife: Conflict or Coexistence?* Cambridge University Press, Cambridge.

Nine distinct populations of geese are found in Scotland, most of which are increasing in number due to increased legislative protection from shooting. They are concentrated in time and space, and increasingly feed on agricultural land, reducing yields in grass and cereal crops. Whilst geese are economically valuable for their recreational amenity, the farmers who suffered yield losses have not shared in these benefits in the past. This caused a conflict of interest between geese and farmers, which has threatened to destabilize the balance between the needs to conserve Scotland's fauna and the needs of farmers to run economic businesses that provide food for the nation. While culling, scaring, the provision of alternative feeding areas or compensatory payments were unlikely to solve this conflict in isolation, a co-ordinated stakeholder-driven approach to solve this conflict was initiated in the 1990s. This approach used payments to encourage farmers adversely affected by the presence of geese to redistribute geese into areas designated as undisturbed feeding refuges. Payments were directed towards farmers for positively managing the land for the benefit of geese, ensuring that Scotland met its international conservation obligations.

## INTRODUCTION

Scotland hosts six species of geese for all or part of the year, comprising nine distinct breeding populations (Table 1). Six of these populations breed in arctic regions (Greenland, Iceland, Svalbard or Russia) and winter in Scotland, making Scotland a vital part of several goose flyways. Many populations are protected under the 1979 European Union Birds Directive (Directive 79/409/EEC) and the 1981 Wildlife and Countryside Act in the UK. Most populations are increasing, largely as a result of hunting controls (Owen 1990). However, their ranges in Scotland remain very restricted in time and space (Table 1 and Fig. 1).

Agricultural damage caused by geese is of two broad types: (i) on grass, where the standing crop may be reduced and sward structure damaged, and (ii) on arable crops such as wheat and oilseed rape, where the yield may be reduced (Patton & Frame 1981, Patterson *et al.* 1989, Percival & Houston 1992). The conflict may be localized, but is often intense, with a small number of farmers incurring a large proportion of the damage, resulting in conflict "hot spots".

## MANAGING THE GOOSE-AGRICULTURE CONFLICT: POSSIBLE SOLUTIONS

A number of solutions to the goose-agriculture conflict have been suggested in recent years.

**Table 1. The size and trend of goose populations occurring in Scotland.**

English name	Scientific name	Population size (1999-2001) <sup>†</sup>	Trend
Bean Goose*	<i>Anser fabalis</i>	300 <sup>1,2</sup>	Stable
Pink-footed Goose	<i>Anser brachyrhynchus</i>	245 000 <sup>3</sup>	Increasing
Greenland White-fronted Goose	<i>Anser albifrons flavirostris</i>	20 660 <sup>1</sup>	Increasing
Greylag Goose (Icelandic population)	<i>Anser anser</i>	80 000 <sup>3</sup>	Stable
Greylag Goose (Scottish population)	<i>Anser anser</i>	6 500 <sup>1</sup>	Increasing
Greylag Goose (naturalized population)	<i>Anser anser</i>	21 000 <sup>1,4</sup>	Increasing
Canada Goose*	<i>Branta canadensis</i>	50 000 <sup>1,4</sup>	Increasing
Barnacle Goose (Greenland population)	<i>Branta leucopsis</i>	37 800 <sup>1</sup>	Increasing
Barnacle Goose (Svalbard population)	<i>Branta leucopsis</i>	21 000 <sup>5,6</sup>	Increasing

<sup>†</sup> Totals for the United Kingdom only.

\* These species do not cause significant goose-agriculture conflict in Scotland, and are not considered in the text.

<sup>1</sup> The Wetland Bird Survey 1999-2000 (Musgrove *et al.* 2001).

<sup>2</sup> Scottish population is around 150 individuals (Musgrove *et al.* 2001).

<sup>3</sup> The 2000 census of Pink-footed Geese and Icelandic Greylag Geese (Hearn 2002). About 80% of Pink-footed Geese and over 90% of Greylag Geese were found in Scotland.

<sup>4</sup> Most naturalized Greylag Geese and Canada Geese are found outside Scotland.

<sup>5</sup> WWT Svalbard Barnacle Goose Project Report 2000-2001 (Griffin & Coath 2001).

<sup>6</sup> The wintering range of Svalbard Barnacle Geese covers both England and Scotland, with more than half using the Scottish range (Griffin & Coath 2001).

### Culling

By culling, we here refer to systematic efforts to reduce population sizes. To be effective in resolving the conflict, this approach must reduce goose populations to levels at which little or no damage is incurred. Geese are relatively long-lived birds, and changes in survival rates therefore have a strong effect on population growth (Rowcliffe *et al.* 2000), as demonstrated by the heavy impact of hunting on goose populations in the past (Ebbinge 1991). Culling by encouraging existing wildfowling and lethal crop protection is being used to reduce “over-abundant” white goose (*Chen* spp.) populations in North America, through greatly liberalized legislation on bag limits, timing and methods of hunting (USFWS 2001). Owen (1990) estimated that an effective cull of Pink-footed Geese *Anser brachyrhynchus* and Greylag Geese *A. anser* in the UK would require 90 000 birds to be shot in each of the first five years and a maintenance cull of 40 000 each year thereafter. This would require a large number of highly active hunters, probably far more than are currently active in the UK where around 32 000 grey geese (*Anser* spp.) are shot annually.

The main arguments against culling are political. Most goose populations are considered “at risk” under the EU Birds Directive. Even though Member States can derogate from the protection rules to prevent serious damage to crops, shooting under the derogation is licensed only where it has been demonstrated that there is no other satisfactory solution. In effect, this means that numbers shot by farmers are kept to a minimum required for localized crop protection. Initiating a systematic cull would require demonstrating first that populations are excessively high, well beyond anything that could be considered

at risk in the long term, and second, that levels of damage are also unacceptably high. No such arguments can be made in the case of any European goose population.

### Scaring

A range of methods has been deployed for scaring geese off agricultural land, from the use of scarecrows or gas guns and barriers in or above fields (streamers on sticks or kites) to the employment of a full time human goose scarer (Vickery & Summers 1992). However, geese become habituated to most scaring techniques relatively quickly (Vickery & Summers 1992) and, since scaring is rarely co-ordinated between farms, it usually serves simply to move the problem elsewhere. Where trials have been carried out, co-ordinated scaring has proved extremely costly (Percival *et al.* 1997) and only effective in reducing damage levels when it is deployed alongside dedicated refuge areas for geese (Vickery & Summers 1992, Vickery & Gill 1999).

### Compensation schemes

Direct financial compensation for goose damage is a third option, but estimating damage is costly, complex and time-consuming (Owen 1990, Patterson 1991). Goose densities or dropping densities have been used as surrogates for actual yield losses, for example on Islay, but agreement on the timing and frequency of counts, and hence payment levels, were difficult to reach (NGF 1998a). Overall, direct compensation for losses has not proved effective in reducing goose-agriculture conflict, either in Britain (NGF 2000) or abroad (Van Eerden 1990).

### Management of reserves for geese

Alternative feeding areas or refuges can be established and managed to attract geese off agricultural land and reduce damage levels (Owen 1990, Percival 1993, Vickery *et al.* 1994). Such refuges have existed in Scotland for some time; for example, Caerlaverock National Nature Reserve in south-west Scotland was designated in 1957.

A great deal is known about how to optimize the design and management of grassland refuges (for a review, see Vickery & Gill 1999). Most species require fields of at least 5 ha, near traditional roost sites with minimal disturbance. The attractiveness of the fields can be greatly enhanced by managing the sward through cutting or grazing and application of fertilizer. However, even well-managed reserves are unlikely to attract and support the entire target population throughout the winter, and so agricultural damage is still likely to occur on land adjacent to refuges. Furthermore, on a local scale the areas required are large, and although they can be reduced by effective management (Vickery & Gill 1999), such management can be costly.

### MANAGING THE GOOSE-AGRICULTURE CONFLICT: A CO-ORDINATED APPROACH

From the preceding sections it is evident that: (i) on their own, neither culling, scaring, compensation nor reserves provides an adequate solution; (ii) the conflict is likely to escalate as goose populations increase; (iii) the problem is highly localized and very variable with respect to damage levels so solutions must be site specific; (iv) at the national level, there must also be a degree of commonality and equity across sites; and (v) because many of the species are migratory and protected by international laws, solutions must meet international conservation obligations.

The Islay Goose Management Scheme addresses the agricultural impacts of Greenland White-fronted Geese *Anser albifrons flavirostris* and the Greenland population of Barnacle Geese *Branta leucopsis*. Photo: Paul Marshall.

Other countries in Europe suffer from goose-agriculture conflict, and the most successful resolution of the conflict appears to be closely linked to the provision of a co-ordinated approach. A mixture of techniques has been used to reduce conflict, from uncoordinated shooting or non-lethal scaring (e.g. Poland, France, Romania), through regional co-ordination of compensation and management (e.g. Germany), to nationally co-ordinated schemes that include scaring, compensation and land management (e.g. The Netherlands, Sweden, Norway). Under the Dutch system, the legislation that regulates the hunting of geese also provides a public body that advises farmers on how to avoid damage. This public body also pays compensation to those farmers adversely affected by geese, with part of the funding coming from hunting license fees. However, compensation payments increased rapidly from 1977 to 1986, so other techniques were developed, such as providing reserves and changing crops away from those favoured by geese (Van Eerden 1990). A national policy was implemented in 1991 that encouraged the planting of less sensitive crops, the use of non-lethal scaring, compensation and dedicated waterfowl reserves (NGF 1998b). In this way, geese could be managed in reserve areas both by attracting them into the reserves through positive land management, and by moving them away from commercial farmland by scaring and planting crops unlikely to be damaged by geese. This co-ordinated approach inside and outside reserves, involving payments, appears to have helped considerably in reducing goose-farmer conflict in The Netherlands.

The approach in Scotland has been to develop a national framework with locally devolved schemes, ensuring a high degree of input from stakeholders at all levels. Local goose management schemes were launched in Scotland in the early 1990s. These local schemes used a combination of scaring, shooting and refuge management alongside payments to farmers (e.g. Cope *et al.* 2003), but initially were independent of one another and uncoordinated at a national level, with no forum for sharing experience. In 1997, the National Goose Forum (NGF) was formed to develop a National Policy Framework (NPF) for the management of geese and agriculture in Scotland (NGF 1997a). The aims of this policy were: (i) to meet the UK's nature conservation obligations; (ii) to minimize the economic losses to farmers; and (iii) to maximize the value for money of public expenditure (SOAEFD 1996). As well as advising ministers on this national policy, the NGF provided advice to local goose management groups, oversaw the monitoring of goose populations in Scotland, and co-ordinated research on geese and agriculture (NGF 1997b). Members

included those with farming, conservation, wildfowling and government interests (NGF 1997b).

The NGF delivered the National Policy Framework in 2000 (NGF 2000), at which point government ministers approved the continuation of local goose management schemes. The National Goose Monitoring Review Group (NGMRG) replaced the NGF as the national co-ordinating organization, with the remit of assessing, on an annual basis, the proposals from local goose management groups for conformity to the guidelines set out in the NPF. These local groups develop proposals tailored to local needs, and are given the primary responsibility for administering schemes on the ground (SOAEFD 1996). Thus, the general parameters for goose management schemes are set at the national level, determined by constraints, while local groups ensure that the details match local needs.

## CONCLUSIONS

Scotland is an important part of the international flyway for several species of geese, especially for those species in which the entire breeding population spends the winter within Scotland. However, the success of international conservation action has, in many cases, brought about a conflict with local agricultural interests. In an attempt to reduce this goose-agriculture conflict, several options have been considered (culling, scaring, compensation schemes and alternative feeding areas), but the most effective way in which to move from a conflict situation to a coexistence situation has been to produce an integrated strategy.

The key strength of the strategy adopted for goose management in Scotland is its combination of top-down and bottom-up management whereby government ministers control the general parameters and local groups ensure that the details are tailored to local needs. This approach should be widely applicable to other cases of wildlife conflict. The clear definition of agricultural, conservation and budgetary goals at the national level has led to a marked reduction in perceived conflict without resorting to a strategy of extermination. At the same time, the fact that local stakeholders in conflict areas have strong input to the form of local schemes has been crucial to their widespread acceptance. This is perhaps best demonstrated by the fact that levels of interest in goose management schemes have increased, as has the geographic spread of proposed schemes.

## ACKNOWLEDGEMENTS

We are grateful to many people who supplied information: G. Banks, B. Bremner, G. Churchill, G. Dalby, J. Doherty,

L. Griffin, R. Hearn, E. Laurie, J. Love, M. MacKay, I. Patterson, E. Rees, A. Robertson, and F. Younger. N. Read, S. Gough and R. Hooper helped in the production of the manuscript. JAV's involvement was partly funded by the Joint Nature Conservation Committee.

### ABSTRACT

During the decade of the 1990s, North American waterfowl managers detected extraordinary increases in populations of Lesser Snow Geese *Chen caerulescens caerulescens*, Greater Snow Geese *C. c. atlanticus* and Ross's Geese *C. rossii*. This led to more intensive study of available information by several teams of scientists who concluded initially that mid-continent Lesser Snow Geese were causing irreversible damage to their Arctic breeding habitats. They recommended that goose numbers should be reduced through proactive management programs to levels that could be sustained for the long term. Other reports concluded that Greater Snow Geese would soon be at similar levels and that Ross's Geese were also more abundant than ever previously recorded. Waterfowl population managers took actions to achieve the recommended objectives through the promulgation of management interventions that have now been in place for several years. We review several critical elements of how managers have responded to these conflicts with the mid-continent Lesser Snow Goose. These were: assure a strong science base existed to support management recommendations; consult fully with all stakeholders associated with the issue; develop clear resolve by management agencies to address the issue; communicate effectively with all stakeholders about the nature of the problem and the proposed management actions; implement management programs; and monitor the response of the targeted resource and adapt to information obtained from monitoring with additional or improved management practices.

### INTRODUCTION

The Lesser Snow Goose *Chen caerulescens caerulescens* is among the most well-studied of the world's waterfowl. In recent years, it has become sympatric throughout most of its range during breeding, migration and wintering periods in the mid-continent region of North America with the congeneric Ross's Goose *Chen rossii* (Fig. 1). Together, these species are generally referred to as 'light geese'.

A seminal publication by Cooke *et al.* (1995) summarized much of the basic biological information on the Lesser Snow Goose. Populations have grown rapidly during the past half century (Abraham *et al.* 1996). Researchers on Arctic and sub-Arctic breeding colonies started to detect changes in body condition and size (Cooch *et al.* 1991) as higher gosling mortality (Cooch *et al.* 1993, Williams *et al.* 1993) and degradation of habitats used by breeding geese (Jeffries *et al.* 1995) were observed as the goose populations grew. Despite these factors, the populations continued to grow as a result of increased adult survival (Francis *et al.* 1992). A variety of cause-and-effect rela-

**Fig. 1.** Generalized breeding, migration and wintering areas used by mid-continent Ross's Geese *Chen rossii* and Lesser Snow Geese *Chen caerulescens caerulescens* in North America (modified from Ridgely *et al.* 2003).

tionships have been explored but the general consensus is that the birds' pre-adaptation to thrive on the vast agricultural landscapes of North America (Fig. 2) is the dominant factor that has resulted in the observed changes (Jeffries *et al.* 2003).

Abraham & Jeffries (1997) provide a variety of data describing population trends of Snow and Ross's Geese. Up-to-date population estimates from the mid-winter period are presented in Fig. 3.

During the mid 1990s, researchers from across the Canadian and U.S. Arctic regions observed similar patterns as populations continued to grow in most breeding colonies. Concern began to emerge that population growth may have been occurring at such a rate that overabundant geese may have been causing serious damage to fragile Arctic habitats and that the populations might be "out of control" (Ankney 1996). The upshot of this concern was the formation of the Arctic Goose Habitat Working Group (AGHWG) by the Arctic Goose Joint Venture (AGJV)

**Fig. 2.** Mid-continent Lesser Snow Geese *Chen caerulescens caerulescens* stage on agricultural lands during spring migration. Waste agricultural grains have been preserved by cold winter weather and snow cover since the previous year's harvest.

**Fig. 3.** Status and population trends of mid-continent light geese from 1970 - 2005 (U.S. Fish and Wildlife Service 2005).

Management Board of the North American Waterfowl Management Plan (Anon. 1986). The Working Group engaged a broad cross-section of scientists, population managers and other interests with a stake in the future management of these geese to review the information available on population growth patterns. They were asked to decide if the burgeoning numbers of birds were a problem that should be corrected by management intervention.

The product of the group's work was a comprehensive report (Batt 1997) that concluded that the population was growing at such a rate that the birds threatened to become so abundant as to permanently destroy large tracts of their Arctic breeding habitats

**Fig. 4.** Geese have been excluded from this fenced area near La Perouse Bay on Hudson Bay, Manitoba, Canada. The grass and sedge vegetation from the surrounding land has been destroyed by feeding geese. High natural salinity of the subsoil has resulted in only the salt tolerant *Salicornia* sp. being able to survive. In time, further increased salinity will also remove the *Salicornia* and result in highly saline bare mineral soil from which there is no known mechanism that will allow recovery of the sward for decades into the future.

(Fig. 4). The destruction was expanding rapidly and thought to threaten the integrity of vast areas of the Arctic that are used by a multitude of other resident and migratory species. This was considered to be an ecosystem in peril, and it was recommended that the population be brought under control by decreasing adult survival through significantly increased harvest by hunters.

Several recommendations called for: legalizing hunting practices that had previously been illegal; extending hunting seasons through the winter and spring months during which hunting had been prohibited for decades; and allowing very high harvest limits for individual hunters. The AGJV Management Board approved the report, and the management community was faced with trying to bring about management interventions that had never been attempted before in waterfowl conservation. These changes were certain to result in considerable conflict among scientists, managers, hunters, aboriginal Canadians, public officials, the general public and interest groups that are opposed to hunting for any reason. Changes to harvest regulations were accomplished, and the management program proceeded following an extensive conflict resolution process that is the subject of this paper.

### RESOLVING CONFLICTS IN NORTH AMERICAN SNOW GOOSE MANAGEMENT

At the onset, we believe that few truly extraordinary measures were undertaken to make dramatic changes to the previous approach to Snow Goose harvest management. Indeed, the authors feel that the main accomplishments came about as a result of patient and disciplined attention to fundamentally important features of conflict resolution that must be followed by others in many situations. The most extraordinary steps required were a result of the international scale at which various phases of the effort had to be accomplished. These steps are reflected in Fig. 5 and are explained below in more detail. Note that most of these are not separate and independent steps that were taken in sequence. Rather, each contributed to the success of all steps as there was always considerable feedback to earlier and subsequent steps as managers developed new information and experience at every step of the way.

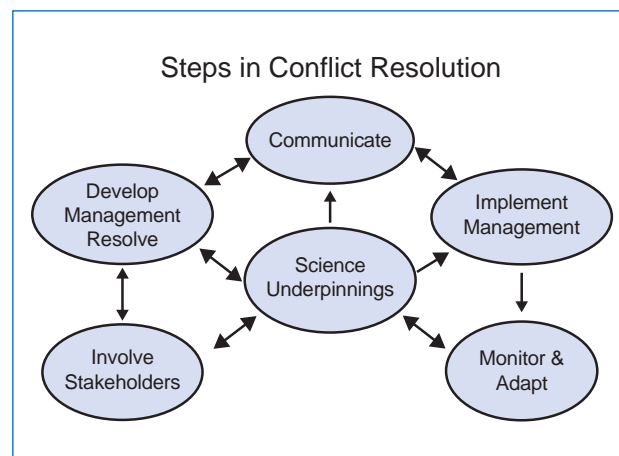

#### Science underpinnings

Wildlife management programs should be based on the best scientific information available. Managers are often faced with imperfect information, so it is simply their responsibility to use everything that is available to them to guide management decisions. This should be done in an open and transparent way, with peer review of the technical syntheses pertaining to the particular subject followed by consultation with all audiences with a stake in the actions that are ultimately undertaken.

With mid-continent light geese, there was a strong scientific record and extensive management experience on which to base the understanding of the threats that overabundant light geese posed to the Arctic ecosystems that they used heavily each year. The scientific literature was rich with information, and several members of the Working Group were considered to be among the most accomplished scientists that had extensively studied the birds and their habitats. This science was thoroughly and critically reviewed by the Group in the preparation of the Batt (1997) report, hereafter referred to as the Arctic Ecosystems in Peril report. In our view, this was the most critical step taken in the whole process, without which the additional actions, discussed below, would not have been warranted or successful.

#### Involve stakeholders

Because so many segments of society have an interest in the proper management of the waterfowl resource, it was critical to

**Fig. 5.** The interaction of steps taken in the resolution of potential and actual conflicts as a result of dramatically changed management strategies applied to mid-continent light geese in North America.

get them involved in the review and development of recommendations from the outset. The 17 members of the Working Group had skills and perspectives that contributed to the synthesis of the science and the generation of management recommendations: seven were research scientists; six were waterfowl managers; and two represented non-government conservation organizations. Further, several of the individuals had additional experience and training that allowed them to cross readily between, and integrate the perspectives of, many different interests.

Once all the technical information was assimilated by the Working Group, they developed a series of specific recommendations (Arctic Goose Habitat Working Group 1997). These were presented to, and fully reviewed by, the Arctic Goose Joint Venture Management Board at two meetings in 1996 and 1997 and during extensive interim discussions and communications between meetings.

After the scientific report had been delivered to the Management Board, it was recognized that taking the recommendations to the point where they could be implemented would require considerable consultation with other interested entities. The following section describes steps taken to focus more closely on the nature of the management interventions that were needed and, at the same time, expand the breadth of stakeholder consultation and communications that were critical to success.

#### Develop management resolve

Following approval of the report by the Management Board, it became the responsibility of the respective federal governments to begin the public decision-making process. At the same time, the lead federal agencies sought a wider review of the report and the recommendations through a Stakeholders' Committee (Appendix I) that was formed by the International Association of Fish and Wildlife Agencies (IAFWA) in the autumn of 1997. That group provided a series of recommendations that substantially supported the recommendations of the Working Group. They also provided an additional summary of concerns by participants that surfaced during the meetings held by the group.

The administrative flyways were all briefed by their representatives on the original Working Group or by one of the participants in the Stakeholders' Committee. This resulted in resolutions from each flyway in which they substantially

endorsed the recommendations that were contained in the Arctic Ecosystems in Peril report. These resolutions were followed by a series of similar endorsements from such diverse national groups as The Audubon Society and The Ornithological Council.

## Communicate

Any major change in the management of an exploited natural resource that has traditional patterns of use and different ethical perspectives will be of great interest to resource “users.” It was recognized from the onset of this initiative that there would be many interested parties that must be informed about the scientific underpinnings of any new management actions and would need assurance that all possible alternative courses of action were properly investigated.

Communications on this issue permeated every step taken by the AGJV Management Board and the Working Group. Initially, this took the form of dialogue between scientists and managers who were charged with making recommendations for future changes in management activities. The review of the Working Group report by the IAFWA Stakeholders’ Committee, and the critical reviews of the flyway councils and the ornithological societies were other steps in communications with organizations that reflect their members’ interests.

Additional communication forums were brought together by the Canadian Wildlife Service and U.S. Fish and Wildlife Service. For example, a series of workshops developed by the U.S. Fish and Wildlife Service was reported in Arnold (1998). There were numerous other formal and informal reports and communication items developed by the federal agencies in each country. Communication was a broadly pursued activity at many events throughout 1997, 1998 and 1999.

An essay by Robert Rockwell and colleagues (1997) in the winter 1997 issue of *The Living Bird*, the magazine of the Cornell Laboratory of Ornithology, was a singularly important first piece to be shared with the public. It was written by three leading Snow Goose research scientists and accurately described, in words and pictures, what was known about the overabundance of Snow Geese and the devastation in some Arctic habitats.

From this point, we only single out the following major items as we believe they had a major influence on establishing the issue in the media. Because of the accuracy of their content, they also helped immeasurably to ensure that the information that was promulgated did not contain a lot of errors that would be prone to proliferation.

The first major newspaper piece was published in the *New York Times* in February 1997 (Brody 1997). It was based on Rockwell *et al.* (1997), but included a broader sampling of information and opinions from a variety of involved parties. It also accurately reported on the science which was critical in helping to ensure that the central messages did not diverge from the solid science that served as the basis for the management recommendations. Because the *New York Times* is one of the world’s leading newspapers, coverage in the *Times* helped put the Snow Goose issue into the mainstream of current news.

Following these two seminal items, there was a proliferation of national and regional newspaper, popular magazine, scientific society magazine, and radio and television stories about the plight of the mid-continent light geese. A detailed record was not maintained by the authors of this report, but each engaged in

between 200 and 300 interviews with the press during 1997 and 1998. Other individual members of the Working Group participated in a similar number of contacts by the press.

One of the most important communication items for the general scientific community was published in *BioScience Magazine* by Ben-Ari (1998). This piece was especially valuable because it was in a technical magazine with very high journalism standards that are constantly under scrutiny by the critical scientific community. It helped to reaffirm to a growing base of scientists that were aware of the issue that there was a strong scientific basis for management intervention.

One very valuable communication tool was a documentary video produced in 1998 by Ducks Unlimited entitled *Snow Geese in Peril*, with an accompanying book (Batt 1998a). Communications about this issue were going to be difficult because very few individuals would ever have the chance to visit the areas where the damage to the Arctic ecosystem was taking place. Video scenes came from several of the affected habitats that were used heavily by the geese and, through interviews with the principal scientists involved, the issue was brought fully illustrated in front of a multitude of audiences. The video was made available free on request to any interested party.

Finally, it was very important to inform public officials in the U.S. and Canada about the issue. This was done through several testimonials given in 1997 and 1998 by the authors to committees and elected officials of the U.S. and Canadian federal governments. Many other testimonials were provided to local, state and provincial governments by members of the Working Group or by individuals that became especially well-informed about the issue.

In summary, communication has been an integral component of the Snow Goose management program in North America - we believe to the extent that the program would have failed if it had not been done as fully as it was. Also, we reaffirm that all of the steps taken, including the extensive communications effort, had their grounding in the strong scientific basis that led to the recommendations for changes in light goose management strategies.

## Implement management

Both the Canadian Wildlife Service and the U.S. Fish and Wildlife Service promulgated changes in their management strategies for mid-continent light geese to come into effect during the 1997-1998 waterfowl hunting season. These actions were followed immediately by court actions pressed by groups in each country that did not agree with the new management programs. A thorough review of the background for these actions is beyond the scope of this paper. However, a legal challenge is a course of action that individuals or groups can take if they do not feel that the conflicts that they have with an issue have been adequately considered.

In each case, the challenge was towards the federal agency’s legal authority to implement the new management strategies under the Migratory Bird Management Treaty of 1916 between the U.S. and Canadian governments. In each case, the presiding judge ruled that the agency did indeed have legal authority to implement management actions that were supported by the best science available.

In Canada, the court ruled that the scientific basis of the Arctic Ecosystems in Peril report did not adequately address the

population status of the Ross's Goose, which would be affected by harvest that was directed at mid-continent Lesser Snow Geese. The Canadian Wildlife Service subsequently implemented regulations that would provide protection for Ross's Geese during the extended spring hunting period. Another working group was formed by the AGJV in 1999 to provide a complete review of the status and management of Ross's Geese (Moser 2001). This information has not yet been used to appeal the decision by the court to exclude Ross's Geese from the new management strategies.

In the U.S., the court also commented that it would rule in favor of any future challenge to the light goose management program if it was based on the need for an environmental impact statement (EIS) of the proposed management action. As a result, the U.S. Fish and Wildlife Service decided to delay implementation of the program until an EIS could be completed and approved.

This potential setback was overcome by the 1999 Arctic Tundra Habitat Emergency Conservation Act of the U.S. Congress (H.R. 2454-3), which authorized the U.S. Fish and Wildlife Service to implement the new management strategies until the EIS was completed. We believe this action was only possible because of two of the fundamental factors that are discussed above, namely: the strong scientific basis for the management actions; and the extensive and effective communication program that was implemented by the members of the AGJV. In short, the issue was so well understood by the policy makers and the public in general that it was broadly agreed that a change in the management of these birds was very desirable for the long-term sustenance of the Arctic ecosystems upon which the geese and other wildlife are dependent.

### Monitor and adapt

The Arctic Ecosystems in Peril report provided initial guidance for an evaluation program to monitor populations and key vital rates of the mid-continent light geese (Rusch & Caswell 1997). The Management Board subsequently assigned the AGJV Technical Committee the task of expanding this report into a more comprehensive monitoring program with detailed plans and initial budgets (AGJV Technical Committee 1998). This report was approved in October 1998 by the Management Board and has provided guidance for the subsequent monitoring of the effects of the new management actions.

The next step in this overall process is soon to unfold with an overall evaluation of what has been accomplished with the management actions that have been undertaken. It will also be critical to integrate information that has been developed through new research that was not available when this program started. Additionally, other syntheses of information about light geese and management alternatives have been developed since this management program started (Batt 1998b, Moser 2001, Johnson & Ankney 2003).

These evaluations will likely result in adjustments to the management strategies that are underway to reduce light geese to levels that can be sustained by their breeding habitats. When that occurs, most of the events and steps outlined in this paper to resolve or prevent future conflicts will be repeated to some extent, as managers seek to continually improve their approaches to managing light geese in North America.

### ABSTRACT

Environmental impact assessment of offshore wind farms requires an assessment of waterbird habitat loss, both physical and as a result of behavioural avoidance. This paper briefly summarizes the aerial survey transect sampling methods and approach adopted to undertake such assessments at two marine wind farms constructed in Danish waters in 2003. At present, bird encounter rates per unit effort on track have been used to assess the “preferences” of bird species for wind farm and adjacent areas and to make a statistical comparison of abundance and distribution before and after construction. Preliminary results from the two case studies are presented. These results suggest that divers (Gaviidae), grebes (Podicipedidae), gannets (Sulidae), some seaducks (Anatidae) and auks (Alcidae) avoid wind farms after the erection of turbines, whilst some species of gulls (Laridae) and terns (Sternidae) show some preference for sites in which wind farms have been constructed compared to the previously undeveloped sites. A description of an improved application is given. This combines distance sampling and spatial modelling techniques currently being developed, and will provide more robust comparisons of waterbird density surfaces with respect to pre and post-construction development scenarios to support more effective environmental impact assessment in marine environments.

### INTRODUCTION

The dramatic development of offshore wind farms in inshore/nearshore marine waters around Europe in recent years has focussed attention on the hazards they present to waterbirds and other migratory birds that encounter these constructions. Direct impacts, such as result from direct collision, cause mortality that affect the demography of populations, but local effects (such as the extra energy costs incurred by avoidance flights or habitat loss) are more difficult to quantify. Habitat gain and loss as a result of the construction of wind turbines can be considered on two spatial and temporal scales. Firstly, long-term but small-scale change results from the physical loss of feeding substrate under foundations and anti-scour protection and the physical gain associated with the creation of these new substrates. However, since the area of foundations and anti-scour protection rarely exceeds 2% of the total sea area covered by a wind farm, this change in food availability is considered trivial in most instances. Secondly, effective habitat loss may result from behavioural displacement of foraging birds, the response to specific stimuli such as rotating turbines and/or the activity of maintenance vessels in the vicinity. In theory, if birds avoid coming closer than half the distance between adjacent turbines, the effective loss of habitat exceeds the entire area of the wind farm. In practice, birds may avoid going between the rows of

turbines because of the confining visual effects, such that even at avoidance distances less than half the distance between turbines, net habitat loss equivalent to the size of the wind farm occurs. Since birds may habituate over time to unfamiliar constructions in their foraging distribution at sea, there may be a temporal component to their avoidance responses.

Environmental impact assessment of offshore wind farms requires a basic evaluation of the significance of such habitat loss. Indeed, assessment of the consequences at local and population/flyway level may be a foregone requirement, for example, under environmental criteria placed on construction. Hence, it is important to quantify habitat loss in a way that accounts for the spatial and temporal heterogeneity in bird distributions prior to and after construction. In this short account, we summarize the approach taken to assess effective habitat loss to foraging waterbirds based on experiences from two wind farms constructed in Danish inshore waters mainly during 2003. These are situated at Horns Rev (off the exposed west coast of Jutland in the North Sea) and Nysted (south of Rødsand in the brackish Baltic). Both projects have already been widely reported elsewhere (e.g. Christensen *et al.* 2004, Kahlert *et al.* 2004, Petersen *et al.* 2004), but are summarized here. We also discuss the current state of development of the necessary tools required for effective assessment of the degree of habitat loss to foraging birds offshore.

### METHODS

The strategic approach adopted in the study of the effects of the two Danish offshore wind farms has been to use aerial surveys to describe changes in bird abundance and distribution as a proxy measure of habitat loss. The problem associated with such assessments is the very large degree of spatial and temporal heterogeneity associated with bird distributions in dynamic media such as inshore marine waters. Benthic feeders (such as eiders *Somateria* spp. and scoters *Melanitta* spp. feeding on marine bivalve molluscs) may show relatively simple responses to factors such as water depth and substrate type that determine the nature and profitability of the benthos they feed upon. Nevertheless, temporal variation in the abundance of benthic feeders will be subject to temporal variation in spat settlement and age class distributions of their prey. Bird species preying on pelagic fish, such as divers (Gaviidae), grebes (Podicipedidae) and auks (Alcidae), are even less predictable, dependent upon temporal and spatial patterns of distribution and abundance of their highly mobile prey.

To enable a pre and post-construction comparison of the bird distribution and abundance in such heterogeneous systems, it is essential to survey and re-survey a sufficiently large geographical area with high temporal frequency. This BACI (before-after control-impact) type of design should encompass sampling bird

**Fig. 1.** Diagrammatic representation of theoretically constant bird densities along a transect prior to construction of offshore wind farms (broken line), compared with post construction (solid line). The features of interest are the extent of complete habitat loss (solid arrow) and the extent of reduced densities (broken arrow).

densities within:

- the area physically affected by the construction area;
- an area around this where behavioural avoidance may also cause an effect (assumed to be a gradient of avoidance with increasing distance from the turbines); and
- a reference area where bird distributions are likely to be unaffected by the construction of the wind turbines.

Such sampling needs to be undertaken as frequently as necessary to characterize changes in temporal abundance throughout the annual cycle. In two-dimensional space, we may hypothesize complete bird avoidance within a specific distance of the turbines (Fig. 1). In this case, the objective is to measure the area of displaced birds, both in terms of defining the extent of areas of water without birds and areas of water with reduced densities relative to the baseline. The ideal objective for any sampling protocol is therefore to generate bird density surfaces over large areas of open sea using data:

- from as large a reference area as possible;
- sampled as simultaneously as possible;
- gathered with the greatest level of spatial precision possible; and
- using observation platforms that cause least disruption to the patterns of abundance and distribution of undisturbed birds.

For this reason, the Danish studies have adopted aerial survey using high-winged twin-engined aircraft to cover large areas of open marine waters as rapidly as possible using internationally agreed standardized data collection protocols (described in Camphuysen *et al.* 2004).

Initially, a very simple analytical approach has been adopted to analyse these transect count data, based on encounter rates of birds or bird clusters observed on transects per unit effort. This approach determines the relative number of birds of different species that would be susceptible to potential disturbance effects from the wind turbines based on encounter rate corrected for observation effort. The method assesses the relative importance of the wind farm area and the adjacent waters, generally a zone within 2 and 4 km of the outermost turbines of a wind farm (see methods in Petersen *et al.* 2004). The method describes the “preference” of bird species for the wind farm area and adjacent zones of differing extent immediately adjacent to the construc-

**Fig. 2.** Diagrammatic representation of theoretical modelled bird densities (with confidence intervals) along a transect sampled prior to construction of offshore wind farms (pecked line), compared with post construction (solid line). The features of interest are the extent of complete habitat loss (solid arrow), the extent of reduced densities (pecked arrow), and hence the difference in overall densities between the two samples.

tion area. In doing so, we define the potential impact of loss of these areas relative to the preference shown by the species for the entire study area. In a typical analysis, species encounter rate was calculated for all pre-construction surveys combined, and compared with the data generated from post-construction surveys. For these zones, the preference of the most numerous occurring species is calculated using Jacob's selectivity index (Jacobs 1974). Jacob's selectivity index ( $D$ ) varies between -1 (all birds present outside the area of interest) and +1 (all birds inside the area of interest), and is calculated as:

$$D = (r - p) / (r + p - 2rp)$$

where  $r$  = the proportion of birds in the area of interest compared to the birds in the whole study area, and  $p$  = the proportion of the survey effort in the area of interest compared to the total survey effort in the whole study area. The difference between the two proportions is tested as the difference between the observed number of birds in the area of interest and the number expected in this area, estimated from the share of the survey effort in relation to survey effort in the total area (one-sample  $\chi^2$ -test). Tests are made on the basis of number of observed clusters, rather than birds, because observations of individual birds fail to meet the statistical criteria of being independent. However, for some species a cluster can represent a wide range of number of individual birds, varying from 1 to 26 000 in the case of the Common Scoter *Melanitta nigra*, so the use of cluster data may appear unhelpful.

An alternative approach has been to compare the pre- and post-construction frequency distribution of birds at increasing distance intervals out from wind turbines. Using GIS and other tools to construct species cumulative percentage frequency distributions of bird numbers in successive 500 m distance intervals away from the wind turbines, it is possible to use non-parametric tests to compare pre- and post-construction distributions for significant displacement effects.

However, the ultimate aim has been to develop a more sophisticated suite of analytical tools to permit more robust comparisons of before/after densities of birds. The use of survey data collected at different distances from the observer aircraft provides transect counts of birds assigned to distance categories out from the transect track-lines. Such a line-transect count approach allows the use of Distance Sampling techniques

(Buckland *et al.* 2001) to generate bird densities, by modelling detectability functions to correct bird density estimates for the decline in detectability probability with increasing distance from the observer. The use of such techniques also enables the incorporation of factors and covariates (such as individual observer functions, differences in sea state and light conditions, etc.) into modelled densities of birds encountered. The ultimate objective for this project has been to develop spatial modelling techniques that use line-transect counts as samples and generalized additive models to construct bird density surfaces as a function of spatially explicit covariates (e.g. Hedley *et al.* 1999, Hedley & Buckland 2004, Clarke *et al.* 2004). This method offers an approach to the theoretical objectives established in Fig. 1 by constructing a modelled bird density surface with confidence intervals over extended areas of sea generated from aerial line-transect census data (see Fig. 2). For benthic feeding birds, the covariates used in the predictive-modelling exercise could include environmental factors such as water depth which determine profitability of shallow inshore waters (e.g. Common Scoters forage more in shallow water depths than would be expected by chance; see Fig. 17 in Petersen *et al.* 2004). In the fullness of time, other environmental covariates, such as bottom substrate type and bottom aspect can be incorporated to improve the effectiveness of such model estimates. For seabirds dependent on a more dynamic food base, such as pelagic fish, the challenges to generating density surfaces are considerably greater. However, incorporation of macro-environmental parameters, such as current, salinity and water temperature profiles (which are now routinely modelled throughout the water column around many European coasts) which correlate with prey abundance, offers some opportunities to generate bird density surfaces for these organisms as well.

At present, software to generate such modelled density surfaces is still being developed in collaboration with the Centre for Research into Ecological and Environmental Modelling at the University of St Andrews in Scotland, for implementation in the near future.

## RESULTS

Results from tests based on the numbers of bird clusters encountered have been used to compare pre-construction and post-construction distributions to look for changes in preference for the wind-farm area and surroundings between the two “treatments”. Use of the Jacobs selectivity index has suggested changes in distribution of different species, both in terms of avoidance of, and attraction to, the structures, as outlined below (see also Christensen *et al.* 2004 and Petersen *et al.* 2004).

At both sites, analysis of the preference indices calculated for different species prior to construction confirmed that the majority of waterbirds avoided the wind farm area at both sites. Bird densities were generally low before any construction activities on the site, making comparisons after construction difficult, especially since at present there is only a single post-construction year available for comparisons.

At Horns Rev, divers, Northern Gannets *Sula bassana*, Common Scoters and Guillemots/Razorbills *Uria aalge/Alca torda* showed an increased avoidance of the wind farm area (and zones within 2 and 4 km of it) after the erection of the wind turbines. In contrast, Herring Gulls *Larus argentatus* showed a decreased avoidance of the wind farm area, while Great Black-

backed Gulls *L. marinus*, Little Gulls *L. minutus* and Arctic/Common Terns *Sterna paradisaea/S. hirundo* showed a shift from avoidance before construction to a preference for the wind farm area after construction (Petersen *et al.* 2004).

At Nysted, Long-tailed Ducks *Clangula hyemalis* and Common Eiders *Somateria mollissima* showed a reduced preference for the wind farm area (and zones within 2 and 4 km of it) after the erection of the wind turbines. Herring Gulls showed a slight increase in preference for the wind farm area and the zones around it after construction (Kahlert *et al.* 2004).

## DISCUSSION

The bird studies being carried out at Nysted and Horns Rev during the period 1999-2006 were initiated under the terms and conditions placed upon the granting of permission to construct wind farms at the two sites by the Danish authorities. These studies have been carried out before, during and after construction of both wind farms. The installation of wind turbines was finished in autumn 2002 (Horns Rev) and summer 2003 (Nysted). However, the construction phase was too short to offer any opportunity to assess the effects of the physical construction of turbines on bird distribution. Construction activities coincided with periods of the year when fewest feeding birds were in the vicinity (by prior design), with the result that no assessment could be made of the disturbance effects of building work during that phase. Furthermore, the data reported here (for the period up to 2004) represent material gathered from one year or less into the initial operational phase of the wind farms. For this reason, it is not possible to quantify natural variation between years, seasons, species and sites and the possible habituation effects during the operational phase. Therefore, it must be emphasized that these results are to be considered as preliminary, and must await further compilation of data before firm conclusions can be drawn with respect to the impact on birds. The final environmental impact assessment for the two wind farms will be undertaken upon termination of the environmental monitoring programmes in 2006.

There remains considerable scope to improve on these methods and to test many of the assumptions associated with their use. In particular, distance sampling necessitates that all objects on the track-line are observed from the count platform, an assumption that has considerable bearing on the ability to generate unbiased density estimates. Studies to assess whether this assumption is met, using double-platform repeat counting, have been attempted, including the use of two aircraft and vertical photographic techniques to capture scenes of the distribution of birds on the sea surface to which count observers were exposed in the following aircraft. Such techniques proved so effective, and the imagery quality sufficient to enable automated computer identification and counting of bird “objects” on the photographs, that alternative methods of counting birds at sea have presented themselves. The use of geo-rectified vertical photography of large areas of sea surface, and subsequent computer based pattern recognition software to identify, position with great spatial accuracy and ultimately count birds on that surface, frees the need for distance sampling to generate bird densities, and offers some very exciting prospects for future developments in this field.

## ACKNOWLEDGEMENTS

We gratefully acknowledge the help and support of our NERI colleagues, especially the aerial survey observers, Ib Clausager,

Johnny Kahlert, Thomas Kjær and Mark Desholm. Our thanks also to David Borchers, Sharon Hedley and colleagues at St Andrews University for support with developing analytical techniques and to E2, Elsam and their staff for funding and support for the two Danish case studies reported here.

Burton, N.H.K. 2006. The impact of the Cardiff Bay barrage on wintering waterbirds. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 805.

Cardiff Bay (51°27'N, 3°10'W), a 200 ha area of intertidal mudflats and saltmarsh at the mouth of the Severn Estuary in the UK, was enclosed by a barrage on 4 November 1999. The consequent inundation of the bay has created a freshwater lake that now forms the centre point for the redevelopment of Cardiff's former docklands.

This paper provides an overview of results from 14 years of monitoring which aimed to determine the impacts of this habitat loss on the waterbirds that formerly wintered in the bay. Peaks of 310 Shelduck *Tadorna tadorna*, 120 Oystercatcher *Haematopus ostralegus*, 790 Dunlin *Calidris alpina*, 120 Curlew *Numenius arquata* and 300 Redshank *Tringa totanus* occurred in the bay in the winter immediately before barrage-closure; both Dunlin and Redshank had declined in number over the 10 pre-barrage years.

Between 1989 and 2003, waterbird numbers were monitored both in the bay and neighbouring areas. The results of these counts were used to show how the waterbird community changed following closure and whether displaced birds were able to re-locate to neighbouring sites.

Impacts on the movements and survival of Redshank were also monitored through colour-ringing and radio-tracking. Prior to closure, individual Redshank were highly site-faithful to the bay both within and between winters (Burton 2000) and were thus seen as being particularly at risk from its loss. Over 450 Redshank were individually colour-ringed in the bay in the five years preceding closure. Twenty Redshank were additionally radio-tagged there in October 1999. Following closure, birds were also caught to look at changes in their body condition.

The inundation of the bay resulted in the loss of all of the mudflats, but left a fringe of saltmarsh. Although the new freshwater lake is used by some waterbirds, the overall numbers and diversity of species have been greatly reduced. The loss of species' diversity (from a mean of 26.5 to 22 waterbird species per year) has been due, primarily, to a loss of waders, which now only use the site as an occasional high tide roost.

Almost all the Shelduck, Oystercatcher, Dunlin, Curlew and Redshank that formerly used the bay were displaced by its inundation. Counts in the first winter following closure indicated that some displaced Shelduck, Oystercatcher and Curlew settled at adjacent sites within 4 km - the Rhymney Estuary and Orchard Ledges. However, these increases were not sustained in following winters. It was not possible to determine whether displaced Dunlin were able to settle elsewhere due to an ongoing decline of the local population (unpubl. data).

Observation of colour-ringed and radio-tagged birds supported the evidence from counts that most Redshank were also displaced to the Rhymney Estuary, though in the winter

following closure, some displaced Redshank were also recorded at other sites up to 19 km away. The loss of birds from the bay could have accounted for the overall increase in numbers observed at Rhymney over the four winters subsequent to closure (Burton *et al.* 2006). Displaced colour-ringed birds using this area were seen on mudflats by the River Rhymney and Cardiff Heliport. Radio-tracking had shown that the Heliport mudflats were formerly used only at night (Burton & Armitage 2005), probably due to disturbance during the day from helicopters.

Although count data suggested that Redshank displaced from Cardiff Bay were able to settle at Rhymney, analysis of biometric data revealed that adult Redshank from the bay had difficulty in maintaining their body condition in the first winter following closure. Adults which were displaced from Cardiff Bay to Rhymney were significantly lighter than those that they joined (Burton *et al.* 2006).

Most significantly, the survival rate of adult Redshank displaced from Cardiff Bay declined between the two years prior to closure and the three following years. Given that there was no significant change in the annual survival rate of Rhymney-based Redshank over this time, it seems likely that this was a direct consequence of the birds' displacement (Burton *et al.* 2006).

The results of this study indicate that waterbirds may have difficulty in settling in new areas following habitat loss. Birds displaced by the inundation of Cardiff Bay only moved to the nearest available alternative sites. There was reduced survival in the population of displaced birds of at least one species. Initial increases in numbers at neighbouring sites were not sustained.

### ACKNOWLEDGEMENTS

The study was funded from 1989 by the Cardiff Bay Development Corporation and from 2000 by the Council of the City and County of Cardiff. Particular thanks are due to those BTO staff who helped with counts and Steve Dodd, Graham Couchman and Peter Ferns for their help in ringing activities.

## The conflict between shellfisheries and migratory waterbirds in the Dutch Wadden Sea

Bruno J. Ens

Ens, B.J. 2006. The conflict between shellfisheries and migratory waterbirds in the Dutch Wadden Sea. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 806-811.

### ABSTRACT

At the end of the 1980s, the supply of nutrients (especially Phosphorus) to the Dutch Wadden Sea strongly declined. It seems likely that this decline in nutrients reduced the maximum shellfish stocks and the productivity of these stocks. Shellfish fishermen did not adapt to this reduced productivity, but attempted to deliver the same amount of shellfish to the market that they delivered during the 1980s. In this paper, I argue that this contributed to the mass mortality observed among Common Eiders *Somateria mollissima* and decline in numbers of wintering Eurasian Oystercatchers *Haematopus ostralegus* from 260 000 to 170 000. Two types of shellfisheries were involved: mussel culture and suction-dredging cockles. Mussel culture has the potential to increase the average stock of mussels in the sub-littoral part of the western Wadden Sea and probably did so by an estimated 15% in the 1990s. However, there is evidence suggesting that transport of mussels to culture lots in the southern part of The Netherlands increases during years of scarcity, thereby actually exacerbating the food shortage for the Common Eiders. During the period of declining productivity, the mussel farmers also increasingly exploited the inter-tidal mussel beds. This increasing exploitation contributed significantly to the decline of the inter-tidal mussel beds, which completely disappeared in 1990 and remained virtually absent for the next four years. The disappearance of the inter-tidal mussel beds is the primary reason for the decline in the number of wintering Eurasian Oystercatchers by an estimated 90 000 birds. Calculations indicate that the mechanized cockle fishery also contributed to this decline by reducing the carrying capacity for oystercatchers by an estimated 15 000 birds. The negative impacts of shellfish fishery on shellfish-eating birds occurred because insufficient quantities of shellfish were reserved for the birds.

### INTRODUCTION

The Dutch Wadden Sea is an internationally acclaimed natural area harbouring large stocks of mussels *Mytilus edulis* and cockles *Cerastoderma edule* which are an important source of food for several species of birds. The stocks of shellfish are also targeted by an intensive mechanized shellfish fishery. This paper reviews the impact of the shellfish fishery on shellfish-eating birds in the Dutch Wadden Sea. It does not consider bird species preying on the smaller sizes of shellfish, such as the Red Knot *Calidris canutus*, or bird species which do not prey on shellfish but whose habitat may be affected by the shellfish fishery. For those species, I refer the reader to Piersma & Koolhaas (1997), Piersma *et al.* (2001), van Gils *et al.* (2004), Leopold *et al.* (2004) and van Roomen *et al.* (2005). Instead, this paper focuses on those bird species that are in direct competition with the fishermen by feeding on the same large sizes of shellfish, i.e. the Eurasian Oystercatcher *Haematopus ostralegus* and the

Common Eider *Somateria mollissima*. Both species breed in the Wadden Sea, but numbers during winter are much higher due to the influx of large numbers of birds that breed elsewhere.

The large numbers of birds are among the natural values that give the Wadden Sea its high international importance. These high natural values receive protection from national legislation (since 1981) and international treaties, including the EU Birds Directive (since 1991) and the EU Habitats Directive (since 1996). Initially, the intense exploitation of shellfish by the mechanized fishery was not considered to be in conflict with proper protection of the birds and other natural values, but this situation changed around 1990 during a period with low shellfish stocks and high mortality of shellfish-eating birds (Steins 1999, Verbeeten 1999). It emerged that the existing legislation did not allow the Government to close areas for shellfish fishery to protect nature. In 1993, a new policy came into effect (the Sea and Coastal Fisheries Policy) that attempted to strike a balance between the interests of the fishermen and the interests of the conservationists, but the debate continued. Between 1993 and 2003, several amendments were made to the policy, but these failed to satisfy the conservationists. The evaluation of the Sea and Coastal Fisheries Policy in 2003 became entangled with another political hot potato: the extraction of gas from under the Wadden Sea. The Government set up a committee to provide advice on both the shellfish fishery and the gas extraction. This committee concluded that gas could be extracted without causing ecological damage, but that the current practices of the mechanized cockle fishery were not sustainable and that the current practices of the mechanized mussel fishery were perhaps not sustainable (Meijer *et al.* 2004). On the basis of this advice, the Government decided to close the Dutch Wadden Sea for mechanized cockle fishery from 1 January 2005 onwards. Remarkably, at the same time the Government issued one last permit for the cockle fishermen to fish in the autumn of 2004. This permit, together with many previous permits, was declared unlawful by the Raad van State because no proper assessment of the possibly significant negative effects on the ecosystem was provided. A recent ruling of the European Court of Justice (7 September 2004, case C-127/02) makes clear that such a proper assessment is required for any activity that does not directly contribute to the conservation of the area. Activities are only allowed when it can be proven that they do not significantly harm nature. This ruling may have important consequences for the mussel fishery that was allowed to continue under the new shellfish policy that came into effect in 2004 (LNV 2004). The Government asked J.M. Verschuuren to investigate if this new policy met with EU requirements. Verschuuren (2004) concluded that the new policy was an improvement over the old policy, but that many questions remained and that a final judgement could only be based on the actual permits.

Throughout this period of conflict and changing policies, mass mortality and declining numbers of shellfish-eating birds fuelled the debate on the impact of the shellfish fishery. Many studies were initiated, and this paper reviews the evidence that has emerged from these studies with regard to the contribution of both types of shellfish fishery to bird mortality and changes in bird numbers. The Sea and Coastal Fisheries Policy that came into effect in 1993 specifically aimed to minimize negative effects on shellfish-eating birds through a policy of food reservation: the shellfish fishery was stopped when shellfish stocks fell below a certain level. If the shellfish fishery contributed to the mass mortality and declining numbers of birds, it can be concluded that the policy of food reservation did not work and we must investigate why.

## METHODS

Ideally, the effect of the shellfish fishery should have been investigated on a strictly experimental basis. For various reasons, this proved to be impossible. Most of the research consisted of analysing and combining data sets collected for other reasons. In addition to statistical analyses of the data, mathematical models were developed and employed to investigate causal relationships. Additional data were collected as part of EVA II, a major evaluation study that ran from 1999 to 2003 (Ens *et al.* 2004). This material included analyses of historical records of mussel beds from fishermen and fishery inspectors, analyses of historical photographs for the occurrence of mussel beds, sampling the sediment to obtain recent estimates of silt content, sampling benthic invertebrates on fished and unfished cockle beds, measuring sediment, benthic fauna and bird densities in a fished and unfished control site, measuring cockle abundance in autumn to check the extrapolation procedure from the spring survey, and experiments on food selection by Common Eiders.

## RESULTS

### Decline in mussel production

Mussel culture was introduced in the Dutch Wadden Sea in 1951. Before that time, the only fishery of mussels was from wild beds. Once mussel culture became established, wild beds

**Fig. 1.** Annual landings of mussels from Dutch coastal waters. A distinction is made between mussels landed from culture lots in the Wadden Sea and from culture lots in the Oosterschelde. The timing of the introduction of mussel culture in the Dutch Wadden Sea and the current target production are also indicated. The year 1953 refers to the season 1953/1954, and so on. From Ens *et al.* (2004).

were only fished for seed mussels. These seed mussels are subsequently transported to culture lots (located in both the Oosterschelde and the western Dutch Wadden Sea) where they are left to grow to marketable sizes. Mussel production from Dutch coastal waters almost doubled between 1951 and 1970 (Fig. 1). Between 1970 and 1985, the total landings fluctuated around 100 million kg fresh weight, and since that time, this has been the target production of the mussel farmers. However, production has declined since about 1985, and an all-time low was reached in the season of 1991/1992, when only 41 million kg of mussels were landed. Production has not exceeded 60 million kg in the four most recent years.

We have no data for fishing pressure on the wild sub-littoral stocks before 1990, but estimates are available from 1991 onwards (Table 1). In the period 1991–2001, there was only one year with good recruitment (1996) and one year with normal recruitment (1992). All other years were below normal. To calculate fishing pressure, we added the amount fished in the following spring to the amount

**Table 1.** Fishing pressure on wild mussel stocks in the sub-littoral part of the western Wadden Sea. For each year, the reconstructed wild stock in autumn, the amount fished in autumn and the amount fished in the following spring (all in million kg fresh weight) are indicated. The penultimate column gives the fishing pressure as a percentage of the initial stock. Basic data from Bult *et al.* (2004). The last column presents the index of recruitment of mussels in the sub-littoral parts of the western Wadden Sea (0 = absent, 1 = local, 2 = normal, 3 = good, 4 = very good). The index is assessed in the spring following the recruitment (van Stralen 2002).

Year	Wild stock in autumn	Fished in autumn	Fished in following spring	Fished as % of initial stock	Index of recruitment
1991	26	14	5	75%	0.5
1992	56	25	23	84%	2.0
1993	45	0	24	53%	0.5
1994	56	17	19	64%	1.0
1995	42	8	15	56%	0.0
1996	78	18	29	60%	3.0
1997	124	20	44	51%	1.5
1998	41	0	18	44%	1.0
1999	51	18	18	70%	1.5
2000	14	0	4	28%	0.5
2001	56	19	23	76%	

**Fig. 2.** Midwinter counts of the Common Eider *Somateria mollissima* (mostly in January) in the Wadden Sea (eastern and western parts) and adjacent North Sea coastal zone. Data before 1993 from literature; data thereafter from RIKZ and Alterra. From Ens *et al.* (2004).

fished in autumn and compared this with the initial stock in autumn. During winter, stocks decline due to mortality, but the calculation assumes that this is compensated for by the growth in early spring, before stocks are sampled. Fishing pressure was always high, averaging 60% for the years 1991–2001 (Table 1). This means that low landings indicate a shortage of mussels.

#### Numbers, distribution and mass mortality of the Common Eider

Sub-littoral mussels have thin shells and a high flesh content, and this makes them a very profitable food item for Common Eiders (Ens & Kats 2004). Large stocks of sub-littoral mussels are only found in the western Dutch Wadden Sea, and this explains why the western Dutch Wadden Sea traditionally held the largest numbers of Common Eiders. However, since 1991, large numbers of eiders have also occurred in the North Sea Coastal Zone, where they feed on *Spisula* (Fig. 2). In the winters of 2000–2002, there were more eiders in the North Sea Coastal Zone than in the western Wadden Sea. During the 1980s, around 130 000 eiders wintered in Dutch coastal waters, but the numbers have decreased in recent years to around 110 000.

The periods with a changed distribution correspond to years with mass mortality, suggesting a link with the food supply (Camphuysen *et al.* 2002). Eider mortality (measured as the number of dead birds per km of beach) was regressed against estimates of different shellfish stocks. Long series of data were available for sub-littoral mussels (using a back calculation from the landings) and littoral cockle stocks (assuming data from the Balgzand to be representative of the entire Wadden Sea). Short and more precise series of data were available for sub-littoral mussels, littoral mussels, sub-littoral cockles, littoral cockles and *Spisula*. In both analyses, a shortage of sub-littoral mussels correlated significantly with increased mortality in Common Eiders (Fig. 3). There was no effect of other shellfish stocks when the stock of (large) sub-littoral mussels was controlled for in the analysis (Ens & Kats 2004).

#### Disappearance of inter-tidal mussel beds from the Wadden Sea

In 1990, the inter-tidal mussel beds virtually disappeared from the Dutch Wadden Sea, and it took more than a decade before they recovered (Fig. 4). According to Dankers *et al.* (2003), the area of inter-tidal beds fluctuated between 1 000 and 5 600 ha in

**Fig. 3.** Relationship between the mortality of Common Eiders *Somateria mollissima* (expressed in number of dead eiders per km of beach) and the stock of immature sub-littoral mussels in the Wadden Sea. When this stock was estimated by direct back-calculation from the landings (and the logarithm of the number of dead eiders was taken), the correlation was  $r = -0.57$ ,  $N = 25$ ,  $P = 0.003$  (Ens & Kats 2004). The stock of half-grown and older sub-littoral mussels can also be reconstructed in a more complex fashion, yielding more precise estimates for a smaller number of years (Bult *et al.* 2004).

**Fig. 4.** Comparison of the amounts of mussels fished from the littoral zone (stacked bars) for the years 1957–2004 (Dankers *et al.* 2003) with the development of the littoral stock (solid line) for the years 1990–2004 (Ens *et al.* 2004).

the 1970s. Assuming 25 000 kg fresh weight per ha (Dankers *et al.* 2003), this amounts to stocks varying between 25 and 140 million kg fresh weight. Mussel farmers (pers. comm.) blame heavy storms in January and February 1990 for the disappearance of the inter-tidal mussel beds. While storms may cause extensive damage to mussel beds, it is unlikely that they are the prime cause of the complete disappearance in 1990 for the following reasons. Firstly, several years with unprecedented high fishing pressure preceded the disappearance of the littoral beds (Fig. 4). Secondly, an estimated 42 million kg fresh weight were left in the spring of 1990, i.e. after the two storms (Fig. 4). Thirdly, the extent of the fishery in 1990 is underestimated because Dankers *et al.* (2003) assumed that the littoral fishery was restricted to the eastern Dutch Wadden Sea. However, in 1990 stocks of littoral mussels were high on the flats of the Balgzand in the western Wadden Sea, and these were all removed by fishermen (Beukema 1993). Fourthly, the littoral beds recovered after the fishery on the littoral beds was stopped (Fig. 4). Thus, there can be no doubt that the fishery was a major factor in the disappearance of the inter-tidal beds in 1990.

**Fig. 5.** Numbers of Eurasian Oystercatchers *Haematopus ostralegus* wintering in the Dutch Wadden Sea (average per year from August until March) for the winters 1975/76 to 2002/03. Missing counts were imputed; see van Roopen *et al.* (2005).

### Decline of the Eurasian Oystercatcher population

Before the inter-tidal mussel beds disappeared in 1990, it was estimated that over half of the Eurasian Oystercatchers wintering in the Dutch Wadden Sea lived on mussels (Smit *et al.* 1998, Ens *et al.* 2004). Model calculations indicate that in the following decade, cockles were the main prey item (Rappoldt *et al.* 2003a). These same calculations indicate that the cockle stocks during the 1990s were of insufficient size to maintain the 260 000 oystercatchers that were present in the 1980s. Without the cockle fishery, the carrying capacity in the 1990s was estimated at about 145 000 oystercatchers. Although this estimate has a large margin of error, there can be no doubt that the prime cause of the decline in the number of wintering oystercatchers (Fig. 5) was the disappearance of the inter-tidal mussel beds. The cockle fishery may have contributed as well, because the carrying capacity in the 1990s with the cockle fishery was estimated to be 15 000 birds lower than the carrying capacity without the cockle fishery (Rappoldt *et al.* 2003a).

## DISCUSSION

### Unravelling the complex chain of events

According to Ens (2003), at least eight different hypotheses exist to explain the decline in mussel production that occurred around 1990. Of these, the hypothesis that the declining production was due to a decline in the eutrophication of Dutch coastal waters recently received support from a study by Brinkman & Smaal (2004). They showed that input of nutrients to the western Dutch Wadden Sea, especially Phosphorus and to a lesser extent Nitrogen, declined during the 1980s. Using the ecosystem model ECOWASP, Brinkman & Smaal calculated that the declining nutrient inputs must have caused a strong decline in benthic productivity. Comparing the 1980s with the 1990s, the maximum stocks of shellfish almost halved. The actual stock will often be lower than the maximum stock, e.g. because of recruitment failure in the preceding years, mortality due to storms or icy winters, and heavy predation by birds or fishermen. However, when the maximum stocks are reduced, we would expect the average stock and the minimum stock to be reduced as well.

Fishermen could have adapted to the declining productivity by reducing their catches, but they did not. In 1990, when cockle stocks were very low, cockle fishermen successfully contested the decision of the Government to close half of the tidal flats for the fishery. Similarly, mussel farmers based their target production on

the years when productivity was at a maximum, and retained this target production during the subsequent years of reduced productivity. As a result, fishing pressure on the wild sub-littoral stocks of mussels was very high during the 1990s, averaging 60% of the stock per year. By comparison, fishing pressure on the total stock of cockles was much lower during the 1990s, averaging less than 10% of the biomass (Kamermans *et al.* 2004). The difference in exploitation pressure between the cockle fishery and the mussel fishery can be explained by 25% of the tidal flats being permanently closed to cockle fishing, the closure of the fishery in years of scarcity, and the extreme variability of the cockle stocks, making it impossible to fish a high percentage in good years.

The difficulty that the mussel farmers experienced in maintaining their target production under conditions of declining eutrophication may explain why they intensified seed-fishing on inter-tidal beds. This intensified fishery was a major cause of the disappearance of the inter-tidal beds, although the possibility that storms also played some role cannot be excluded. In addition, recruitment of mussels was reduced in the early 1990s (Ens *et al.* 2004). However, this could have been a consequence of the low mussel stocks, rather than a cause. Mussel spat preferentially settle on or nearby old mussels, and the current exceptionally low recruitment of littoral mussels in The Wash in the UK is explained as a consequence of the over-fishing of littoral stocks in the early 1990s (Dare *et al.* 2004). Irrespective of these details, there is no doubt that the mussel fishery played an important role in the disappearance of the inter-tidal mussel beds in the Dutch Wadden Sea, which was the primary cause of the decline in the number of wintering oystercatchers.

The relationship between the mussel fishery and Common Eiders is more complicated. Fishing pressure on sub-littoral mussels was high, but this does not prove that the mussel fishery was responsible for low stocks and thus for high mortality among Common Eiders. Culture lots are located in areas where natural recruitment of mussels is low, but where they grow and survive well (Bult *et al.* 2004). Transport of mussels to areas where they grow and survive better will increase the mussel stock, while transport from the culture lots in the Wadden Sea to culture lots in the Oosterschelde or to auction will decrease the mussel stock in the Wadden Sea. In the 1990s, the net effect of these opposing effects was probably positive. It has been estimated that the sub-littoral stock in the western Dutch Wadden

**Fig. 6.** Mussels landed from the Dutch Wadden Sea as a proportion of the total landings from Dutch waters, plotted against the total landings for the years 1970-2004. Each dot represents an entire season. Based on the data shown in Fig. 1.

**Table 2.** Estimates of the physiological food requirement and ecological food requirement of the Eurasian Oystercatcher *Haematopus ostralegus* (in kg wet flesh per bird per winter) at various locations with either mussels or cockles as the main winter food. The ratio between the ecological food requirement and the physiological food requirement is also given. The kg AFDM estimates of Goss-Custard *et al.* (2004) were transformed to kg wet flesh, assuming that 1 kg wet flesh corresponded to 0.1 g AFDM (Beukema & Cadée 1997).

Study location	Prey species	Physiological food requirement	Ecological food requirement	Ratio	Source
Exe Estuary	mussel	41	321	7.7	Goss-Custard <i>et al.</i> (2004)
Bangor Flats	mussel	41	263	6.4	Goss-Custard <i>et al.</i> (2004)
Burry Inlet	cockle	41	232	5.6	Goss-Custard <i>et al.</i> (2004)
The Wash	cockle	42	105	2.5	Goss-Custard <i>et al.</i> (2004)
Baie de Somme	cockle	35	174	5.0	Goss-Custard <i>et al.</i> (2004)
Wadden Sea	cockle	65	200	3.1	Rappoldt <i>et al.</i> (2003a)
Oosterschelde	cockle	60	150	2.5	Rappoldt <i>et al.</i> (2003b)

Sea was increased by an average of 15% during this period (Bult *et al.* 2004). However, if the transport of mussels from culture lots in the Wadden Sea to culture lots in the Oosterschelde is increased during years of scarcity, it is still possible that mussel culture actually decreases the stock during poor years. There is some evidence that this may actually happen, as the proportion of the landings that is obtained from the Wadden Sea is especially low during years of scarcity, i.e. when total landings are low (Fig. 6). A counter argument is that Bult *et al.* (2004) did not find a relationship between the amounts of mussels transported to the Oosterschelde and the total stock in the Wadden Sea on the basis of the reconstructed sub-littoral stocks. The problem with this argument is that the reconstruction assumes constant flows of mussels between culture lots in the Wadden Sea and Oosterschelde. Finally, apart from the possibility that the amounts transported increase during years of scarcity, there is also the possibility that sub-littoral stocks, like the littoral stocks, can be over-fished, thereby hampering recruitment.

### Policy of food reservation

The policy of food reservation that was part of the Sea and Coastal Fisheries Policy introduced in 1993 was specifically aimed at preventing additional food shortages for shellfish-eating birds in years of scarcity as a result of the shellfish fishery. Why did this policy fail? The simple answer is that insufficient amounts of food were reserved for the birds. A distinction must be made between the physiological food requirement and the ecological food requirement of a bird (Ens *et al.* 2004). The physiological food requirement is the total amount of food that an individual bird consumes during the winter to stay in good health. The ecological food requirement is the amount of food that must be present in the ecosystem at the start of winter so that the bird can satisfy its physiological food requirement during the course of winter. There are many reasons why the ecological food requirement is much higher than the physiological food requirement. In areas with high food stocks, interference between the birds sets a maximum limit to the level of exploitation. Furthermore, stocks cannot be exploited if shellfish size is too small, or stock density too low. Finally, even without bird predation, stocks decline in the course of winter due to mortality from other sources and individual shellfish losing body condition. The best data on the relationship between the physiological food requirement and the ecological food requirement are available for Eurasian Oystercatchers (Table 2). For

Oystercatcher populations that feed primarily on cockles, the ecological food requirement is between three and five times higher than the physiological food requirement. When mussels are the staple food, this ratio is even higher. Given the aim of the policy of food reservation, this policy should have been based on the ecological food requirement of the birds. Yet from its inception, the policy basically assumed that reserving food on the basis of the physiological food requirement would be sufficient. This assumption was criticized (Ens 2000), and some amendments were made following mass mortality of Common Eiders in the winters of 1999/2000 (Camphuysen *et al.* 2002) and 2001/2002 (Ens *et al.* 2002), making it more complicated but offering little improvement for the birds. In essence, policy makers continued to ignore the fact that a proper policy of food reservation should be based on the ecological food requirement. The new policy has abandoned food reservation as a management tool (LNV 2004). Whether this new policy offers sufficient protection for the birds remains to be seen.

### ACKNOWLEDGEMENTS

Without the persistent harassment and encouragement of Gerard Boere, this paper would not have been written.

### ABSTRACT

Requirements for the conservation of shorebird habitat are changing as human use of coastal wetlands has shifted from traditional, low-level, resource-conservative patterns to intense “frontier-style” occupation and conversion. Within coastal wetlands, salt flats are being targeted for development because they are considered barren wastelands, are “non-mangrove”, and are not protected by national legislation in most countries. In the Neotropics, the role of these wetlands as stopover sites for migratory shorebirds remains ignored or unknown by resource managers in most countries. We believe that increasing awareness is required to promote coordination efforts at regional and flyway level, to conserve these shorebird habitats and the potentially threatened migratory processes of these birds.

### INTRODUCTION

At a meeting of the International Wader Study Group (IWSG) in 2003, it was concluded that most species of shorebirds (waders) with known population trends were in decline all around the world, making this issue a matter of international conservation concern. Forty-eight percent of populations with known trends were found to be declining, in contrast to 16% which were increasing. The reasons for these declines were stated to be diverse and poorly understood (IWSG 2003). The IWSG was reluctant to state explicitly that there was a relationship between the decreasing shorebird populations and the considerable loss of coastal wetlands that had occurred as a result of recent human activities such as transformation of coastal wetlands for industrial aquaculture. Although the loss of mangroves and its resulting environmental effects have been well publicized and this awareness has triggered massive and effective conservation campaigns and conservation legislation, the loss of mangrove-associated salt flats remains unrecognized as a threat to coastal ecological processes including the long-distance migrations of shorebirds. Salt flats are extremely important components of stopover habitats for shorebirds in the Neotropics as elsewhere in the world. In this paper, we suggest that the declines of populations of shorebirds in the Western Hemisphere must be assessed in the context of the widespread loss of a naturally limited habitat (upper inter-tidal salt flats) and the exponential rate at which the remaining salt flats are being converted by a rapidly growing shrimp-farming industry on both the Pacific and Atlantic coasts of South America, as well as on the Pacific coast of Mexico and Central America. Salt flats are now, *de facto*, open-access areas into which anyone can encroach, or worse, are seen by governments as wastelands that should be reclaimed for the development of highly profitable activities.

Forty-nine species of shorebirds regularly breed in North America and undergo extraordinary migrations to wintering grounds as far south as the tip of South America (Tierra del Fuego). These birds migrate through some 13 countries in South America and seven in Central America. Many of these shorebird populations are showing significant decreases (Brown *et al.* 2001). Comprehensive management to ensure the survival of these species is made difficult by the fact that events occurring at migration stopover habitats are often unknown to resource managers and management agencies in the breeding grounds of the birds.

### Coastal wetlands: a resource of unknown extent

The extent of coastal wetlands in the Neotropics is poorly known. In general, it is estimated that coastal wetlands comprise less than 3% of the land surface of the Western Hemisphere (Bildstein *et al.* 1991). Large-scale development of coastal wetlands in the region is limited by physiographic and hydrological features to relatively few locations where tides and local hydrology act synergistically. Information on the extent of wetlands at a global scale has been found to be inadequate, but even the most basic information is not readily available for much of the Neotropics (Finlayson & Davidson 1999). Of even greater concern is that there is little agreement on what constitutes a wetland, and there are numerous gaps and inaccuracies in the information that is available. The resulting fundamental discrepancies in estimates of wetland cover and wetland type make the few existing estimates of dubious usefulness (Finlayson & Davidson 1999). Thus, too little information is available to make even an approximation of the current extent of coastal wetlands in the Neotropics, or to calculate the loss of habitat for migratory shorebirds on a regional basis.

Although salt flats are important elements of stopover habitats and constitute a significant feature of coastal seascapes in the Neotropics, they remain unrecognized as wetlands because they are frequently confused with dry, barren, non-tidal lands. The banded or zonal arrangement of associations inland from the sea or tidal channels is well recognized and described, but the hypersaline upper portions where high salinity is inimical to mangrove trees are mistakenly considered to be “bare” when, in fact, they maintain inconspicuous but important associations of epipellic (mud-living), tapetic (felt-forming) microorganisms. Although lacking above-ground vascular vegetation, the algal mats and bacterial films that grow on upper inter-tidal substrates are extraordinarily productive, and build up a complex and very rich trophic structure. Features such as salinas, albinas, coastal sabkhas or apicum-like structures are, in fact, productive marine depositional environments characterized by distinctive sedi-

ments (evaporitic mudflat facies, algal mats and mud-halite crusts) that reveal marine influence and origin (Galloway & Hobday 1996). The sediment bacteria, including autotrophic cyanobacteria and chemo-autotrophs, are food sources for a diverse and rich invertebrate fauna, and this crustacean/molluscan-dominated assemblage in turn provides an abundant and reliable food source for shorebirds of the suborder Charadrii that use these “bare” flats as staging areas during their long-distance migrations. Plovers, sandpipers and some migratory waterfowl are the major and most conspicuous users of these habitats as food sources. Hypersaline flats are a dominant feature of low-gradient coastal landscapes where climatic and oceanographic conditions give rise to extreme aridity and prolonged droughts. Examples of coastlines dominated by salt flats are those of north-eastern Brazil on the Atlantic coast, and those of northern Peru (Tumbes), most of the Ecuadorian coast, Panama, the Gulf of Fonseca and western Mexico on the Pacific coast. These habitats, which are of high value for shorebirds, are not generally recognized as wetlands by resource managers; they have remained unreported in the few available wetland inventories, and remain unprotected by national legislation in most countries in the region.

#### Industrial shrimp farming in the Western Hemisphere

Aquaculture is not a novel development in the Neotropics (the Incas practiced mariculture 500 years ago). However, shrimp farming on an industrial scale is a new development. This began in Ecuador in 1969 and has grown at a phenomenal rate of 10-30% per year in the last two decades, spreading rapidly to Peru, Panama, Mexico, Colombia and Central American countries during the 1980s. Industrial shrimp farming as practiced in

the Western Hemisphere differs from that in Asia by being an export-oriented and industrial-scale activity since its establishment. This is significant because the impacts of industrialized activities, in terms of demand for conversion of natural wetlands and degradation of the surrounding areas, are greater than those of subsistence-level aquaculture. Industrial-scale aquaculture is characterized by extremely detrimental impacts in terms of demands for space, intensity of development and the magnitude of the transformation of the coastal landscape.

On a global scale, shrimp farming has transformed itself from a traditional, small-scale endeavor into a US\$ 6 billion business with severe environmental repercussions for resources associated with coastal ecosystems. In 1995, aquaculture accounted for 30% of the total world shrimp production. If current trends continue, it will supply 50% of global demand by 2005 (the total world production of marine-farmed shrimps in 2001 was 1 270 875 MT). Much of the expansion required to meet the projected demand is expected to take place within Neotropical coastal wetlands, particularly in the remaining shorebird habitats in Central America, Mexico and Brazil. Brazil is projected to produce 160 000 MT by 2005: a 400% increase from the 2001 production level of 40 000 MT (Rocha 2004).

#### METHODOLOGY

This paper was developed in an effort to evaluate a probable cause for the observed declines in shorebird populations in the Western Hemisphere despite increasing conservation efforts and increasing regulatory structures on the breeding grounds. We use the term “shorebird” to refer to birds of the Suborder Charadrii. The words “shrimp” and “prawn” are often used interchangeably in the literature. Here the term “shrimp” is used to refer to

**Table 1. Shrimp production in converted coastal wetlands (mangrove and salt-flat habitats) in Latin America in recent years.**

Country	Marine farmed shrimp production (MT)	Coastal wetlands converted (ha)	Shrimp production ÷ coastal wetland area (MT/ha)
Ecuador (1996) <sup>(5)</sup>	120 000	130 000	0.92
Ecuador (1998) <sup>(1)</sup>	130 000	200 000	0.65

Peru (1996) <sup>(5)</sup>	5 000	3 000	1.66
Peru (1998) <sup>(1)</sup>	6 000	3 200	1.88
Nicaragua (1996) <sup>(5)</sup>	3 000	4 000	0.75
Nicaragua (1997) <sup>(6)</sup>	4 000	5 000	0.80
Brazil (1998) <sup>(1)</sup>	4 000	4 000	1.00
Brazil (2002) <sup>(2, 4)</sup>	50 000-60 000	11 016	4.54-5.44
Honduras (1996) <sup>(3)</sup>	10 000	12 000	0.83
Honduras (1998) <sup>(6)</sup>	12 000	14 000	0.86

Sources: <sup>(1)</sup> Hinrichsen (1998); <sup>(2)</sup> FAO (2002); <sup>(3)</sup> Rosenberry (1996); <sup>(4)</sup> Rocha (2004); <sup>(5)</sup> World Bank *et al.* (2002); <sup>(6)</sup> Rodríguez & Windevoxhel (1998).

Peneaid or tropical marine shrimps. In the US market, “shrimp” is the usual name for marine shrimps, but the term “prawn” often refers to freshwater shrimps or to large saltwater shrimps.

Shrimp farms are preferably established on upper inter-tidal flats. Recent awareness of the need to conserve mangroves has driven most new pond construction into salt flats. Because of the lack of information on wetland transformation in the hemisphere, the rate at which coastal wetlands are being transformed was estimated indirectly from production and yield figures from various sources. For Latin America and the Caribbean, we used FAO shrimp aquaculture statistics for the period 1984–1995 (FAO 1997). For Brazil, we used a data set derived from various sources spanning the time period 1997–2003 (Hinrichsen 1998, World Bank *et al.* 2002, Rocha 2004, WRM 2004, FAO 2005). Because the reported yields per hectare for individual farms are highly variable, depending on farm management procedures, local conditions and the emergence of disease, we have chosen to use aggregate (country-level) production statistics to assess the space requirements of the industry. Estimates of the potential space requirements for pond complexes and the resulting annual loss of wetlands were based on three levels of aggregate yield: low yield (<1 MT/ha), medium yield (1–3 MT/ha) and high yield (>3 MT/ha). Yields lower than 0.5 MT/ha are considered to be below the profit threshold and were disregarded. Low yields reflect poor farm performance, unsuitability of environmental conditions or emergence of disease, whereas high yields reflect higher farm performance and adequate environmental subsidies but require larger investments and involve greater risks (Quarto 2004, WRM 2004).

## RESULTS

Shrimp production in Latin America was reported to be 146 000 MT in 1995, and the industry has shown a steady linear increase in production of approximately 10 000 MT per year since 1984 (FAO 2005). Production yields range from 0.65 to 4.50 MT/ha (Table 1). Based on reported production and production trend figures, the rate of conversion of salt-flat habitat is currently estimated to be in the range of about 4 000 ha/year (medium yield) to 10 000 ha/year (low yield). Medium yields are most likely to be the result of frequent disease outbreaks in all production areas, the large number of idle ponds (>20%) due to disease and environmental problems (such as El Niño events and other flood causes), and the need to clean and disinfect ponds regularly. Projections for the expansion of the industry in Brazil suggest that the rate of occupation of coastal wetlands (16 000 ha/year) will exceed by a factor of four the present estimate of the annual conversion rate based on recent production levels. This is because of the unrestricted growth of the industry in Brazil, driven by the current potential for expansion (availability of undeveloped salt flats) and government policies that support the occupation of up to 80% of tidal lands (Federal-level CONAMA Resolution No. 312/2002 and state-level subsidies).

The rate of occupation of coastal wetlands (mangrove/salt flat system) in Brazil is in an exponential growth phase ( $Y = b_0 e^{212t}$ ;  $r^2 = 0.984$ ). Making projections in aquaculture is particularly speculative because of the large number of factors that influence production and demand. However, applying the exponential model described above projects a requirement of salt flats ranging from 37 000 to 55 000 ha by the year 2010. The actual rate of occupation may be much greater than this because of land speculation and the tendency to seize the most

accessible sites as rapidly as possible.

Brazil's plans for the development of aquaculture are extremely optimistic. Of Brazil's 16 coastal states, nine north-northeastern states have moderate salt flat/apicum development. The area of salt flats in north-eastern Brazil with potential for transformation into shrimp ponds has been estimated by the industry to be 350 000 ha, but the basis for this estimate is unknown. Government agencies have not carried out an inventory of coastal resources to assess the potential for sustainable expansion or for potential resource allocation. Although Brazil has a National Coastal Zone Management Plan (PNGC), this has yet to be implemented. New areas are being explored and opened up for production along the northern coastline of Brazil, where local governments consider that they have been left out of the “Blue Revolution” in aquaculture that has taken place elsewhere. The coast of north-central Brazil, between Belém (Pará State) and São Luiz (Maranhão State), stands out as one of the most spectacular areas in the Western Hemisphere, in terms of its importance for migratory shorebirds. This coastal segment contains the “Reentrâncias Maranhenses”, a geomorphologically diverse landscape that comprises 2 680 911 ha, of which 1 775 036 ha have been designated as a Western Hemisphere Shorebird Reserve Network (WHSRN) site and a Ramsar site.

## DISCUSSION

Currently one of the greatest obstacles to the protection of shorebird habitat in the Western Hemisphere is the lack of explicit national legislation throughout the hemisphere to protect salt flats, even if these are ecologically a part of mangrove ecosystems and functional elements of coastal wetlands (Box 1). Regrettably, the returns brought by the “Pink Gold” economic growth in many of the hemisphere's developing nations have been invested in further exploitation of the remaining natural resources, rather than in increasing efforts to develop means to manage the residual coastal systems on a sustainable basis to ensure delivery of ecological services and food security for coastal populations.

The Neotropical Realm of Central America, the Caribbean and South America was, until recently, one of the least disturbed and most biologically rich of the Earth's biogeographical regions. Coastal wetlands, in particular, remained relatively undisturbed. The emergence of industrial-scale shrimp farming has now changed this because of its aggressive expansion and the fact that shrimp aquaculture in the region is embedded in a governance context which is extremely frail and generally incapable of developing strong policies to protect valuable resources. Regional and international funding and development agencies (the World Bank, the Interamerican Development Bank and the U.S. Agency for International Development in Central America) have fueled the growth of aquaculture despite its negative environmental and social impacts. This points towards the need for changes in the operational policies for development lending. Throughout the Neotropics, government and state-level policies support perverse subsidies and prescribed plans of actions that promote escalating coastal degradation in support of industrial-scale aquaculture and coastal development.

The impacts of shrimp monoculture on coastal wetlands are unambiguous. The occupation of coastal habitats takes place on a landscape scale, and involves extreme hydrological and topographical transformation. For instance, Ecuador lost half of its

**Box 1. Summary of findings and conclusions.**

- 1) Aquaculture is a significant threat to shorebird populations on both the Atlantic and Pacific flyways in the Western Hemisphere. High rates of habitat conversion are taking place despite total ignorance of the extent of the remaining habitat.
- 2) Salt flats must be considered as an intrinsic part of coastal wetland ecosystems. They are ecologically important habitats that support migratory shorebirds as well as coastal processes which provide key services including maintenance of local fisheries that contribute to food security. Resource managers must consider coastal wetlands as a functional whole that includes all inter-tidal habitats such as mangroves, salt flats and mudflats.
- 3) Shorebird conservation is given little priority in most Western Hemisphere countries. High-value habitats such as salt flats are not considered to be wetlands and remain unreported in wetland inventories and unprotected by legislation in most countries. Salt flats are, *de facto*, open-access areas into which anyone can encroach, or worse, are seen by governments as wastelands that should be reclaimed for development of highly profitable activities.
- 4) Although the exact extent of the resource is unknown, it is being allocated without consideration of quantity, quality or ecological function. The role of these wetlands as stopover sites for migratory birds remains ignored or unknown by resource managers in the region.
- 5) Shorebird population levels should be seen as indicators of coastal wetland health. Decreasing populations are the result of transformation and degradation of habitats.
- 6) The greatest obstacle to the protection of shorebird habitat is the lack of national legislation throughout the Neotropical region to protect salt flats, even when these are a functional part of mangrove ecosystems.
- 7) Industrial aquaculture should be relocated away from ecologically important wetlands such as mangroves and salt flats.
- 8) Development organizations, such as the World Bank and the Interamerican Development Bank, must be alerted to the impacts of their lending policies on salt-flat conversion and migratory shorebirds. Shorebirds have the potential to be used as indicators of the functional integrity of coastal wetlands that is required to meet the "Millennium Development" (MD) goals and targets agreed by most countries in the region.
- 9) Unless extraordinary measures are taken, unrestricted free trade agreements within the region, operating without strict environmental safeguards, could fuel further degradation and destruction of stopover habitats for shorebirds.
- 10) Shorebird conservation must be seen as an essential component of coastal resource and biodiversity conservation to support integrated coastal zone management and sustainable fisheries.

mangrove forests in the last two decades (Lacerda *et al.* 2002) and 77% of its salt flats (c. 4 000 ha/year of c. 66 000 ha) in the last fifteen years (Southgate 1992). In Honduras, a significant increase in shrimp farming is destroying important coastal wetlands and polluting coastal waters. Even a Ramsar site (No. 1000) in Honduras has been invaded by shrimp farms (Lal 2002). The government continues to encourage further development, although it is estimated that over 280 km<sup>2</sup> of shrimp farms have been developed in a region which USAID has estimated could support a maximum of only 200 km<sup>2</sup> (NAWCC 1993). Whereas in most of the Western Hemisphere the growth of industrial aquaculture faces a number of constraints such as diminishing space (most salt flats being already occupied), frequent and severe outbreaks of disease and increasing local community awareness and resistance to further development, in north-eastern Brazil, investors have found favorable conditions that include resource availability (large areas for development) and government policies that subsidize occupation and transformation of salt flats.

The increasing proliferation of shrimp aquaculture is evident in satellite images of the coast of northern Peru, Ecuador, Central America (Gulf of Fonseca) and the northern and north-eastern coastal states of Brazil. International agreements such as the Ramsar Convention have proven unable to limit the large-scale conversion of salt flats despite resolutions expressing concern for such conversion (Ramsar Resolution VII. 21) and the pledge of Contracting Parties to conserve the ecological character of designated wetlands.

**CONCLUSION**

Although the loss of mangrove ecosystems and resultant environmental effects have been well publicized, the potential impact of the loss and degradation of bare salt flats in the upper inter-tidal zone on shorebirds has been largely disregarded, even though this may threaten flyway phenomena at hemispheric level. The loss of these salt flats now constitutes the greatest threat to the conservation of entire populations of shorebirds in the region because of its scale and the high rates of conversion. Shorebirds have the potential to be used as indicators of the functional integrity of coastal wetlands within the region, and shorebird conservation must be seen as an integral part of coastal resource and biodiversity conservation to support sustainable fisheries.

Unless extraordinary measures are taken, unrestricted free trade agreements within the region, without strict environmental safeguards, could encourage further conversion and loss of stopover habitats for shorebirds on a regional scale. The loss or alteration of even small areas may be critical because of the degree to which migratory shorebirds concentrate at particular sites. Regrettably, shorebird conservation now has little priority for most countries in the Western Hemisphere. However, coastal wetlands, including mangroves and salt flats, are important productive units that support local fisheries, and are also a source of food for large segments of coastal communities. Furthermore, it is a requirement of the "Millennium Development" goals and targets agreed by most countries in the region that the ecological integrity of these coastal wetlands be safeguarded by 2015.

Shorebirds, because of their "flagship" status, could be used as indicators of the ecological integrity of these coastal systems, as well as a tool to promote shrimp production under more envi-

ronmentally and socially acceptable conditions, if it were made possible to differentiate these products in the market (shrimps that were not grown in converted inter-tidal zones). Ironically, farmed shrimp is now sold in the USA as “turtle safe” because it is not trawled and does not endanger sea turtles, but consumers are unaware of how environmentally unfriendly these farmed shrimp are, particularly for shorebirds. We trust that increasing awareness will promote efforts at both regional and flyway level to conserve these important shorebird habitats and thereby help to safeguard migratory shorebird populations throughout the hemisphere.

## ACKNOWLEDGEMENTS

Many of the ideas presented here originated from a brainstorming workshop on the issue of shrimp farming, coastal environments and migratory bird conservation sponsored by the U.S. Fish and Wildlife Service, the U.S. Environmental Protection Agency and the BIOMA Laboratory at the University of São Paulo, Brazil. Significant contributions were made by officials in the Brazilian Federal Prosecutor Office while sharing their legal and environmental concerns regarding this topic. Dr Liette Vasseur (Université de Moncton, Canada) provided valuable insights based on her experience in Asia. Wetlands International and Wetlands International/US supported this activity directly or indirectly by providing support to the authors to participate in the 27th Annual Meeting of the Waterbird Society’s “Wetland Conservation and Aquaculture” Workshop held in Cuiabá, Brazil, in 2003. Drs Frank Rivera assisted with the statistical analysis of the data and Melanie Steinkamp made substantive contributions throughout the preparation of the manuscript. To our colleagues at the BIOMA Lab, we are grateful for their constant encouragement and enthusiastic support.

Buurma, L. 2006. Waterbirds and aviation: how to mediate between conservation and flight safety? *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 817-821.

### ABSTRACT

Waterbirds contribute disproportionately to the problem of collisions between aircraft and birds. World-wide, civil airlines suffer an annual loss of several billion US dollars. Certain waterbird species, especially some geese, have adapted very well to man-modified landscapes, even to the level of becoming pests. Furthermore, many airports have been located in relatively cheap wetland areas, asking for bird problems. The International Civil Aviation Organization has recently upgraded its recommendations on the prevention of bird strikes into standards. This paper briefly explores the phrasing of some of the new standards, and emphasizes the need to develop best practice, especially with respect to wildlife control in the vicinity of airports. It is a plea for the co-operation of good hunters and realistic scientists, and emphasises the need to focus on the study of bird migration and local flight behaviour near airports. In particular,

studies of the evasive manoeuvring of birds in response to approaching aircraft, as well as to hunters, might help to mediate between conservation and flight safety.

### BIRD STRIKES: THE SIZE OF THE PROBLEM

Collisions between aircraft and birds have occurred ever since the first powered flights of man. However, only during the past decade has it become clear that the number of reported strikes is just the proverbial tip of the iceberg. Furthermore, quieter aircraft, increasing numbers of birds weighing over four pounds (1.8 kg) and tougher safety regulations could transform the bird strike problem into a major issue, especially where airports adjoin nature reserves, particularly wetland sites. Strategic alliances with local conservationists provide a solution.

The historical record of bird strikes in civil aviation world-wide documents the loss of 80 aircraft and 231 lives (Thorpe

Gulls taking off from the runway of Woensdrecht air force base, as regularly observed from the cockpit.

2003). Indicative of the huge number of military aircraft written-off is a recent overview by Richardson & West (2005) of 110 aircraft lost by Britain's Royal Air Force during the period 1923-2004. Sixty-three of the write-offs were in the UK, the others elsewhere. The majority of bird strikes, however, have not been recognized or reported.

The truth of the problem, as old as aviation itself, is now becoming clearer. A recent estimate of the world-wide costs due to collisions between large civil transport aircraft and birds amounts to US\$ 1.0-1.5 billion annually (Allan 2003). Allan made his estimate with the help of two major U.S. carriers who could not be identified for commercial reasons. The basis of the estimate was a one-year data set of 1 326 "routine bird strikes" from only one company, and without major engine write-offs or hull losses. Consequently, Allan (2003) emphasises that his estimate is probably conservative. Costs due to delay and cancellation were about seven times higher than the costs of repairing damage. Updated estimates using a three-year data set from the same company show the estimate to be broadly consistent from year to year. Pilots report only 20% of the number of collisions based on comparisons with bird remains collected from the runway. Off-airport bird strikes might also be overlooked. In the case of damage to engines, recognizing and identifying bird remains may only be possible with microscopic or DNA analysis, further hampering data collection.

This paper explores some of the consequences of the new and much stronger, but as yet not very clearly explained, safety regulations ratified by the world community (ICAO 2003) that force the conservation movement to join the debate on planning and management of wetlands near airports.

## NEW ICAO STANDARDS ON PREVENTION OF BIRD STRIKES

The International Civil Aviation Organization (ICAO) was established in 1944 by 54 nations with the aim of assuring the safe, orderly and economic development of international air transport. This specialized agency of the United Nations now has 189 participating States, and has grown into a very influential regulator that also deals with environmental protection. The ICAO has recognized the need to raise awareness of the bird strike issue and to understand the true size and nature of the problem. In order to initiate an airport bird-control certification process, three recommendations of ICAO's Annex 14 were recently upgraded into standards (ICAO 2003). Chapter 9.5.1. of Aerodromes Volume I (modified on 27 November 2003) now reads as follows: "The bird strike hazard on, or in the vicinity of, an aerodrome shall be assessed through: a) the establishment of a national procedure for recording and reporting bird strikes to aircraft; and b) the collection of information from aircraft operators, airport personnel, etc., on the presence of birds on or around the aerodrome constituting a potential hazard to aircraft operations."

The ICAO realized, of course, that the bird strike problem would not be solved simply by order. Although there is an ICAO Bird Strike Information System (IBIS) to which reports of bird strikes should be forwarded, international reporting is not yet mandatory. It is left to the national authorities to develop their own procedures.

A small proportion of the bird corpses found on runways have been shown to be slipstream victims that did not hit the aircraft at all. A greater part of the killed birds grazed against the

Canada Goose *Branta canadensis* family intruding into a Dutch airport.

A Common Goldeneye *Bucephala clangula* damaged the wing of this small airplane above California.

fuselage, only leaving a small smear of blood for those keen to find it, and a thud mostly passing unnoticed in the cockpit. Then, there is a whole array of incidents from a minuscule dent in the aircraft skin through a crack in a window to an obvious hole in the leading edge of the wing. In these cases, the aircraft is usually still perfectly able to fly, but when noticed in flight, the incident may create doubts about what to do or whether or not to turn back. Later on, it is very tempting to ignore a small dent in order to avoid the potential accumulation of delay costs. Ultimately, it is the engineer who signs off the aircraft as fit to fly, but this person might miss the incident. An internal cockpit or company dispute about what to do and whether or not to report the incident can be avoided by more refinement in the safety regulations. It is, of course, the task of the aviation industry to solve this, but the ICAO can help to create a platform for developing internationally agreed procedures.

The definition of a bird strike is simple: any physical contact between a bird and an aeroplane on the move. However, a majority of these strikes do not damage the fuselage or engine, while bird remains may be almost invisible to the non-specialist. Consequently, improving the prevention of bird strikes mostly results in an initial increase in the bird strike rate because of better reporting. The less diligent air companies and airports may show a low record of bird strikes, if judged superficially, until a serious accident alerts the aviation community. Openly reporting on bird strike statistics, especially occurrences, is a difficult as well as a delicate matter, often creating confusion if not undeserved blame.

Who is making the difference between “blame-free reporting” and “naming and blaming”? A few centimetres can

make the difference between a blood smear and a fatal accident (seen from the human point of view; the birds will always die). Reporting procedures should therefore be depersonalised and dedicated to safety improvement only. Due to their stochastic nature, all bird strikes, occurrences as well as incidents (thus irrespective of damage), can and should be used in the analysis. Blameworthy human behaviour can easily be separated from the open debate on bird strike statistics.

Assessing the severity of the bird strike is the key for deciding what type of bird presence should be considered as a potential hazard to aircraft operations. Again, this cannot be answered by the ICAO. While the definition of the different classes of bird strikes can (and should) be solved globally, the evaluation of bird presence on and around the aerodrome needs the involvement of local bird expertise. Birds will always seek new ways for survival. They vary geographically in ecology and behaviour, not only between but also within species. Consequently, even local flight behaviours are very diverse as the birds try to adapt to the predictability of a certain airport and its environment. Understanding this behaviour implies the need for an interest in the life strategies of the birds, which often does not parallel the obvious safety obligation to harass or even kill them. Only when good hunters and responsible ornithologists are brought together might the gap between theory and practice be closed.

#### LAW OF DIMINISHING RETURNS

Airport managers often tend to underestimate the difficulties that have to be faced when setting up a sound bird-control

programme. This is partly understandable, as the law of diminishing returns is clearly applicable here. Making an airport unattractive for large concentrations of birds and scaring away flocks of birds that nevertheless visit the runway do not seem to require high skills, but predicting the emergence of new problems may require considerably larger sums of money. The cost effectiveness of these investments is not yet clear, but a wide variety of measures indicating state-of-the-art practice can be found in the industry guide “Sharing the Skies” (Transport Canada 2001).

However, the story does not end here. It does not require a great imagination to understand the risks involved in building an airport besides a bird sanctuary or flying at low altitude over a nearby area with a high concentration of birds. However, many airports have not been very well located with respect to local bird flight-lines. In the past, potential bird problems were often not considered because of economic priorities or lack of knowledge about local bird movements. With the considerable improvement in safety regulations, existing airports are now forced to reconsider their bird strike prevention policy. This certainly requires clear management commitment, not only because relatively high costs in relation to relatively low rewards might be involved, but also because the image of the airport is at stake with respect to safety and environmental responsibility.

With the recent change in ICAO regulations, countries are now required to contribute to an improvement in the general level of flight safety by re-evaluating their national procedures for prevention of bird strikes. The gap between current practice and state-of-the-art practice provides governments with the opportunity to allow their aviation sectors to choose between taking a role as a pioneer or fighting a rear-guard action. Ultimately, however, the overall safety level will be above, between or below an internationally agreed upper and lower threshold. As yet, nobody has succeeded in quantifying these levels very precisely. Consequently, no airport should relax. But safe and rich aerodromes might consider the possibility of “adopting” an unlucky and poor airport. Spending a dollar on bird strike prevention in Africa will certainly create more safety than spending a dollar in the USA or Western Europe. As passengers expect the same level of safety at both ends of their flight, they might appreciate such “safety help agreements” and credit in one way or another the donor airport and/or air carrier.

### FLIGHT SAFETY VERSUS NATURE CONSERVATION?

While expressing extreme concern for the future of many shore-bird species, the Edinburgh Conference has also drawn attention to a number of conflict situations that have arisen because of the superabundance of some waterbird species, notably certain species of geese. Superabundance indicates that the ecosystem is out of balance as a result of human interference. While biodiversity as a whole is threatened, certain species turn into pests. The only way out of these human-induced problems is through a combination of applied and fundamental scientific research.

The most controversial issue in the debate is the application of the shotgun. A shot bird cannot, of course, collide with an aircraft anymore, but simply reducing bird numbers is only effective very locally and for a short period of time. Attempting to widen a culling zone beyond the periphery of the runway will create an empty space which attracts new birds. Moreover, these newcomers are not yet adapted to aircraft movements, and might pose a greater risk than the local population. Many bird

controllers agree that bird-scaring is more effective than killing. However, they also agree that shooting a flock member from time to time helps to reinforce the non-lethal scaring. Finding the balance between “zero tolerance” (at or near the runway) and “optimal scaring” (from intense scaring near the runway to mild scaring far away) is a delicate matter. Dolbeer *et al.* (2003) showed that the scaring effect of a very large shooting programme at John F. Kennedy International Airport, New York, was about four times more effective than the simple reduction in numbers of Laughing Gulls *Larus atricilla*. Wild birds cannot be controlled fully and consequently absolute rules do not exist. This may open up a complicated liability debate in the case of a serious bird strike. A more scientific evaluation of the effect of shooting and scaring is urgently needed. Modelling bird behaviour will help to judge the quality of the bird control programme.

The deeper philosophical challenge is how to deal with almost opposing forces: the wish to maximize profits by developing and exploiting natural resources versus bird conservation and the wish to secure wetlands from reclamation. Safety is a tangible field of mediation here. However, profit/safety dilemmas very often end up in conflicts between market-oriented and science-oriented groups. In the case of the bird strike issue, the key problem is how to deal with flocks of birds flying over the aerodrome from somewhere in the airport vicinity. It is relatively easy to monitor and predict the commuting flights of large gregarious birds such as wintering geese. However, the introduction of a warning system for flocks of swifts feeding on insects above the runways in summer, although scientifically feasible, will not be easy. Even hard-liners in aviation are now beginning to understand that it is necessary to accept and pay for a model of local goose movements, but very few aviators see the need to develop and finance systems that will facilitate avoidance of the smaller bird species.

### LOCAL EXPERTISE WITH BIRD BEHAVIOUR IS CRUCIAL

Recent research shows that many birds successfully avoid aircraft. Given the frontal area of aircraft and the numbers of birds in the air, as determined by radar studies in The Netherlands, the number of bird strikes is much lower than expected. A research team led by Dr Tom Kelly in Ireland has very nicely described the flight performance of Rooks *Corvus frugilegus* and Wood Pigeons *Columba palumbus* in response to approaching aircraft (Kelly *et al.* 1999). The avoidance reactions explain why quieter aircraft hit more birds. Together, the Irish and Dutch observations strongly emphasise the need for more research on evasive behaviour. Can we stimulate the birds to start their escape manoeuvres earlier by giving them the appropriate signals, and can we determine the responses of different bird species according to their age class, condition and local experience, as well as the influence of different weather and environmental factors on the birds flying behaviour? Several observations indicate that the answer to these questions is at least partially yes.

To date, the aviation industry has not recognized the relevance of this work and the need to give it substantial support. Indeed, we have a long way to go before we can speak the language of birds in flight. The conservation problem may be a short-term trigger. The new standard 9.5.3. in Annex 14 reads as follows: “When a bird strike hazard is identified at an aerodrome, the appropriate authority shall take action to decrease the

number of birds constituting a potential hazard to aircraft operations by adopting measures for discouraging their presence on, or in the vicinity of, an aerodrome.”

Many countries have conflicting laws for aviation and bird conservation which present problems to the authority responsible for the management of a nature reserve in the vicinity of an airport. Decreasing the number of birds may be the exact opposite of the primary aim of the management authority. Understandably, this authority will question the supposed hazard caused by protected birds at the nearby airport if their threat to aircraft operations is not very clear. Simultaneously, at the airport, the bird control unit will tend to maintain a policy of zero tolerance. This might result in the bizarre situation in which ducks sitting on the airport side of a border ditch will be shot while their fellows on the other side may sleep peacefully. Draconian legal subtleties can be avoided by relying upon the third new standard 9.5.4.: “The appropriate authority shall take action to eliminate or to prevent the establishment of garbage disposal dumps or any such other source attracting bird activity on, or in the vicinity of, an aerodrome unless an appropriate aeronautical study indicates that they are unlikely to create conditions conducive to a bird hazard problem.”

By focussing on garbage dumps, the ICAO apparently starts with an emphasis on birds that make a living from human waste. We could rank birds from nutrient-rich water bodies, heavily fertilized grassland and certain arable fields in the same category. It is possible that these individuals have adopted a way of life that makes them more accident prone, or their offspring find it easier to invade the airfield niche while showing less fear of aircraft. This effect has yet to be proven, and if it exists, it is certain that it will be only partially true.

## MODELLING LOCAL BIRD FLIGHT PATTERNS

Conservationists might be able to obtain support for their cause if they could conduct an aeronautical study which demonstrated that most bird species and individuals are unlikely to create a bird hazard problem. To formulate this more precisely: such a study might reveal that even at a fairly limited distance from the runway and aircraft flight paths, the flight activity of birds from a local source does not significantly exceed the average level of bird flight activity measured over a much larger area. It might also reveal that only certain individuals develop a dangerous flight behaviour which could be eliminated or selectively brought under control. However, in coastal zones and wetland regions in particular, local bird flight-lines may cover tens of kilometres, while bird migration may become intensified at certain times of the year, thus creating a danger that can only be coped with by adapting operations.

The type of study needed implies the application of sophisticated detection and tracking equipment such as radar (Buurma & Bruderer 1990, Walls 2005) or devices carried by individual birds. Monitoring the behaviour of the birds at very small scale (near departing and arriving aircraft) as well as at larger scales (local movements and migration) appears to be very promising. This type of research will not only bring safety-minded and conservation-minded people together on speaking terms, but will also stimulate the development of affordable warning systems to improve local bird control. Ultimately, these technical improvements might also enhance conservation by contributing to the understanding of bird mobility from local to global scale (Leshem *et al.* 2001).

## ACKNOWLEDGEMENTS

I would like to thank Richard Dolbeer, Derek Scott, John Thorpe, John Allan, Anastasios Anagnostopoulos and an anonymous reviewer for improvements of this text which remains a reflection of my personal views.

## POSTSCRIPT

The International Bird Strike Committee (IBSC) offers a platform for the exchange of local experiences and the development of global guidelines. Through the integration of theory and practice and the involvement of all relevant disciplines, best practices will emerge. Participation of representatives from aviation as well as the conservation side is encouraged at the world conferences. Further details and a large amount of “grey literature” can be found at <http://www.int-birdstrike.com>. Given the new ICAO policy, a number of controversial issues will be identified. Anyone wishing to discuss general bird strike matters and the constitutional consequences for IBSC is welcome to contact the author at [luitbuurma@worldmail.nl](mailto:luitbuurma@worldmail.nl).

## Recent measures to control Ruddy Ducks *Oxyura jamaicensis* in the United Kingdom

Iain S. Henderson

Central Science Laboratory, York, YO41 1LZ, UK. (email: i.henderson@csl.gov.uk)

Henderson, I.S. 2006. Recent measures to control Ruddy Ducks *Oxyura jamaicensis* in the United Kingdom. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 822-825.

### ABSTRACT

The Ruddy Duck *Oxyura jamaicensis* is a native of the Americas, but was introduced to wildfowl collections in the UK in the 1940s. Following escapes, Ruddy Ducks became established in the UK, and by 2000, there was an estimated feral population of c. 6 000 birds. As the feral population in the UK increased, so did the number of records in mainland Europe. Hybridization in Spain between the globally-threatened White-headed Duck *Oxyura leucocephala* and Ruddy Ducks, presumably originating from the UK, was first recorded in 1991, and this is now regarded as the greatest threat to the long-term survival of the White-headed Duck. The UK Government began research into Ruddy Duck control in 1994, and further research was undertaken between 1999 and 2002 and in 2003/2004. A total of 4 332 Ruddy Ducks have been culled since 1999. Between February 2003 and February 2004, numbers nationally were reduced by almost 20%, and regional reductions of up to 70% have been achieved annually with limited manpower. Shooting, particularly of large winter flocks, has proved to be the most effective method of control. Modelling suggests that the UK population could be reduced to less than 50 birds within five years if eight full-time staff were available to carry out control in all seasons.

### INTRODUCTION

The Ruddy Duck *Oxyura jamaicensis* is a native of the Americas and is common in its native range, with a stable population of over 500 000 (Wetlands International 2002). However, since being introduced into wildfowl collections in the UK from North America in the 1950s, it has become established as an invasive, non-native species in Britain and is now beginning to colonize other north-west European countries. By January 2000, the UK population was estimated at c. 6 000 birds (WWT Wetlands Advisory Service 2002). In 1983, the first feral Ruddy Duck was recorded in Spain, raising concerns about the risk of hybridization with the globally-threatened White-headed Duck *Oxyura leucocephala*. Ruddy Ducks have been recorded annually in Spain since 1991, and the first Ruddy Duck x White-headed Duck hybrids were observed in the same year (Hughes *et al.* 1999). At least 139 Ruddy Ducks have been recorded in Spain since 1991, at a minimum of 43 different locations. Hybrids are fertile to the second and possibly third generation in the wild. Despite an active and well-organized control programme to cull any Ruddy Ducks present, 59 hybrids have been recorded (José Antonio Torres pers. comm.) on at least 23 sites (Hughes *et al.* 1999).

The numbers of White-headed Ducks in Spain have risen from 22 in 1977 to 2 600 in 2003, and Spain is the only region in which the White-headed Duck has expanded its breeding range and population size in recent years. There has been a major expansion of breeding sites eastwards and northwards

since 1980, from Andalucia to Valencia and Castilla-La Mancha (Ayala *et al.* 1994 and Torres & Moreno-Arroyo 2000, cited in Green & Hughes 2001), following protection of habitat and a ban on hunting. Breeding now occurs annually at over 20 sites (Torres 2003). The Council of Europe Species Action Plan for the White-headed Duck highlights hybridization with the Ruddy Duck as being of critical importance, and regards this as the most severe threat to the long-term survival of the White-headed Duck, particularly in Europe (Green & Hughes 1996).

Initial research into control of Ruddy Ducks in the UK in order to protect the White-headed Duck began in 1993, and further research took place in 1999-2002 and 2003/2004. The UK Government recognizes that eradication of Ruddy Ducks from the UK is the desired outcome (Morley 2003). As the UK holds an estimated 95% of the European feral population of Ruddy Ducks, control in other countries (including Spain) is likely to be futile unless eradication occurs in the UK.

### METHODS

#### Introduction

In general terms, it is recognized that no eradication programme should begin unless a specific assessment study has shown that this is technically and financially feasible (European Commission 2004). Control of Ruddy Ducks in the UK has been viewed from the beginning as a three-phase process, with the first two phases addressing the issues surrounding the feasibility and cost of eradication.

Small-scale research was carried out between 1993 and 1996, concentrating on the feasibility of control. This work was carried out by the Wildfowl and Wetlands Trust (Hughes 1996), and involved testing different methods of control, namely shooting during the breeding season, shooting in winter, trapping females at the nest, trapping in winter, and egg-oiling. The results showed that shooting during the breeding season was the most effective method of control, followed by shooting in winter. Although trapping at the nest had a high intrinsic efficiency, the rate of control in terms of staff effort was very low. The report concluded that eradication was feasible, but that larger-scale control was required to obtain a better indication of the time-scale and costs involved.

#### Regional control trials and control on major sites nationally

Research into large-scale control was undertaken between 1999 and 2004. This work concentrated on control by shooting in line with the results of the initial research, and was conducted by the Central Science Laboratory (CSL), an Executive Agency of the Department for Environment, Food and Rural Affairs (Defra). Four full-time and two part-time control staff were employed on the project. The principal aims of the research were to assess the

feasibility and cost of reducing the UK population by over 95%, to reduce the breeding population on Anglesey, Wales, by a minimum of 70% within three years, and to conclude whether compulsory access to land would be necessary to ensure the success of any future national control strategy.

Access to all sites was by agreement in advance with site owners and tenants. The owners, tenants and principal users of all the known breeding, post-breeding and wintering sites for Ruddy Ducks within the trial areas were contacted and asked for permission to control Ruddy Ducks by shooting.

Control by shooting during the breeding season (1 March to 31 August) was carried out in two regions during this phase of research: the Western Midlands in England and the Island of Anglesey in Wales. Control of birds early in the breeding season, especially of adult females, is important in an eradication programme as it minimizes the numbers of young birds hatched and the total number of birds which must be killed. It is more efficient early in the season as by late May more cover is available for both sexes and the females begin to spend a large part of their time sitting on eggs and are thus more difficult to shoot. Most birds were shot from the bank with either a .223 rifle or a shotgun.

Control by shooting during the post-breeding and winter periods (defined as 1 September to 28 February) was carried out in all trial areas, including the Western Midlands and Anglesey. Ten visits were made to sites outside the trial areas in the winter of 2000/2001, and work was carried out at a range of sites nationally in the winter of 2003/2004. At this time of year, a high proportion of the UK population is found on a small number of sites (Fig. 1). For example, in January 2000, 83% of the UK population was recorded on only 25 sites, with 67% occurring on only ten sites. Thus access to these sites and the ability to carry out control effectively are critical to the feasibility of eradicating

Ruddy Ducks from the UK. Four to six Field Officers were usually involved, and the ducks were either herded towards guns on the bank by means of a boat or, on the larger waters, shot from the boats themselves. With very few exceptions, only shot-guns were used for post-breeding and winter control.

## RESULTS

### Access

Agreement to control Ruddy Ducks by shooting was forthcoming from 58% of the landowners and tenants approached (at both breeding and wintering sites), with little variation between the two main trial areas of Anglesey and the Western Midlands. However, this proportion rose to 78% for major wintering sites nationally, which contain large flocks of Ruddy Ducks in the post-breeding and winter periods. Thus access to a relatively small number of sites gives access to a large proportion of the UK population.

### Breeding season control

A total of 249 control visits were made during the period April 1999 to March 2002, and a total of 793 Ruddy Ducks were shot (255 adult females, 398 adult males and 140 immature birds). This figure represents 30.1% of the total number of Ruddy Ducks killed during the period. However, this figure would have been higher had control operations in the 2001 breeding season not been severely curtailed as a result of an outbreak of foot and mouth disease in the UK.

The mean amount of time per staff member spent on site for each bird killed in the breeding season was 1.98 hours. On average, 47.3% of the Ruddy Ducks present were shot at each visit (range 0-100%). In over 85% of cases where at least one bird was shot, the staff input was four hours or less on site (Defra 2002).

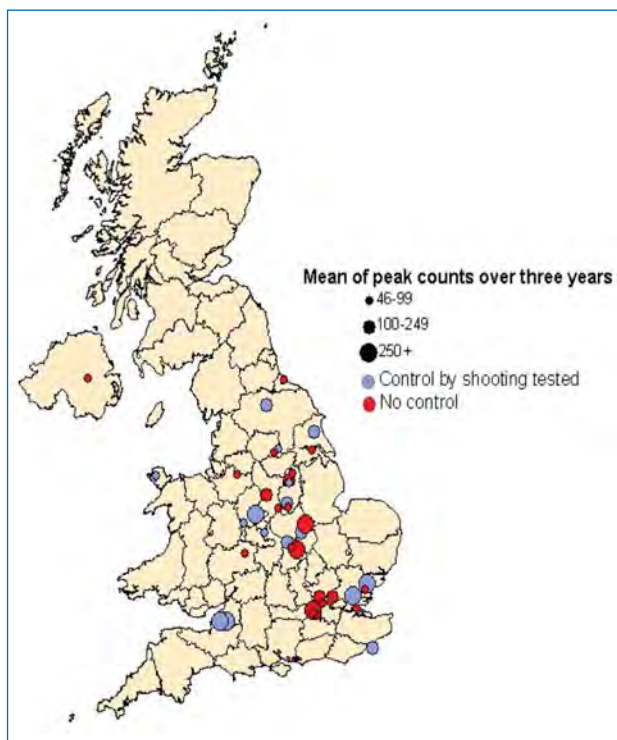

### Post-breeding and winter control, September 1999 – March 2002

A total of 1 841 birds (727 adult males, 491 adult females and 623 immature birds) were shot on seventeen sites. This figure represents 69.9% of the total number culled between April 1999 and March 2002 (Defra 2002). Because of the range of sizes of post-breeding and wintering sites and the effect that this had on efficiency, data for sites of less than 1 sq. km in size ("small wintering sites") were analysed separately from data for sites greater than 1 sq. km in size ("large wintering sites").

Data from the 54 visits to thirteen small post-breeding and wintering sites showed that the average staff time on site per bird killed was 1.11 hours in these situations (1 107 birds shot in total). On average, 53.9% of the Ruddy Ducks present were shot per visit (range 8% to 92%).

Many of the major wintering sites used by Ruddy Ducks are large reservoirs ranging from 1 sq. km to 12 sq. km in extent. A total of 21 control visits were made to four water bodies of this size, although in one case shooting was limited to two bays and not permitted in the main body of water. A total of 651 Ruddy Ducks were shot on these sites. Data from these visits show that although a smaller proportion of the Ruddy Ducks was killed per visit (mean 18.7%, range 1% to 56%), the staff input, at 0.81 hours per bird shot, was lower than on the smaller sites.

The main wintering site in the Western Midlands is approximately 3.5 sq. km in extent. A total of 522 Ruddy Ducks were

**Fig. 1.** The major post-breeding and wintering sites for Ruddy Ducks *Oxyura jamaicensis* in the UK.

**Fig. 2.** Number of Ruddy Ducks *Oxyura jamaicensis* shot and number present per visit at a major wintering site in the Western Midlands: 1999-2002.

**Fig. 3.** Number of Ruddy Ducks *Oxyura jamaicensis* shot and number present per visit at larger wintering sites: 1999-2002 (blue diamonds) and 2003/04 (red squares).

**Fig. 4.** Staff time per Ruddy Duck *Oxyura jamaicensis* shot at larger wintering sites: 1999-2002 (blue diamonds) and 2003/04 (red squares).

shot on 15 visits to this site during the September to February period. The results from this site showed that similar numbers of Ruddy Ducks were culled on each visit, regardless of numbers present (Fig. 2). Therefore as numbers were reduced, a larger proportion of those present was removed at each visit. Evidence from the 1999-2002 research suggested that at sites with high numbers of birds, the presence of more staff and the availability of more boats on the first few visits would allow a greater proportion of the birds present to be removed per visit (a maximum of four boats was available between 1999 and 2002). In order to test this, further research on large wintering sites was carried out in the winter of 2003/2004.

### Post-breeding and winter control, winter of 2003/2004

Three additional boats were bought in March 2003. Although of similar design to three of the boats used during the Regional Control Trials, these were slightly larger (14ft in length rather than 12ft) and had more powerful engines (20hp rather than 9.9hp). Thus, for the control operations on large wintering sites in 2003/2004, the CSL had a total of seven boats available: three 12ft aluminium boats with 10hp engines, three 14ft aluminium boats with 20hp engines, and one 12ft RHIB with a 25hp engine. In addition to the six staff used during the Regional Control Trials, a further three were trained in Ruddy Duck control and used on the large wintering sites in 2003/2004. One other member of staff was used to drive a boat on these sites. Thus, where operations during the period 1999-2002 typically involved three to four boats and five to seven staff, visits during the winter of 2003/2004 typically involved five to seven boats and up to ten staff.

Nine visits were made to five large wintering sites between December 2003 and February 2004. These five water bodies hold 70% of the Ruddy Ducks occurring on the ten most important wintering sites in the UK, and 30% of those on the forty most important wintering sites. A further sixteen visits were made to twelve small wintering sites between September 2003 and February 2004. The results of this further research show substantially increased efficiency on both larger and smaller wintering sites when compared with the results from the Regional Control Trials. There was a 58% increase in efficiency in terms of the proportion of Ruddy Ducks shot per visit on the large wintering sites (Fig. 3). This increase in efficiency was due principally to the availability of additional staff and, in particular, additional boats allowing better coverage of the waters bodies involved. There was also an 18% increase in the proportion of ducks shot per visit on the smaller sites. This was due principally to the refinement of site-specific methods for carrying out the control operations. Importantly, this increase in the proportion of birds shot was not at the cost of a large increase in staff time. On the large wintering sites there was a 55% reduction in the staff time on site per bird killed (Fig. 4), while on smaller wintering sites the comparable figure was 72%.

### CONCLUSIONS

The research on Ruddy Duck control in the UK since 1999 has shown that it is highly feasible to eradicate the species from the UK. A number of factors have led to this conclusion.

- 1 Ruddy Ducks are highly visible, particularly in the autumn and winter, when very large numbers of birds congregate on known traditional sites. For example, in January 2000, 83% of the UK population was recorded on only 25 sites, with 67% occurring on only ten sites. This makes control easier than if the birds were widely dispersed, and permits a more accurate estimation of the national population.
- 2 High quality data are available on the location, numbers and spread of Ruddy Ducks in the UK. There have been regular counts of Ruddy Ducks on many sites as part of the Wetland Bird Survey (WeBS) counts, and in recent years the number of sites for which these data are available has risen to over 1 500. These data, supplemented by data from County Bird Reports, allow better planning of an eradication programme.

- 3 In 2002, the Wildfowl and Wetlands Trust carried out a detailed analysis of all available WeBS data. This gave an estimated total UK population of almost 6 000 in January 2000 (WWT Wetlands Advisory Trust 2002), and an annual growth rate of between 6% and 7% in recent years (without control), compared to a mean annual rate of 24% in the years 1976-1996. Count data from 20 key wintering sites in February 2004 suggest that the national population now stands at around 5 000 following the recent control measures.
- 4 Several years of active control have allowed the development of a model which predicts the response of the Ruddy Duck population to further control (Smith *et al.* in press). This model suggests that eradication from the UK is feasible as part of a five-year control programme. The mean time predicted to reduce the population to less than 50 individuals (i.e. by over 99%) is five years.
- 5 Analysis of the WeBS data and experience of control since 1999 have shown that Ruddy Ducks move freely between sites in response to changes in weather conditions and during seasonal migrations. This makes access to all sites unnecessary, as it is highly likely that birds will occur at some time on sites where permission to carry out control has been granted. Ruddy Ducks move between sites in large numbers in response to changes in weather conditions in winter. During cold weather, birds move from smaller waters to larger ones, which are less likely to freeze over. Movement between sites also occurs as a result of the birds' mating strategy during the breeding season, when unattached males move between sites in search of females.
- 6 A range of control methods has been tested and the most effective identified. Shooting is the most effective method in all seasons, but trapping during the breeding season, trapping at the nest and egg-oiling are also effective on some sites. In the winter of 2003/2004, with additional staff and equipment available, it proved possible to cull between 20% and 60% of Ruddy Ducks per visit on the larger wintering sites. On smaller wintering sites, the mean proportion culled per visit rose to 59% (up to 220 birds) during the same period. On breeding sites, the mean proportion culled per visit was 47%.
- 7 Agreement has been obtained for access to a high proportion of sites. The owners of 37 of the 40 most important wintering sites in the UK have been approached, and 78% of these have given permission for Ruddy Ducks to be shot on their sites. As discussed above, the regular movement of this species between sites means that it is not necessary to secure access to all sites in order to meet the aims of the project.
- 8 The much reduced numbers of Ruddy Ducks on Anglesey during the 2000 breeding season allowed an assessment of the likely time requirements when dealing with very low numbers of birds. The count information from Anglesey suggests that reduced numbers of birds are not distributed across all the potential breeding sites. Rather, the birds appear to concentrate in the best breeding habitats in the area.

### ABSTRACT

The Double-crested Cormorant *Phalacrocorax auritus* has been protected by the Migratory Bird Treaty Act since 1972, as a result of a bilateral treaty with Mexico. Since that time, the U.S. Fish and Wildlife Service has had authority for cormorant management and conservation. From the late 1970s to the present, Double-crested Cormorants experienced dramatic population growth. Management policies and practices to address resource conflicts associated with cormorants have evolved over the last 30+ years, culminating most recently in new regulations that were adopted following the development of an Environmental Impact Statement and considerable public involvement. The new regulations expand the authority of certain agencies to address conflicts between cormorants and aquacultural, recreational, and ecological resources. In this paper, we discuss the past and present of Double-crested Cormorant management and possible directions for the future.

### INTRODUCTION

Long a concern of commercial fishermen, the Double-crested Cormorant *Phalacrocorax auritus* was never so great a problem as after it underwent, in the mid- to late 1970s, a population explosion in parts of the eastern United States and Canada. In the Great Lakes (U.S. and Canadian), which experienced the most significant increases, the number of Double-crested Cormorant breeding pairs increased from 89 in 1970 to an estimated 115 000 in 2000. A combination of mostly anthropogenic factors influenced this population rebound: elimination of the use of organochlorine contaminants (e.g. DDT), expansion of commercial aquaculture, growth in the number of fish-stocked artificial water bodies, changes in fish populations in the Great Lakes and elsewhere, and legal protection of Double-crested Cormorants. On the one hand, the comeback of the cormorant, like that of the Bald Eagle *Haliaeetus leucocephalus* and Brown Pelican *Pelecanus occidentalis*, was a positive event signaling a healthier environment. On the other hand, by the 1980s increasing Double-crested Cormorant populations were raising concerns in a number of areas, namely in fishing hotspots in the Great Lakes. In time, commercial aquaculture producers, particularly commercial catfish farmers in the southern United States, were becoming increasingly concerned about the economic impacts caused by Double-crested Cormorant depredation.

### EARLY APPROACHES TO DAMAGE CONTROL

Protected under the Migratory Bird Treaty Act (MBTA) since 1972, Double-crested Cormorants cannot be lawfully killed unless the U.S. Fish and Wildlife Service (hereafter referred to as

the Service) provides authorization, either through the issuance of a permit or through special regulations (for example, a depredation order). In the case of addressing damages to resources such as aquaculture stock or sport fish, a “depredation permit” is the relevant permit. Policy on issuing these permits refers to “the nature of the crops or other interests being injured,” indicating that depredation permits could be issued rather broadly (i.e. for damage to agricultural and any other interests). The Service’s Migratory Bird Program focused on issuing permits in situations in which depredation either caused economic loss to a person’s livelihood, or involved a threatened or endangered species (or one that was the focus of a restoration effort).

In 1990, formal guidance on the issuance of depredation permits for fish-eating birds (including cormorants) came in the form of Director’s Order No. 27. This policy statement established internal Service policy stating that “kill permits for migratory, fish-eating birds preying on fish aquaculture and hatchery facilities” can be issued under certain circumstances, and then outlined those circumstances. Its objective was “to provide immediate, short-term relief to the aquaculture producers from the economic and resource losses occurring from fish-eating birds.” The Director’s Order is still in place (although it now exists as a Service Manual chapter) and continues to provide permit issuance guidance to Service Regions that do not fall under special regulations relevant to cormorants.

In 1998, in response to complaints from aquaculture producers about the depredation permit process, the Service developed regulations to create a “depredation order” for the protection of aquaculture stock from damage caused by Double-crested Cormorants. The order allows “landowners, operators, and tenants [and their agents] actually engaged in the production of commercial freshwater aquaculture stocks” in 13 States (12 south-eastern States and Minnesota) to take depredating Double-crested Cormorants without a depredation permit. This depredation order is one of five in existence for various bird species, all of which have the purpose of protecting some form of agricultural interest.

### DEVELOPMENT OF A NEW POLICY

The aquaculture depredation order, however, did not put an end to resource conflicts related to Double-crested Cormorants. The question that could not be avoided was what, if anything, should be done about Double-crested Cormorants and open water fisheries? For a long time, the answer was simple because there was limited scientific evidence that Double-crested Cormorants had actual impacts on fisheries. Eventually, studies emerged providing strong evidence that cormorant predation had negative

Double-crested Cormorant *Phalacrocorax auritus*. Photo: Stan Tekiela, USFWS.

impacts on recruitment of certain fisheries, for example, small-mouth bass in New York's eastern Lake Ontario (Ross & Johnson 1999, Schneider *et al.* 1999, Johnson *et al.* 2000, Lantry *et al.* 2002) and walleye in Oneida Lake (Van De Valk *et al.* 2002). In addition, evidence of natural resource impacts (for example, on vegetation and other bird species) was growing stronger and becoming a greater cause of concern among resource professionals (Bédard *et al.* 1995, Jarvie *et al.* 1999, Shieldcastle & Martin 1999). Thus, in 1999, the Service decided to re-examine its policy on Double-crested Cormorant management, perhaps even to develop a national cormorant management plan, and determined that this process would require the completion of an Environmental Impact Statement (EIS) under the National Environmental Policy Act.

In late 1999, the Service officially announced its intention to prepare an EIS, with the U.S. Department of Agriculture's Wildlife Services program (USDA/WS) as a formal cooperating agency. The purpose of the EIS was to provide a detailed explanation of the environmental (e.g. natural, economic, social, and cultural) consequences associated with various management options. The EIS process also gave the public the opportunity to be involved in the decision. To that end, the Service initiated a "scoping" period that allowed the public to help define the scope of the problem and possible solutions. This comment period lasted for over 100 days and included 12 public meetings around the nation (mostly in the eastern U.S.), culminating in publication of a draft EIS (DEIS) in December 2001.

The DEIS examined six management "alternatives" for addressing conflicts with Double-crested Cormorants: these consisted of a status quo option, an option allowing only non-lethal control, an option that would liberalize issuance of depredation permits, an option that would create a new depredation order to protect public resources, an option emphasizing regional population reduction, and an option that would authorize regulated hunting. These alternatives were analyzed with regard to their potential impacts on Double-crested Cormorant populations, fish, other birds, vegetation, federally-listed threatened and endangered species, and socio-economic issues such as aquaculture.

The purpose of the change in strategy would be threefold: (1) to reduce resource conflicts associated with Double-crested Cormorants in the contiguous United States, (2) to enhance the flexibility of natural resource agencies in dealing with Double-crested Cormorant conflicts, and (3) to ensure the conservation of viable Double-crested Cormorant populations. To that end, the Service selected its preferred alternative. This alternative

proposed to establish a "public resource depredation order" that would authorize certain resource agencies to take Double-crested Cormorants without a permit to protect public resources (e.g. fish, wildlife, and plants). In response to problems at fish hatcheries and continued problems at aquaculture facilities, the preferred alternative would also authorize take of Double-crested Cormorants at Federal and State hatcheries and allow USDA/WS officials to control Double-crested Cormorants at winter roost sites.

The DEIS was followed by a 100-day public comment period and 10 more public meetings from Portland, Oregon, to Burlington, Vermont. The Service received about 1 000 letters and/or emails on the DEIS with the range of comments running from "cormorants are being scapegoated and should be left alone" to "cormorants are a scourge and their populations should be greatly reduced." Overall, the greatest public support (c. 45%) was for the preferred alternative, with many who commented also supporting the regional population management elements of another alternative. The public comment period closed in late February 2002 and a year later, in March 2003, the Service published a draft of the new regulations (i.e. proposed rule) that would implement the preferred alternative. The proposed rule gave the public an opportunity to comment on the draft regulations. In 60 days of public comment, we received over 9 700 letters, faxes, and emails on the rule. About 85% of these comments were opposed to the rule and were part of mass letter campaigns sponsored by interest groups.

## THE FINAL OUTCOME AND OPTIONS FOR THE FUTURE

In August 2003, a final EIS was completed and shortly after that, in October 2003, the final rule and Record of Decision were published. The final rule made two important changes from the status quo that the Service believes are biologically justified and legally sound under the MBTA. First, it revised the 1998 aquaculture depredation order to specifically authorize take at Federal and State fish hatcheries and to give USDA/WS authority to take cormorants at winter roost sites. Second, it created a public resource depredation order to give State fish and wildlife agencies, USDA/WS, and Federally recognized Tribes in 24 States in the eastern U.S. the authority to control Double-crested Cormorants without a depredation permit when necessary to alleviate damages to publicly-owned natural resources such as fish, wildlife, and plants. Each depredation order has a number of terms and conditions which must be followed by participating agencies and individuals. These include limitations on allowable control techniques, requirements for obtaining landowner permission and abiding by all applicable State laws, disposal procedures, and measures to avoid take of ESA-protected species or any migratory birds other than Double-crested Cormorants. Additionally, there are requirements for reporting and evaluation and, in the case of certain activities under the public resource depredation order, advanced notification.

This approach is balanced and responsive in that it gives the on-the-ground resource management agencies more authority, while maintaining accountability (through reporting and record-keeping requirements and other terms and conditions) to ensure the conservation of healthy Double-crested Cormorant populations. The Service's role in implementation of the new regulations is largely one of coordination and oversight. It is the State

fish and wildlife agencies and USDA/WS who will conduct most of the actual management activities. The Service will work to promote coordination among the action agencies, and will oversee control activities and gauge their population impacts at the regional and continental scales.

Some of the Service's partners, including USDA/WS, would have preferred a population management, even reduction, program to a localized damage control program. However, the analysis of the best available information on Double-crested Cormorants led us to conclude that there is currently insufficient justification for a large-scale population management strategy. In the final rule, the Service acknowledged that there is a need for more information about Double-crested Cormorants and their resource impacts, but that in weighing these deficiencies against the costs of taking no action, it concluded that it is prudent to move forward with the new regulations. The Service also stated in the final rule that if supported by biological evidence and appropriate monitoring resources, the Service would, in the future, consider a management approach that focuses on setting and achieving regional population goals. But until then, the strategy will continue to focus on alleviating localized damages.

Over the summer of 2004, control activities (including nest destruction, egg oiling, and shooting) authorized under the public resource depredation order were carried out in the states of Arkansas (193 birds killed and 95 nests destroyed), Michigan (1 424 birds killed and 3 114 nests oiled), New York (482 birds killed, 2 818 nests destroyed, and 11 450 nests oiled), and Vermont (208 birds killed and 1 458 nests oiled). State wildlife agencies and USDA/WS worked cooperatively with the Service to develop plans for implementing these actions, and carried out the work in a responsible and professional manner. It will take both time and new knowledge resulting from adaptive management efforts to tell how effectively the new regulations help resolve conflicts with cormorants.

Clearly, the process of addressing Double-crested Cormorant conflicts has been an evolving one in which the Service's policies shifted from a fairly narrow emphasis, mainly on private resource conflicts, to one that addressed, as the need to do so became increasingly apparent, a broader range of resource conflicts. The process has certainly not been without contention, as revealed by the fact that we received nearly 10 000 public comments on the proposed rule alone. In the Service's efforts to develop a balanced but effective wildlife

damage management strategy, it has been accused of a range of evils, from being politically driven (either beholden to "the sport fishing industry" or "the animal rights wackos," depending on the individual's perspective) to initiating a war against fish-eating birds. As a public agency that seeks to conserve wildlife in the context of the diverse interests of all Americans, the Service must act in a manner that is well-balanced, responsive, and guided by the best available science. As times and issues related to cormorants and other abundant migratory bird species change, so too must the strategies used to address them.

## Variation in the behavioural responses of Whooper Swans *Cygnus cygnus* to different types of human activity

Eileen C. Rees<sup>1</sup>, Jennifer H. Bruce<sup>1</sup> & George T. White<sup>2</sup>

<sup>1</sup> The Wildfowl & Wetlands Trust, Slimbridge, Gloucestershire, GL2 7BT, UK. (email: eileen.rees@wwt.org.uk)

<sup>2</sup> 107 Hollows Avenue, Foxbar, Paisley, PA2 0RD, UK.

Rees, E.C., Bruce, J.H. & White, G.T. 2006. Variation in the behavioural responses of Whooper Swans *Cygnus cygnus* to different types of human activity. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 829-830.

The impact of human activity on bird populations has been studied and discussed extensively in recent years (Hill *et al.* 1997, Gill & Sutherland 2000, Nisbet 2000, Gill *et al.* 2001) but variation in the birds' response to disturbance is still poorly understood. Variation in the behaviour of wintering Whooper Swans *Cygnus cygnus*, wintering in and around the Black Cart Special Protection Area (SPA), near Glasgow (55°53'N 04°27'W), was analysed to:

- assess the effects of the different conditions and different types of disturbance on the swans, by testing whether the type and timing of disturbance, and location of swans, affected the distance at which the swans became alert;
- determine whether the swans become habituated to human activity, by testing whether their response to disturbance events diminishes over time;
- describe variation in the time taken for the swans to resume feeding following disturbance, to determine whether recovery rates are more rapid at times (e.g. late in the day) when pressure to resume feeding might be greater; and
- describe temporal and spatial factors affecting the time that

the swans spend feeding and being alert, to determine the landscape features (including the frequency and type of human activity) likely to influence the behaviour of the birds, with a view to advising on site management for the species in the wintering range.

This short note presents a summary of the results; they are presented in full in Rees *et al.* (2005).

Observations were made in winters 1997-98 to 1999-2000 inclusive at the Black Cart SPA in Scotland, which receives at least 1% of the Icelandic-breeding Whooper Swan population in winter. The site is semi-rural, consisting of mixed farmland interspersed with light industrial development, adjacent to Glasgow Airport and within two km of the Paisley conurbation (Fig. 1, Rees *et al.* 2005).

All fields and sections of river within the study area were visited at least two days a week to map the number and distribution of swans, and note the crop type in each field. The swans' behaviour and human activity at the site were monitored during three main periods each winter, in autumn (late October-early November), mid-winter (January) and spring (March). The data

**Fig. 1.** Whooper Swans *Cygnus cygnus* on the Black Cart Water, Scotland, with Rolls Royce factory in the background. Photo: Rebecca Woodward, WWT.

**Fig. 2.** Mean distance ( $\pm$  SE) at which different types of disturbance alerted the swans over the 3-year study. Note: 1 = car, 2 = van, 3 = tractor, 4 = other farm vehicle/lorry, 5 = construction vehicle, 6 = bicycle, 7 = pedestrian, 8 = pedestrian with dog, 9 = farm worker on foot, 10 = angler, 11 = wildfowler, 12 = cattle, 13 = bird scaring at airport, 14 = helicopter, 15 = aircraft. From (Rees *et al.* 2005).

were analysed using two-way and three-way ANOVAs in SPSS (version 11), and generalised linear modelling in GLIM (version 4).

Overall, the swans' feeding activity varied within and between years, and in relation to the feeding site, but there was less variation in the amount of time spent alert. Disturbance frequency resulting from human activity was lower with increasing flock size and with increased distance to the nearest road or track.

Distances that humans could approach before alerting the birds similarly varied with field characteristics (e.g., size and proximity to roads or tracks), and also with the type of disturbance involved. Helicopters and other aircraft alerted the swans at longer distances than ground-based disturbances (Fig. 2), but the proportion of birds alerted was lower. On the ground, anglers and wildfowlers alerted the swans at greater distances than other pedestrians. Similarly cars and bicycles were able to approach closer than other vehicles.

**Fig. 3.** Distance ( $\log_{10}$  transformed; open squares) at which Swans became alert in relation to the number of previous disturbances recorded in the day. The linear regression line is for fitted disturbance distance  $n$  values (closed circles; distance =  $0.0545 \times \text{disturbance number} + 5.46$ ). From (Rees *et al.* 2005).

The distance at which >5% of the flock became alert because of human activity decreased with the number of previous incidents in the day (Fig. 3), indicating that swans become less sensitive to disturbance events if daily disturbance frequency is high, but there was no evidence that habituation to disturbance persisted over longer periods. The time taken for the birds to resume undisturbed behaviour varied with the duration of the disturbance event, which in turn depended on the type of disturbance involved, with pedestrians alerting the birds for longer periods than vehicles and aircraft. Recovery rates following disturbance were also associated with field size, flock size and the proportion of the flock alerted.

Feeding activity was influenced by a range of variables, including: year, season, field location, crop type and the number of days that the flock had used the field (32.9% of variance in the data explained by these variables), with disturbance factors explaining an additional 4.9% of variance in the proportion feeding per hour. Conversely, alert activity was influenced mainly by disturbance events.

The range of factors influencing the swans' feeding behaviour, and variability in their response to human activity, has implications for management programmes and for attempts to predict the effects of human activity on the birds at a local and wider scale.

Given the variation in feeding activity for undisturbed swans, and in their response to different types of disturbance under different conditions, information on factors affecting both disturbed and undisturbed behaviour is needed to determine whether changes in disturbance levels affect food intake for other species over a winter season. Factors influencing behaviour also may vary at different parts of the flyway, depending on changes in food availability, predation risks and energetic requirements. Determining variation in a species' response to human activity throughout the year and migratory range would be necessary for any assessment of the impact of disturbance at a population level.

## 6.2 Let the waterbirds do the talking. Workshop Introduction

Christine Prietto

The Wetlands Centre, NSW Department of Education and Training, PO Box 292, Wallsend, NSW 2287 Australia.  
(email: priettoclub@aapt.net.au)

Prietto, C. 2006. Let the waterbirds do the talking. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 831.

The launch of an educational booklet on the critically threatened Siberian Crane *Grus leucogeranus* at Fereydoon Kenar city in Mazandaran Province of I.R. Iran as part of the UNEP/GEF Siberian Crane Wetlands Project. Communication, education and public awareness is an essential component to such programmes. Photo: Crawford Prentice.

Waterbirds, through their often charismatic behaviour, their international migrations, and association with 'untamed nature' have great potential to increase support for biodiversity conservation at all levels.

The processes of communication, education and public awareness (CEPA) are all invaluable complements to waterbird conservation but must be valued and funded accordingly. Conservation efforts may not realise their intended aims without CEPA.

The workshop was constructed to present a range of strategies, products and initiatives that deliver educational outcomes among various target audiences. This range of examples, presented in the papers that follow was significantly broader than what is normally considered under the classification of communication, education and public awareness.

The ultimate aim of those working for the conservation of waterbirds and their wetland habitats is to increase support for

biodiversity conservation across all sectors of society. The CEPA workshop aimed to show that these processes produce real outcomes on their own but also add value to other conservation activity more generally. However, CEPA strategies and products must be tailored to the framework and needs of the target audience: a high degree of targeting is necessary to ensure successful outcomes.

A number of the presentations and following papers summarise information on formal and community educational programs, community events, networks and partnerships.

All speakers emphasised the value of these initiatives in increasing support for conservation efforts and strongly underscored the need for adequate funding.

Participants agreed that there is a need for communication components to be fully integrated with management efforts. Even in a conference such as this it would have been good to have relevant CEPA papers slotted into other presentations.

## Shorebird Sister Schools Program — shorebird education in North America and beyond

(email: Brad\_Andres@fws.gov)

Chapman, H., Andres, B.A. & Fellows, S. 2006. Shorebird Sister Schools Program - shorebird education in North America and beyond. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 832.

The Shorebird Sister Schools Program (SSSP) uses the tool of environmental education to integrate shorebird conservation across geographic scales, cultural experiences, and shared ecologies (Andrew & Andres 2002). The linkage of students along the North American Pacific Coast migration route of the Western Sandpiper *Calidris mauri* was the major impetus for launching SSSP. Learning about sandpipers during their brief spring stopover in Kachemak Bay, Alaska, students questioned where the sandpipers spent the rest of the year. Educators responded by initiating an electronic network of 17 Pacific coast schools that tracked the progress of the spring Western Sandpiper migration, and the U.S. Fish and Wildlife service began developing an Arctic-nesting shorebirds curriculum. Growing from these local beginnings, SSSP has expanded to cover all Western Hemisphere, Central Pacific, and East Asian-Australasian flyways, and involves teachers, students, youth groups, nature center interpreters, and protected areas educators at sites that support breeding, migrating, or wintering shorebirds. Equally important is the involvement of professional biologists and amateur enthusiasts who share their research and observations with other participants. Their participation greatly enriches the experience and knowledge gained by students and educators.

The vision of the SSSP is to engage public participation in the conservation of shorebirds and their wetland, grassland, and shoreline ecosystems. Public participation begins with increasing understanding and awareness of local species and habitats, which participants gain through the primary components of the program; an educator's guide for school grades 2–12 (ages 7–18), a student's activity booklet, and a website. The website provides background shorebird information in English, Spanish, and Japanese (<http://sssp.fws.gov>). Field trips create first-hand awareness of shorebirds, their habitats, and their conservation issues, and information is provided to educators on how to conduct meaningful field trips. In the U.S.A., seven regional coordinators have committed, in conjunction with other professional duties, to develop materials and conduct workshops to familiarize teachers with the activities and resources of the program. These SSSP coordinators focus on “train the trainer” workshops rather than on making individual schoolroom visits. SSSP activities are communicated via professional education journals (Grafe 2004).

Sharing cultural experiences among SSSP participants has always paralleled the geographic linkages of shorebirds. E-mail and written letter exchanges expand the students' education beyond biology. In Japan, staff of the World Wide Fund for Nature (WWF) have translated and modified SSSP materials and have held workshops in Japan and South Korea (<http://www.chidori.jp/education/>). WWF has developed educational materials specific to the Yellow Sea, which is a critically important stopover site for

many migratory shorebirds. Using efforts in Japan and the U.S.A. as a model, the Wetland Centre Australia developed a website, “Feathers, Flyways, and Friends”, that contains information on East Asian-Australasian migratory shorebirds and has been translated into Chinese and Japanese (<http://www.wetlands.org.au/shorebirds>). Their “postcard program” invites children to use the blank side of the postcard to draw a picture about shorebirds and send it to another school. Within the Western Hemisphere, coordinators in Argentina and Mexico have dedicated time to promote and adapt concepts of the SSSP for use in Latin America (Streeter 2004); the educator's guide and student activity booklet have been translated into Spanish. A strong partnership, in which SSSP plays a central role, has been formed between biologists and educators at the Great Salt Lake, Utah, U.S.A., and Marismas Nacionales, Nayarit, Mexico.

Integration across taxonomic boundaries is accomplished in SSSP by developing activities that promote the general conservation of grassland, wetland, and beach ecosystems. Activities have also been designed to reach beyond biology: the educator's guide is correlated to the U.S.A. National Science Education Standards in science, geography, social studies, visual arts, language arts, and mathematics. Shorebird tracking projects, field trips, and other participatory activities engage students in real-life science - the successes, challenges, and setbacks. Students learn that habitats in their own community are part of a chain of healthy habitats critical to shorebirds and other migratory species. In keeping with the program's primary goal of flyway conservation, SSSP connects with researchers and managers through the U.S. Shorebird Conservation Plan Council (<http://shorebirdplan.fws.gov>). This linkage ensures that SSSP is integrated with shorebird conservation priorities, which in turn strengthens the program's relevance. The success of this education program is due to agency support, partner commitment, and participant enthusiasm. Cruise the super shorebird highway with Shorebird Sister Schools at: <http://sssp.fws.gov>. For further information, e-mail the National Shorebird Sister Schools Program Coordinator at: [sssp@fws.gov](mailto:sssp@fws.gov).

### ABSTRACT

Public awareness and concern are crucial components of migratory bird conservation. Citizens who are enthusiastic about birds, informed about threats, and empowered to become involved in addressing those threats can make a tremendous contribution to maintaining healthy bird populations. In the Americas, a successful vehicle for public education on migratory birds is International Migratory Bird Day (IMBD), a day of recognition created to foster appreciation and stimulate conservation action. This paper describes how IMBD has grown from a good idea to a significant, annual occurrence marked by hundreds of public celebrations. It provides a brief history of IMBD, a review of the partnerships that sustain it, and a discussion of future directions for the program.

### INTRODUCTION

IMBD, held annually on the second Saturday in May, is an invitation to celebrate and support migratory bird conservation. Like any day of recognition, IMBD exists to focus attention on a valuable resource – the nearly 350 species of migratory birds that travel between nesting habitats in North America and wintering grounds in South and Central America, Mexico, the Caribbean, and the southern USA. IMBD was created in response to disturbing findings in the late 1980s that many of these bird species were in decline, facing a growing number of threats on their migration routes and in both their summer and winter habitats. Thus, IMBD, in addition to being a day to foster appreciation, was created as a call to action.

### A RETROSPECTIVE

The history of IMBD is one of growth – the event was launched with a tremendous amount of energy and has continued to gather momentum over time. Below are some of the highlights in the IMBD story:

#### 1993

- Saturday 8 May 1993 marked the first annual IMBD. It was conceived to “provide a platform for the numerous conservation efforts already underway through the Partners In Flight – Aves de las Americas Program, as well as to inspire others into action.”
- The Smithsonian Migratory Bird Center compiled The Migratory Bird Handbook, providing activists and educators with strategies, ideas, and resources.
- A Partners In Flight poster with art by Kendahl Jan Jubb was created for distribution.
- The IMBD was considered a glowing success, with 130 events in 39 states, two Canadian provinces, and several locations in Guatemala and Mexico.

International Migratory Bird Day has been a successful vehicle for public education on migratory birds in the Americas. Photo: Jennifer Wheeler.

#### 1994

- An Organizer's Information and Media Packet was coordinated by Cornell Laboratory of Ornithology and the National Audubon Society, with a Latin American version produced by the Smithsonian Migratory Bird Center.
- A total of 2 300 packets were mailed by the IMBD date.
- An IMBD 1994 poster was created by Kendahl Jan Jubb, and depicted a wide variety of birds.
- Events tallied at about 100, in at least 30 states and three provinces. The apparent drop in numbers since 1993 was likely due to reporting, as those reports received indicated increases (e.g. the number of events doubled in Alaska).

#### 1995

- Coordination moved to the U.S. Fish and Wildlife Service (USFWS) and National Fish and Wildlife Foundation (NFWF), with major sponsorship by Phillips Petroleum Company and others. For the first time, a contractor was hired as a coordinator.
- A new annual Organizer's Packet and an IMBD-specific tee-shirt were developed for distribution on an order basis, and over 30 000 free IMBD 1995 posters were distributed, again featuring art by Kendahl Jan Jubb.
- Promotional material touted “more than 400 events.”
- The focus was put on the economic values of non-game birds and non-consumptive, bird-related recreation.

#### 1996

- Two separate and expanded packets were produced: an Organizer's Packet and an Educator's Packet.

- Sales of IMBD products were initiated, including banners, tee-shirts, tote-bags, pins, and stickers, on top of distribution purely by sponsorship. Over 40 000 Partners In Flight posters were distributed, featuring art by Margo McNight.
- It was estimated that there were between 250 and 500 local events, and that “tens of thousands” of people were reached by IMBD activities.
- The focus was on the production of the Partners In Flight “Flight Plan”.

#### 1997

- The first formal products catalogue was produced, including promotional banners, tee-shirts, pins, patches and stickers. Products were distributed by the USFWS.
- The IMBD 1997 poster featured a montage of bird profiles created by Keith Hanson.
- The theme switched from “Sharing A Passion for Birds” to “Join the Flock” – encouraging measurable steps towards conservation. A concerted effort was made to offer the media “solutions.”
- Substantial supplements were created for the nearly 1 500 Organizer’s and Educator’s Packets distributed.

#### 1998

- A catalogue was published in full color; the theme was “Catch the Migration Sensation” and highlighted the importance of coastal beaches to neotropical migrants.
- The IMBD 1998 poster by artist John Sill depicted migrants on a Gulf Shore beach.
- IMBD went on-line via an American Birding Association web-site, which included data entry.
- Approximately 24 000 posters were distributed; about 500 contacts were compiled on the sales list.

#### 1999

- IMBD highlighted the critical importance of wetlands to migratory birds.
- The IMBD 1999 poster illustrated wetland diversity through art by Carol Decker.
- Product sales were handled out of the American Birding Association’s Sales Office.
- Events continued to number in the hundreds.

#### 2000

- Art by Roger Tory Peterson featured on IMBD products. The theme was the recovery of an Endangered Species, the Peregrine Falcon.
- A USFWS web-site, including access to an Events Registry, went on-line.
- The first IMBD Distance Learning Program was provided by the National Conservation Training Center.
- A focused effort to tally IMBD activities supported an estimate of hundreds of thousands of people reached via at least 500 public events, countless private events, distance learning and media coverage.

#### 2001

- The theme was the benefits of shade-grown coffee, resulting in many new connections and partnerships. The artist Terry Isaac was flown to Guatemala to produce original art for the IMBD 2001 poster.

- Product distribution moved to a NFWF contractor in Colorado Springs; on-line ordering via a NFWF web-site was established.
- A total of 25 000 catalogues were distributed.
- The poster and education piece were translated into Spanish for the first time.

#### 2002

- IMBD turned 10 years old! The theme was “Celebrating Special Places for Birds,” highlighting habitat conservation especially via the Important Bird Areas programs.
- The IMBD 2002 poster featured a popular print “Mystery of the Missing Migrants” by artist Charley Harper.
- Approximately 40 000 catalogues and 75 000 posters were distributed; about 1 500 contacts were now on the sales list.
- Data from the Events Registry indicated that IMBD was reaching a growing audience.

#### PARTNERSHIPS

From its beginnings, IMBD has drawn on the ideas, talents and energies of many individuals and organizations. The principal responsibility for coordination has been shouldered by a few parties, but IMBD is an event that belongs to all who celebrate it.

IMBD’s first and lasting affiliation is with Partners In Flight (PIF), recognized by the PIF logo on IMBD products. When PIF formed in 1990, education was identified as a critical element of bird conservation. Members of the PIF Information and Education Working Group and associated Task Group on Education and Outreach produced the first IMBD materials. IMBD is now considered the hallmark outreach event for PIF, and continues to be supported by partners through sponsorship, creation and review of products, promotion, coordination, and celebration. It is particularly effective when a geographic working group or partnering agency takes on local coordination, as has occurred in Colorado, Georgia, Nebraska, Georgia, and Utah, among others.

IMBD also owes much of its success to individuals and organizations not directly affiliated with PIF. For example, sponsors over the years have included Birder’s World Magazine, BirdLife International, Canon, the Center for Conservation Research and Technology, Eagle Optics, Harcourt Brace, Mark Feldstein and Associates, Inc., Mill Pond Press, Phillips Corporation, Sanctuary Coffee, The Summit Foundation, Swift Optics, Thanksgiving Coffee, and the Wild Bird Feeding Institute/National Bird Feeding Society (with apologies to any omitted).

The American Zoo and Aquarium Association and its members have promoted and celebrated IMBD; a formal campaign in 2000 resulted in 100 facilities hosting activities, most of which continue to do so. Via an arrangement with Eagle Optics, IMBD catalogues are sent out with every order and taken to trade shows and festivals. The non-profit Kids for Saving Earth mails out catalogues supplemented with their poster. Schools and school systems have embraced IMBD; in 2001, a consortium of 23 school districts highlighted IMBD as part of their county-wide, internet-based project on migratory birds. IMBD has recently partnered with the Council for Environmental Education (Project WILD) to support a new middle-school based program, Flying WILD.

IMBD belongs to all who celebrate it, and IMBD coordinators are eager to develop new partnerships that advance its goals.

## FUTURE DIRECTIONS

By definition, IMBD is a single-day observance. In hindsight, perhaps it might have been easier to have International Migratory Bird Week or Month. Also, its annual date – the second Saturday in May – often conflicts with the timing of bird counts or surveys. However, these issues really are not limiting. Event planners are encouraged to schedule activities on the date or dates best suited to the presence of migrants in their area and are certainly not discouraged from celebrating IMBD on an alternative date. The date of IMBD has intentionally been left off IMBD products to avoid drawing attention to necessary or appropriate rescheduling. Moreover, for those skilled birders with commitments on the second Saturday in May, what better way to celebrate IMBD than to involve new enthusiasts in their activities?

More importantly, IMBD is a movement as well as a day of recognition. The materials and messages created for IMBD are useful year-round. And indeed, IMBD posters are distributed at bird walks and talks all summer long. As another example, IMBD-related educational materials, including the new Junior Birder packets, have been embraced by the Girl Scouts. Wild Bird Centers and Wild Birds Unlimited shops stock IMBD items. Public festivals will always be a core element of IMBD, but providing year-round resources for migratory bird educators is also an important aspect of the program.

How secure is IMBD's future financially and organizationally? Sales of IMBD products provide income, and prices are set to recover the costs of production and some development. However, an objective of IMBD coordinators is to provide celebrants, educators especially, with resources at the lowest price possible. Thus, it is likely that IMBD products development will always require sponsorship. "External" funding is also necessary to continue IMBD coordination, the bulk of which is performed under contract. However, IMBD itself has been embraced and institutionalized by many organizations. For example, the National Wildlife Refuge System holds IMBD as one of its primary observances. Many zoos and aquariums report IMBD as one of their most successful events. Festivals providing positive economic returns are unlikely to be cancelled. IMBD as an observance will persist as long as it is needed.

Has IMBD been effective? Those involved with IMBD at the time of its creation asked three questions of the program, the answers to which can help us decide if IMBD is achieving its goals.

### Does IMBD educate the public about migratory birds: their habitats, the challenges they face, and status of their populations?

Yes. The materials and messages crafted for IMBD each year always include conservation issues (i.e. they are not limited to natural history or ornithology topics). Given the increasing size of the audience reached, IMBD has certainly been an effective vehicle for education.

### Does it raise awareness of our biological and economic ties to Latin America?

Needs improvement. While IMBD materials and messages have traditionally focused on neotropical migrants, more could be done to connect northern audiences directly to individuals and organizations in Latin America. For example, some festivals

highlight an adopted sister-city in the tropics. Alternatively, correspondence programs could be developed enabling students to communicate internationally. Also, it has been a challenge to provide affordable IMBD materials to Latin America to encourage them to celebrate IMBD. Additional sponsorship to support Latin American celebrants would be welcomed.

### Does it prompt the initiation of conservation projects or support existing ones?

We do not know. A primary purpose of IMBD is to stimulate the audience to engage in activities that provide real benefits to populations of wild birds. To this end, IMBD coordinators have striven to integrate suggestions for how people can support bird conservation through specific actions. Themes in recent years have promoted ongoing conservation projects (e.g. shade coffee campaigns, the IBA Programs). However, no evaluations have been conducted to determine if audiences have actually changed their behaviors as a result of exposure to IMBD activities. This question is at the heart of all environmental education programs, and researchers are invited to conduct studies as a means of answering it.

## ACKNOWLEDGEMENTS

The authors wish to acknowledge the sponsorship and support of the National Fish and Wildlife Foundation and the U.S. Fish and Wildlife Service. Special thanks to those individuals – Mary Deinlein and Terry Rich – who reviewed the manuscript.

## Wetlands International's Communication, Education and Public Awareness Programme on wetlands for west Africa

Mame Dagou Diop<sup>1</sup> & Charles Beye<sup>1</sup>

<sup>1</sup> Wetlands International, West Africa Programme, PO Box 8060, Dakar Yoff, Senegal. (email: dagouwet@sentoo.sn)

Dagou Diop, M. & Beye, C. 2006. Wetlands International's Communication, Education and Public Awareness Programme on wetlands for west Africa. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 836-837.

The Wetlands International West Africa Regional Programme established a Wetland Communication, Education and Public Awareness (CEPA) Programme as part of a sub-regional project between 1998 and 2003. At a sub-regional level it aims to improve knowledge of wetlands and their wise use within the general public, decision makers, the private sector and other target groups. This paper reports on activities carried out by the programme.

The Wetlands CEPA Strategy is a framework that supports the integration of various local, national, regional and international concerns on wetlands, including those of the Information Programme of the Ramsar Convention. It also aims to enable direct training policies that are applicable at different levels. The development of a draft Wetlands CEPA Strategy for West Africa was finalised after wide consultation with stakeholders through questionnaires and a regional workshop. During this process, partners were encouraged to define problems and solutions for adopting CEPA as a central instrument towards satisfying wetland conservation objectives.

Training course for protected area managers, Khartoum, Sudan. Wetlands International has organised a wide range of courses for protected area personnel in East and West Africa. Photo: Tim Dodman.

CEPA started in 2001 with the circulation at the regional level of a questionnaire to inventory and identify CEPA needs in West Africa and two Central African countries, Cameroon and Chad. A background document was developed after analyzing the questionnaire responses and subsequently adopted during a regional workshop held in September 2002 in Dakar. After consultation on regional priorities, an action framework was proposed and embodied in the strategy document.

Several opportunities were identified in the sub-region:

- the existence of educational and training institutions interested in the issue of wetlands and which already offer training opportunities on various themes (general knowledge of wetlands, development, conservation, management);
- the existence of proven expertise in this field, and networks and advisory groups offering skill and experience;
- the support of various international organizations for wetlands conservation and restoration (IUCN, Wetlands International, Birdlife International); and
- the involvement of local, national and regional associations in education and public awareness activities.

In order to supplement and strengthen these opportunities, the strategy needed to focus on two major objectives:

- enhance awareness of the values and functions of wetlands through education, awareness and training; and
- provide support and tools for the practical implementation of the communication, education and public awareness (CESP) activities at the national and local levels.

Fig 1. Booklet for students on wetlands and waterbird migration in Guinea-Bissau.

These are essential elements in the overall strategy to conserve wetland environments, and are a prerequisite to the adoption of wetland issues by local stakeholders, and to their effective involvement in the sustainable use of resources. Within the framework of the draft strategy and related projects, a range of activities have already been carried out, including:

- publication of a bilingual newsletter on wetlands, “Fadama”. This is intended as a forum for the interchange of knowledge of wetlands management and the conservation of wetlands wildlife, including its distribution and threats to the habitat;
- “Better Understanding our Wetlands” is a series of four publications which aims to raise awareness among NGO decision-makers and planners, administrative authorities, national aid organisations, donors and the national education sector to promote wetland related issues and environmentally-friendly decisions in development matters favourable to the preservation of these ecosystems and the sustainable use of their resources;
- development and publication of a “Wetland Games” manual for primary schools after a trial in Senegalese schools. The present manual is intended help teachers of elementary schools define and present environmental concepts to their pupils;
- publication of a waterbird exercise book and booklet on migration in Mali; and
- publication of CEPA booklets for students on wetlands and waterbird migration in Guinea-Bissau (Fig. 1).

In June 2004, a series of Conferences was held at the Department of Geography, Cheikh Anta Diop University (Dakar, Senegal) on “Waterbirds Biodiversity in Coastal Wetlands: Conservation, Monitoring and Management.”

Field activities on Education and Public Awareness on wetlands have included:

- support of World Wetlands Day celebrations (conferences, field trips, competitions, TV and radio broadcast) in Burkina Faso, Côte d’Ivoire, The Gambia, Guinea, Guinea-Bissau, Ghana, Mauritania, Senegal, Sierra Leone and Nigeria;
- regular production of diverse CEPA materials including T-shirts, caps, posters and calendars; and
- creation of local clubs and site guardians to build awareness of wetlands and threatened species at key sites.

Although a sub-regional strategy is now available, a key challenge is raising funds for its implementation. Limited funds are a key obstacle to the implementation of CEPA by many environmental NGOs in the sub-region. Another challenge at the sub-regional level is the need to provide materials in many local languages to make them widely accessible, especially in rural communities.

Overall, some key actions are required for the continued sustainable operation of the programme:

- develop an implementation plan for the regional CEPA Strategy;
- establish a sub-regional CEPA Specialist Group to guide implementation and identify national needs;
- establish a framework for consultation on wetlands CEPA, especially between environmental and development NGOs; and
- enable CEPA to act through the development of a sub-regional funding mechanism to which partners across the region may apply for support to carry out CEPA activities.

## Wetland Link International (WLI): a global network for wetland centres

Malcolm Whitehead

The Wildfowl & Wetlands Trust, London Wetland Centre, Queen Elizabeth's Walk, Barnes, London, SW13 9WT, UK.

Whitehead, M. 2006. Wetland Link International (WLI): a global network for wetland centres. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 838-840.

### ABSTRACT

The importance of wetland centres for connecting people to nature is discussed. Wetland centres are important vehicles for delivering CEPA (communication, education and public awareness) about wetlands. In this way, they assist countries to meet their commitments as Contracting Parties to the Ramsar Convention on Wetlands. The potential of wetland centres is increased when they are able to share ideas and expertise. Hence the need for a global umbrella network – WLI – or Wetland Link International. This paper outlines the objectives of WLI, the benefits of membership, and how to join.

### WHY HAVE WETLAND CENTRES? THE CONTEXT

Without wetlands, there is no water for life. Of the world's water, 97% is salty and oceanic. Of the remaining 3%, nearly all is frozen in polar regions or imprisoned underground. Most life – including human life – depends on 0.26% of global freshwater. This water is stored in wetlands: from lakes and lagoons to marshes, ponds, pools, fens, bogs and rivers.

Wetlands store water and carbon. They filter and clean water. They mitigate against the effects of storms and floods. They stabilize shorelines and prevent coastal erosion. They are the source of numerous products from food and fibre to fuel and pharmaceuticals. They are homes for a wealth of biodiversity. They reveal clues to historic and modern human cultures through archaeology. They are enormously productive and of immense economic, political, developmental and socio-cultural importance.

People need wetlands. Life needs wetlands. This is not always immediately apparent. City dwellers may not know or consider how their household water supply depends on local wetlands. Many people world-wide have to travel long distances for fresh, clean water. In some countries, access to water is a major health and security issue.

Wetlands disappear under development, drainage and pollution; underground aquifers recede with over-consumption; species are lost; the combination of extreme weather and diminishing wetlands causes major flooding, affecting countries as diverse as Bangladesh, China, the USA and the UK.

The solution depends on many things, but primarily on people. First, though, people must become aware and engaged with wetlands. They must be connected, concerned and competent to make informed decisions and take positive action for wetland environments.

This is where wetland centres come in.

### THE ROLE AND DIVERSITY OF WETLAND CENTRES – REAL VALUE FROM REAL LIFE

Wetlands are a great conduit – a “way in” – for exploring all sorts of topical environmental issues. These include basic ecological literacy, the conservation of species and habitats (biodiversity),

and local/global water issues. Further, they are amphitheatres of experience where feelings, emotions and values are developed.

Wetland centres are prime vehicles for raising awareness, focusing experience and catalysing environmental action on behalf of wetlands.

There are several hundred wetland centres throughout the world. They range from embryonic, community-led initiatives in Lagos, Nigeria, to high-tech, multi-media interactive exhibits in Hong Kong's International Wetland Park. Many are managed by non-governmental organizations (NGOs) such as the Wildfowl & Wetlands Trust (WWT, with nine centres in the UK) and Worldwide Fund for Nature (WWF, with wetland centres including those at Karachi, Pakistan, and Mai Po, Hong Kong). Some are run by governments (e.g. Sungei Buloh Wetland Reserve in Singapore, managed by the government's National Parks Board). A few are managed by NGOs for governments (e.g. Kota Kinabalu City Bird Sanctuary in Sabah, Malaysia).

Wetland centres may operate in partnership with other sectors. The WWT's London Wetland Centre in the UK was developed by the WWT, Thames Water (a public water company) and Berkeley Homes (a private housing developer). The Point-a-Pierre Wildfowl Trust in Trinidad is sited within a major petrochemical complex (Petrotrin). The Soonabai Pirojsha Godrej Foundation Mangrove Project in India is a public charitable Trust linked to M/s Godrej & Boyce Mfg. Co. Ltd., a multi-product Indian corporate.

### WETLAND CENTRES – THE PEOPLE POTENTIAL

Wetland centres bring people and wildlife together for the benefit of both. They offer major opportunities for CEPA (communication, education and public awareness) about wetlands: their biodiversity, functions and values. Globally, wetland centres provide numerous learning programmes for formal (school and university) and non-formal (the general public – adults and youth) audiences. Many have education staff and volunteers. At The Wetland Centre at Shortlands in Australia, a successful schools programme is run in partnership with the State Government (New South Wales) Department of Education and Training.

Wetland centres provide amazing natural spectacles. They are wildlife havens, conservation centres, visitor attractions and eco-tourism venues operated as sites for public learning, access to green space, and biodiversity/heritage conservation. During the southern summer, over two million migratory shorebirds visit Australian wetlands on migration. Visitors to coastal wetland centres marvel at the diversity and sheer numbers. Most of the Svalbard population of the Barnacle Goose *Branta leucopsis* winters in and around the WWT wetland centre at Caerlaverock on the banks of Scotland's Solway Firth in the UK.

Cultural heritage is also a major feature of wetland centres. At the WWT Martin Mere centre in the UK, interpretation

reveals the rich history of the mere through “biofacts” and artefacts, from Pleistocene mammals to Neolithic wooden pathways and “bog bodies” buried in the mere in Roman times. The Pointe-a-Pierre Wildfowl Trust in Trinidad has an Amerindian Museum.

The sense of place engendered by immersion in a wetland centre can be a significant life experience leading to concern and care for the planet. Who could not be affected by the big skies of the WWT Welney centre in the fens of eastern England, the haunting peat bog landscapes associated with Peatland World in Ireland’s Bog of Allen, the tropical coastal paradise of Cousin Island in the Seychelles, and the majesty of Chesapeake Bay around the Horsehead Wetland Centre in the eastern USA?

Wetland centres offer unparalleled close encounters and access to secret worlds. Hidden cameras bring the breeding dramas of seabird colonies to the comfort of the Scottish Seabird Centre; Denmark’s Aqua Ferskvands Aquarium is an inside-out aquarium with fresh views of grebes, otters and others; and at Het Zwin in Belgium, visitors can come eyeball to eyeball with a White Stork *Ciconia ciconia*. The Caneo Visitor Centre near Trieste in Italy provides an opportunity to stay in the middle of reed-beds and salt-marsh, while at Wye Marsh Wildlife Centre in Canada, visitors can canoe, ski cross-country, hike or snowshoe across the site during different seasons.

Connection to nature at wetland centres relieves stress and is spiritually uplifting. At the WWT’s London Wetland Centre, yoga groups and “green” gym members escape the stresses of city life. Everyday, a host of urban dwellers walk, cycle and roller skate around the Costanera Sur Ecological Reserve on the edge of Buenos Aires in Argentina. The health benefits of being around nature are only beginning to be understood.

Wetland centres link local communities to “their” wetlands, encouraging ownership and stewardship. At Lake Elementeita in Kenya’s Rift Valley, a group of local people have built an Education Centre to encourage local engagement and environmental action around this important site for flamingos.

Wetland centres may be a mixture of nature reserve, wilderness area, botanical garden, collection of captive animals, museum, science centre and cultural heritage site. They may be important wildlife and landscape features in the integrated management of urban water catchments. They are inclusive and offer access to all. In much of Europe, Australia and North America, they offer exposure to real life in safe surroundings. This is vital where people are increasingly alienated from nature through prescriptive school-based curricula, health and safety fears, litigious societies, and the dominance of virtual media

## POLICY AND PARTNERS – THE RAMSAR CONVENTION AND CEPA

The Ramsar Convention on Wetlands is an intergovernmental treaty providing the framework for countries to adopt local, regional and national actions and international co-operation for the conservation and wise use of wetlands and their resources. The Convention was launched at the Iranian town of Ramsar in 1971. Today, some 152 countries have joined Ramsar as Contracting Parties, and have designated nearly 1 400 sites world-wide as wetlands of international importance, totalling over 145 million hectares (Ramsar Convention 2004).

Ramsar Resolution VIII. 31 defines the CEPA Programme of the Convention. The vision of the Ramsar CEPA Programme is

“people working for the wise use of wetlands.” The programme is underpinned by the following guiding principles (Ramsar Convention 2004b):

- Wetlands provide important goods and services which help sustain human life, conserve biological diversity, and combat the impacts of climate change and desertification. CEPA are the tools for placing people’s social, political, economic and cultural realities within the context of the goods and services provided by wetland ecosystems.
- The Ramsar Convention seeks to motivate people to appreciate the values of wetlands so that they become advocates for wetland conservation and wise use and may act to become involved in relevant policy formulation, planning and management.
- The key actors in the implementation of the Ramsar Convention need effective CEPA tools and expertise to engage major stakeholders and to convey appropriate messages in order to mainstream the wise-use principle throughout society.
- Wise-use issues and concepts need to be communicated effectively to ensure participation of major stakeholders from different sectors and mainstreaming of the issues in sector plans and actions. This communication needs to operate laterally, across and between sectors, and also vertically from stakeholders to governments and back.
- Support for the CEPA Programme should be recognized by Parties to the Convention as an investment which will reduce conflicts over wetland resources, increase the number of advocates, actors and networks involved in the issues, and build an informed decision-making and public constituency. CEPA mobilizes actions directed at achieving the wise use of wetlands. CEPA should form a central part of implementing the Ramsar Convention by each Contracting Party.

Operational Objective 3.3 of the Ramsar CEPA Programme identifies Wetland Education Centres as key locations for promoting the principles of wetland conservation and wise use through CEPA activities. It seeks to establish wetland education centres at Ramsar and other wetland sites to provide Ramsar focal points for local and national CEPA activities.

The programme also identifies the Wetland Link International (WLI) network as a key organization to assist the Ramsar Contracting Parties in this area of work. It encourages participation in the Wetland Link International of the Wildfowl & Wetlands Trust, UK, as a mechanism for gaining access to global and national expertise in CEPA (Ramsar Convention 2002).

## WETLAND LINK INTERNATIONAL (WLI)

WLI is a global network of Wetland Education Centres. The network defines Wetland Education Centre as “any place where there is interaction between people and wildlife, and CEPA activity occurs in support of wetland conservation” (WWT 2004).

The WLI network embraces wetland nature and cultural heritage reserves with a diverse range of visitor facilities (e.g. centres run by the WWT), environmental education centres, field study centres, zoos and botanical gardens, interactive natural history museums, and a wide variety of site-based community projects and programmes.

WLI was founded in 1991 and developed from a range of wishes and desires. These included:

- the wish to reduce feelings of isolation of those involved with on-the-ground CEPA activities;
- the wish to share knowledge and practical expertise;
- the wish to raise the profile and status of CEPA activity as part of conservation and sustainability objectives;
- the desire to produce solutions.

WLI is co-ordinated by the Wildfowl & Wetlands Trust, the UK's largest NGO dedicated to international wetland conservation. The network is endorsed by the Ramsar Secretariat and supported by the HSBC Bank plc.

## WLI OBJECTIVES

WLI has the following objectives:

- To encourage and support the exchange of information and expertise internationally between those involved in wetland education programmes, particularly those operating from Wetland Education Centres, field study and environmental education centres, zoos and botanical gardens, and aquariums.
- To advocate for, and assist in, the development of new Wetland Education Centres and their associated programmes world-wide.
- To improve the effectiveness of operations at Wetland Education Centres by sharing expertise through training and exchange programmes.
- To lobby for the greater inclusion of CEPA programmes within wetlands and related conservation initiatives and instruments, and to support the development of frameworks for subsequent implementation at national, regional and global levels.

No-one knows how many wetland centres exist world-wide. A compilation of national Ramsar reports reveals several hundred, but if other categories are included (e.g. non-Ramsar sites, public aquariums, zoos), the number may be thousands. About 200 of these from six continents are included on the WLI database

## WLI MEMBERSHIP

WLI membership is site-based and open to any organization, group or individual who is planning, designing or operating a place or places that conform to the definition of a Wetland Education Centre above. Members may be governmental, non-governmental, professional, amateur, paid or voluntary. Details of specific Wetland Education Centres may be found in the "WLI World Global Directory" on the WLI web-site, or by emailing the WLI Co-ordinator. Benefits of membership include the following: WLI members become part of an international community of Wetland Education Centres.

- There is a WLI e-group to share ideas and expertise, from the design and planning of centres to specific programmes and events, such as World Wetlands Day.
- A quarterly E-newsletter will be sent to all WLI members and key contacts (e.g. Ramsar focal point) from 2005.

- All WLI members have access to advice, support and expertise from the WLI Co-ordinator and membership.
- There will be opportunities for training, meetings and staff exchange as the WLI Professional Development programme progresses.

WLI is keen to develop regional networks that assist with local, national and regional issues in wetland education. For example, a local network may be well suited to pool ideas and resources for events such as World Wetlands Day. National networks can be presented to governments as evidence that they (the governments as Contracting Parties to the Ramsar Convention) are "ticking the boxes" in terms of fulfilling their obligations to the Ramsar CEPA Programme.

Currently there is a WLI Australia, co-ordinated by The Wetlands Centre, Shortlands, and a WLI UK, co-ordinated by the Wildfowl & Wetlands Trust. A WLI-Asia network is in the development stage, with a preliminary meeting booked for mid-2005, and a WLI Europe-Africa is at the planning stage, with an intended launch in late 2005. Efforts will be made in the future to organize WLI regional representation on all continents.

## HOW TO JOIN WLI

Prospective members should email the WLI Co-ordinator, [Malcolm.whitehead@wwt.org.uk](mailto:Malcolm.whitehead@wwt.org.uk), or write to: The WLI Co-ordinator, WWT London Wetland Centre, Queen Elizabeth's Walk, Barnes, London SW13 9WT, UK. Membership is free, but members will be asked to submit a WLI site profile for inclusion in the "WLI World Global Directory" on the WLI web-site ([www.wli.org.uk](http://www.wli.org.uk)).

## Birding in the United States: a demographic and economic analysis

Genevieve Pullis La Rouche

Division of Federal Aid, U.S. Fish and Wildlife Service, Washington, D.C. 20240, USA. (email: genevieve\_pullis@fws.gov)

Pullis La Rouche, G. 2006. Birding in the United States: a demographic and economic analysis. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 841-846.

### ABSTRACT

Bird-watchers are an untapped source of support for bird conservation. Data from the United States Fish and Wildlife Service's 2001 National Survey of Fishing, Hunting and Wildlife-Related Recreation provide socio-demographic and economic information about birders that can be used when planning outreach and building public backing for bird conservation plans. The Survey, conducted since 1955, is one of the oldest and most comprehensive continuing recreation studies. Conducted every five years, it was initially created to collect participation and expenditures of sportspersons, but was expanded in 1980 to include non-consumptive recreation – feeding, photographing and observing of wildlife. In August 2003, the Survey's first report on bird-watching was released as an Addendum to the 2001 Survey (Pullis La Rouche 2003). It revealed that in the United States 46 million people watched birds – nearly one in five adults – and they spent US\$ 32 billion in retail sales thereby contributing US\$ 85 billion in economic output and creating 863 405 jobs. The data also provide a wealth of information about the kind of birds being watched (47% of bird-watchers watch waterbirds), and trends in participation, avidity, and spending.

### INTRODUCTION

In January 2002 an unprecedented major media event unfolded in a Louisiana swamp. A team of top ornithologists set out to find the Ivory-billed Woodpecker *Campephilus principalis*, a bird last seen in the United States in 1943 and, until a recent credible sighting by a turkey hunter, considered extinct in the U.S. The expedition, funded by a corporate sponsor, received worldwide media attention including coverage by the New York Times, USA Today, and National Public Radio. This high-profile search for the Ivory-billed Woodpecker is just one indicator of the growing popularization of birds and birding. Other evidence abounds. A field guide, *Sibley's Guide to Birds*, became a New York Times bestseller. And a quick search of the internet yields numerous birding sites, some of which list hundreds of birding festivals held around the country each year.

This growing awareness of birding comes at an odd time; birds are in jeopardy. According to 35-year trend data (1966-2001) from the U.S. Geological Service, almost one-in-four bird species in the United States show "significant negative trend estimates" (Sauer *et al.* 2003). This decline is attributed primarily to the degradation and destruction of habitat resulting from human population growth and short-sighted environmental practices such as the razing of wetlands needed by migratory birds. Although there is a certain irony in people becoming enthusiastic about birds as they disappear, it also presents an opportunity: birders may be the economic and political force that can help save the birds. The following report provides up-to-date information so birders and policy makers can make informed decisions regarding the protection of birds and their habitats.

This report identifies who birders are, where they live, how avid they are, where they bird and what kinds of birds they watch. In addition to demographic information, this report also provides two kinds of economic measures. The first is an estimate of how much birders spend on their hobby and the economic impact of these expenditures. The second is the net economic value of birding, that is, the value of birding to society.

By understanding who birders are, they can be more easily educated about pressures facing birds and bird habitats. Conversely, by knowing who is likely *not* a birder, or who is potentially a birder, information can be more effectively tailored. The economic values presented here can be used by resource managers and policy makers to demonstrate the economic might of birders, the value of birding – and by extension, the value of birds. In fact, research shows that these kinds of values help wildlife managers make better decisions and illustrate the value of wildlife to American society (Loomis 2000).

All data presented here are from the wildlife-watching section of the 2001 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation (FHWAR). It is the most comprehensive survey of wildlife recreation in the U.S. Overall, 15 300 detailed wildlife-watching interviews were completed with a response rate of 90 percent. The Survey focused on 2001 participation and expenditures by U.S. residents 16 years of age and older.

### BIRDERS

In 2001 there were 46 million bird-watchers or birders, 16 years of age and older, in the United States – a little over one in five people. What is a birder? The National Survey uses a conservative definition. To be counted as a birder, an individual must have either taken a trip a mile or more from home for the primary purpose of observing birds and/or closely observed or tried to identify birds around the home. So people who happened to notice birds while they were mowing the lawn or picnicking at the beach were not counted as birders. Trips to zoos and observing captive birds also did not count.

Backyard birding or watching birds around the home is the most common form of bird-watching. Eighty-eight percent (40 million) of birders are backyard birders. The more active form of birding, taking trips away from home, is less common with 40 percent (18 million) of birders partaking.

The average birder is 49 years old and more than likely has a better than average income and education. She is slightly more likely to be female, and highly likely to be white and married. There is also a good chance that this birder lives in the northern half of the country in a small city or town. Does this paint an accurate picture of a birder? Like all generalizations the description of an "average" birder does not reflect the variety of people who bird, with millions falling outside this box. The tables show in numbers and participation rates (the percentage of people who participate) birders by various demographic breakdowns.

**Table 1.** Age distribution of the United States population and birders: 2001. (Population 16 years of age and older; numbers in thousands).

Age	US population	Number of birders	Participation rate
16 and 17	7 709	1 043	14%
18 to 24	22 234	1 894	9%
25 to 34	5 333	5 990	17%
35 to 44	4 057	10 414	24%
45 to 54	40 541	10 541	26%
55 to 64	25 601	7 177	28%
65 plus	36 823	8 893	24%

**Table 2.** Income distribution of the United States population and birders: 2001. (Population 16 years of age and older; numbers in thousands).

Income	US population	Number of birders	Participation rate
Less than \$10 000	10 594	2 212	21%
\$10 000 to \$19 000	15 272	2 754	18%
\$20 000 to \$24 000	10 902	2 335	21%
\$25 000 to \$29 000	11 217	2 392	21%
\$30 000 to \$34 000	11 648	2 618	22%
\$35 000 to \$39 000	9 816	2 005	20%
\$40 000 to \$49 000	16 896	4 116	24%
\$50 000 to \$74 000	31 383	7 476	24%
\$75 000 to \$99 000	17 762	4 771	27%
\$100 000 or more	19 202	5 224	27%

**Table 3.** Educational distribution of the United States population and birders: 2001. (Population 16 years of age and older; numbers in thousands).

Education	US population	Number of birders	Participation rate
11 years or less	32 820	4 627	14%
12 years	73 719	13 933	19%
1 to 3 years at college	49 491	11 363	23%
4 years at college	34 803	8 922	26%
5 years or more college	1 646	7 107	33%

**Table 4.** Racial and ethnic distribution of the United States population and birders: 2001. (Population 16 years of age and older; numbers in thousands).

Race/ethnicity	US population	Number of birders	Participation rate
Hispanic	21 910	1 880	9%
White	181 129	43 026	24%
African-American	21 708	1 243	6%
Native American	1 486	321	22%
Asian	7 141	436	6%
Other	833	55	7%

The tendency of birders to be middle-age or older is reflected in both the number of birders and participation rates. Looking at the different age breakdowns in Table 1, the greatest number of birders were in the 35 to 44 and 45 to 54 age groups. People aged 55 to 64 had the highest participation rates while the participation rate was particularly low for people aged 18 to 24. Birders who take trips away from home to pursue their hobby were on average slightly younger, at 45 years old compared to backyard birders who were on average 50 years old.

The higher the income and education level the more likely a person is to be a birder. Twenty-seven percent of people who live in households that earn US\$ 75 000 or more were bird-watchers – 5 percent above the national average of 22 percent. Education, which is often highly correlated with income, shows the same trend. People with less than high school education participated at 14 percent – far below the national average – while people with five or more years of college had the highest participation rate at 33 percent. See Tables 2 and 3 for more information.

Unlike hunting and fishing where men were overwhelmingly in the majority, a slightly larger percent of birders were women – 54 percent in 2001. And most birders, 72 percent, were married.

Excepting Native American participation, birders are not a racially or ethnically diverse group. Ninety-four percent of birders identified themselves as white. The scarcity of minority birders is not just a reflection of their relatively low numbers in the population at large, it is also a function of low participation rates. The participation rates of African-Americans, Asians, and Hispanics were all 9 percent or lower while the rate for whites, 24 percent, was slightly above the 22 percent national average. Native Americans on the other hand had a participation rate (22 percent) on par with the national average. See Table 4.

The sparser populated an area, the more likely its residents were to watch birds. The participation rate for people living in small cities and rural areas was 28 percent – 6 percent above the national average. Whereas large metropolitan areas (1 million residents or more) had the greatest number of birders, their residents had the lowest participation rate, 18 percent. See Table 5.

When measured in terms of the percent of state residents participating, states in the northern half of the United States generally had higher levels of participation than did states in the southern half. While 44 percent of Montanans and 43 percent of Vermonters watched birds, only 14 percent of Californians and Texans did. See Table 6.

The participation rate was highest (30%) in the West North Central region of the United States. The New England states had the second highest participation rate at 27 percent with a close third going to the Rocky Mountain states (26 percent). The West South Central states had the lowest rate of 17 percent while the Pacific and South Atlantic states yielded slightly higher rates, both 19 percent. However, in terms of sheer numbers, the Pacific and South Atlantic states had the most resident birders – 7 million and 8 million respectively, while New England had the least, 3 million.

Bird-watching by state residents tells only part of the story. Many people travel out-of-state to watch birds and some states are natural birding destinations. Wyoming reaped the benefits of this tourism with a whopping 67 percent of their total birders coming from other states. The scenic northern states of New Hampshire, Vermont, Montana, and Alaska also attracted many birders – all had more than 40 percent of their total birders coming from other states. See Table 7.

**Table 5.** Percentage of United States population who birded by residence: 2001. (Population 16 years of age and older; numbers in thousands).

Metropolitan Statistical Area	US population	Number of birders	Participation rate
1 000 000 or more	112 984	20 868	18%
250 000 to 999 999	41 469	8 991	22%
50 000 to 249 000	16 693	4 622	28%
Outside MSA	41 151	11 470	28%

**Table 6.** Birding participation rates by state residents: 2001. (Population 16 years of age and older).

	US average		22%
Montana	44%	Vermont	43%
Wisconsin	41%	Washington	36%
Minnesota	36%	Maine	36%
Alaska	36%	Kentucky	35%
Oregon	35%	New Hampshire	34%
Wyoming	34%	Iowa	34%
South Dakota	33%	Idaho	29%
Indiana	29%	New Mexico	28%
Virginia	28%	Utah	27%
Oklahoma	27%	Pennsylvania	27%

### Where and what are they watching?

Backyard birding is the most prevalent form of birding with 88 percent of participants watching birds from the comfort of their homes. Forty percent of birders travel more than a mile from home to bird, visiting a variety of habitats on both private and public lands. Of the 18 million Americans who ventured away from home to watch birds, public land rather than private land was visited more frequently, although many visited both. Eighty-three percent of birders used public land such as parks and wildlife refuges, 42 percent used private land, and 31 percent visited both.

The most popular setting to observe birds was in the woods (73%), followed by lakes and streamside areas (69%) and brush-covered areas and fields (62% and 61%). Less popular sites were the ocean (27%) and manmade areas (31%) such as golf courses and cemeteries. See Table 8.

What kinds of birds are they looking at? Seventy-eight percent reported observing waterfowl, making them the most spied on

**Table 7.** Birding by state residents and non-residents: 2001. (Population 16 years of age and older; numbers in thousands).

1-20 bird species	74%	74%
21-40 bird species	14%	13%
41 or more bird species	5%	8%
Kept birding life list	4%	5%

\* In 1980, the question was asked of all wildlife-watchers (formerly called non-consumptive) and in 2001 the question was asked of only birders.

type of bird. Songbirds were also popular with 70 percent of birders watching them, followed in popularity by birds of prey (68%) and other waterbirds such as herons and shorebirds (56%).

### Birding trends

Is birding increasing? Despite recent popularization (high visibility within the media and popular culture and increased recognition of the sport within American homes) of birding, past FHWAR Survey results point to a more complicated story. A comparison of results from the 1991, 1996, and 2001 estimates show that bird-watching around the home has decreased rather than increased over that 10-year period (USFWS 1993, 1997, 2002). In 1991, 51.3 million people reported observing birds around their homes. In 1996 that number dropped to 42.2 million and in 2001 to 40.3 million. Because the 2001 Survey is the first time people were asked if they specifically watched birds on trips away from home, it cannot be said conclusively if this activity increased or decreased. However, in all three Surveys, people were asked if they observed, fed, or photographed birds away from home. These numbers indicate a net decrease in away-from-home birding from 24.7 million in 1991 to 18.5 million in 2001 but a slight uptick from 1996 (17.7 million) to 2001.

### Avidity

All people identified as birders in this report said that they took an active interest in birds – defined as trying to closely observe or identify different species. But what is the extent of their interest? In order to determine their “avidity” the following factors were considered: the number of days spent bird-watching; the number of species they could identify; and if they kept a bird life list.

Presumably because of the relative ease of backyard birding, birders around the home spent nine times as many days watching birds as did people who traveled more than a mile from home to bird-watch. In 2001, the median number of days for backyard birders was 90 and for away-from-home birders it was 10.

Although birders are investing a fair amount of time pursuing their hobby, most do not appear to have advanced identification skills. Seventy-four percent of all birders could identify only between 1 to 20 different types of bird species, 13 percent could identify 21 to 40 birds and only 8 percent could identify more than 41 species. Skill levels are higher for birders who travel from home to bird-watch compared to backyard birders – 10 percent of away-from-home birders could identify 41 or more birds as opposed to 6 percent of backyard birders. Tallies of birds seen during a birder’s life, sometimes called birding life lists, were kept by only 5 percent of birders. This was roughly the same for backyard birders and away-from-home birders alike.

### Avidity trends

If we can’t say there are more birders can we say that birders are more knowledgeable about their hobby than in the past? In order to gauge birders’ avidity and level of expertise, the 2001 Survey asked birders how many birds they can identify – a question last asked in the 1980 Survey (USFWS 1982). A comparison of responses shows that skill levels did not change much in that 20 year time period. For both years, the same percent, 74, was in the beginner category (1 to 20 species of birds) and roughly the same percent, 13 and 14, respectively, fell into the intermediate (21 to 40 birds) level. A slightly higher percentage of expert birders, however, (41 or more species) was found in the 2001 Survey, 8 percent versus 5 percent in the 1980 Survey. Yet another sign that the more things change the more they stay the same, almost the same portion, 4 and 5 percent, kept birding life lists. See Table 9.

## THE ECONOMICS OF BIRD-WATCHING

### Measures of economic value

Putting a dollar figure on birding can appear a tricky business. How can dollars be used to value something as intangible as the enjoyment of birds and birding? Looked at from a practical perspective we live in a world of competing resources and dollars. Activities such as golfing and industries such as computer software are regularly described in terms of jobs generated and benefits to consumers. The same economic principles that guide the measure of golf and software apply also to birding.

Expenditures by recreationists and net economic values are two widely used but distinctly different measures of the economic value of wildlife-related recreation. Money spent for binoculars in a store or a sandwich in a deli on a trip has a ripple effect on the economy. It supplies money for salaries and jobs which in turn generates more sales and more jobs and tax revenue. This is economic output or impact, the direct and indirect impact of birders’ expenditures and an example of one of two economic values presented in this paper. Economic impact numbers are useful indicators of the importance of birding to the local, regional, and national economies but do not measure the economic benefit to an individual or society because, theoretically, money not spent on birding (or golf, or software) would be spent on other activities, be it fishing or scuba diving. Money is just transferred from one group to another.

However, from the perspective of a given community or region, out-of-region residents spending money for birding represents real economic wealth.

Another economic concept is birding's economic benefit to individuals and society: the amount that people are willing to pay over and above what they actually spend to watch birds. This is known as net economic value, or consumer surplus, and is the appropriate economic measure of the benefit to individuals from participation in wildlife related recreation (Bishop 1984, Freeman 1993, Loomis *et al.* 1984, McCollum *et al.* 1992). The benefit to society is the summation of willingness to pay across all individuals. Net economic value is measured as participants' "willingness to pay" above what they actually spend to participate. The benefit to society is the summation of willingness to pay across all individuals.

**Table 10. Birders' expenditures for wildlife-watching: 2001. (Population 16 years of age and older; numbers in thousands of US dollars).**

Expenditure item	Expenditure (thousands of US\$)
<b>Total: all items</b>	<b>31 686 673</b>
<b>Total: trip-related expenditures</b>	<b>7 409 679</b>
Food	2 646 224
Lodging	1 851 206
Public transportation	682 202
Private transportation	1 790 951
Guide fees, pack trip or package fees	110 374
Private land use fees	48 999
Public land use fees	108 414
Boating costs	135 381
Heating and cooking fuel	35 928
<b>Total: equipment and other expenses</b>	<b>24 276 994</b>
Wildlife-watching equipment, total	6 010 141
Binoculars, spotting scopes	471 264
Cameras, video cameras, special lenses, and other photographic equipment	1 431 807
Film and developing	837 868
Bird food	2 239 259
Nest boxes, bird houses, feeders, baths	628 060
Daypacks, carrying cases and special clothing	288 648
Other wildlife-watching equipment (e.g. field guides, maps)	113 235
Auxiliary equipment, total	523 700
Tents, tarps	163 999
Frame packs and backpacking equipment	121 217
Other camping equipment	238 835
Other auxiliary equipment (such as blinds)	117 267
Special equipment, total	11 158 302
Off-the-road vehicles	5 512 624
Travel or tent trailers, pickups, campers, vans, motor homes	4 657 752
Boats, boat accessories	946 688
Other	41 238
Magazines	297 780
Land leasing and ownership	4 197 666
Membership dues and contributions	808 101
Plantings	639 986

**Table 11. Economic impact of birders: 2001. (Population 16 years of age and older).**

Retail sales (expenditures)	US\$ 31 686 673 000
Economic output	US\$ 84 931 020 000
Salaries and wages	US\$ 24 882 676 000
Jobs	863 406
State income taxes	US\$ 4 889 380 000
Federal income taxes	US\$ 7 703 308 000

#### Facts-at-a-glance

- 46 million birders
- US\$ 32 billion in retail sales
- US\$ 85 billion in overall economic output
- US\$ 13 billion in State and Federal income taxes
- 863 406 jobs created

#### Birders' expenditures and economic impact

Birders spent an estimated US\$ 32 billion on wildlife-watching in 2001 (see Table 10). This estimate includes money spent for binoculars, field guides, bird food, bird houses, camping gear, and big-ticket items such as boats. It also includes travel-related costs such as food and transportation costs, guide fees, etc. When using the numbers in Table 10 it is important to know that these dollar figures represent the money birders spent for all wildlife-watching recreation – not just birding. The 2001 Survey collected expenditure data for people who fed, photographed, or observed wildlife. Expenditure data were not collected solely for birding. It is possible that people who watched birds in 2001 may have spent money on other types of wildlife-related recreation such as binoculars for whale-watching or gas for a moose-watching trip rather than only bird-watching. Therefore, these estimates for birding expenditures may be overestimates.

This US\$ 32 billion that birders spent generated US\$ 85 billion in economic benefits for the nation in 2001. This ripple effect on the economy also produced US\$ 13 billion in tax revenues and 863 406 jobs. See Table 11.

The sheer magnitude of these numbers proves that birding is a major economic force, driving billions in spending around the country. On a local level, these economic impacts can be the life-blood of an economy. Towns such as Cape May, New Jersey, and Platte River, Nebraska, attract thousands of birding visitors a year generating millions of dollars – money that would likely otherwise be spent elsewhere.

**Table 12. Net economic values for wildlife-watching: 2001. (Population 16 years of age and older).**

Net economic values	State residents	Non-residents
Net economic value per year	US\$ 257	US\$ 488
Standard error of the mean	12	37
95 percent confidence interval	US\$ 233-282	US\$ 415-561
Net economic value per day of bird-watching	US\$ 35	US\$ 134
Standard error of the mean	2	12
95 percent confidence interval	US\$ 32-39	US\$ 110-158

### Estimated net economic values

As stated earlier, the willingness to pay above what is actually spent for an activity is known as net economic value. This number is derived here by using a survey technique called contingent valuation (Mitchell & Carson 1989). Respondents to the 2001 Survey were asked a series of contingent valuation (CV) questions to determine their net willingness to pay for a wildlife-watching trip. Please note that the data presented here are net economic values for wildlife-watching trips – not for bird-watching trips solely. However, since the vast majority of away-from-home wildlife-watchers are birders (84 percent), the values presented here are acceptable for use in valuing birding trips.

As seen in Table 12, the net economic value per year for a wildlife-watcher in their resident state is US\$ 257 per year or US\$ 35 per day. Wildlife-watchers who travel outside their state have a different demand curve (they generally take fewer trips and spend more money) and therefore have their own net economic values of US\$ 488 per year and US\$ 134 per day. When and how can these values be used? These numbers are appropriate for any project evaluation that seeks to quantify benefits and costs. They can be used to evaluate management decisions (actions) that increase or decrease participation rates. In a simple example, if a wildlife refuge changed its policies and allowed 100 more birders to visit per year, the total value to society due to this policy change would be US\$ 25 700 ( $257 \times 100$ ) per year (assuming all visitors are state residents). This value, however, assumes that these 100 birders could and would watch birds only at this refuge and that they would take a certain number of trips to this refuge. In a more realistic example, if the refuge changed its policy and stayed open two more weeks a year and knew that 100 people visited each day during this period then the benefit to society could be estimated by multiplying the number of people by days ( $100 \times 14$ ) by the average value per day (US\$ 35) for a total of US\$ 49 000. If the refuge had data on the number of in-state and out-of-state visitors then the numbers could be adjusted to reflect their appropriate value.

Net economic values also can be used to evaluate management actions that have a negative affect on wildlife-watching. For example, if a wildlife sanctuary was slated for development and birders were no longer able to use the site, and if the sanctuary manager knew the number of days of birding over the whole year (e.g. 2 000 days) it is possible to develop a rough estimate of the loss from this closure. This estimate is accomplished by multiplying net economic value per day (US\$ 35) by the days of participation (2 000) for a value of US\$ 70 000 per year.

Two caveats exist to the examples above: (1) if bird-watchers can shift their birding to another location then the values are an over-estimate; and (2) if a loss of wildlife habitat causes an overall degradation in the number of birds and in the quality of birding then the values are an under-estimate.

### CONCLUSION

Back in Louisiana, the search for the Ivory-billed Woodpecker ended in disappointment. After an exhaustive two week search, none were found. Optimism, however, continues to prevail. In a group statement the expedition team said they think the bird may exist based on the availability of good quality habitat and other evidence. This optimism of always looking hopefully into the next tree is the *esprit-de-corps* of birders. As this report shows, birders come from many walks of life and watch a variety of birds in different settings. Their enthusiasm for birding also translates into

spending, thereby contributing significantly to national and local economies. The high values birders place on their birding trips is a solid indicator of birding's benefit to society. While the numbers of birders may not have grown statistically, the power of a mobilized birding community and the willingness of mass media sources and the general public to give play to birding issues has an impact felt deeply in the economy and promotes the sustainability of bird habitats. Hopefully, the information in this paper will allow resource managers and policy makers to make informed management decisions when birds and birding are involved.

### ACKNOWLEDGMENTS

The author thanks Sylvia Cabrera, Richard Aiken, Grant La Rouché, John Charbonneau and Jim Caudill for reviewing earlier drafts of this paper.

## Wetlands as part of the natural heritage: the educational response

Yu.L. Mazourov<sup>1,2</sup> & T.Yu. Zengina<sup>2</sup>

<sup>1</sup>Russian Heritage Institute, ul. Kosmonavtov 2, Moscow, 129366 Russia. (email: jmazourov@yandex.ru)

Mazourov, Yu.L. & Zengina, T.Yu. 2006. Wetlands as part of the natural heritage: the educational response. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 847.

Wetlands are not only a human resource but are also part of the natural heritage. Public awareness, through high quality environmental education, is needed to generate adequate protection of these areas. The *UN Decade of Education for Sustainable Development* is an opportunity for a radical 'greening' of educational curricula so that wetland studies are included. This paper explains the authors' experience of teaching wetland conservation issues as part of a course on heritage studies.

Wetlands have long been perceived as unimportant habitats or even as 'badlands'. It is only since the 20th century that their huge ecological importance has been highlighted, and conservation actions undertaken. However, this recognition is still not widespread among the general public, and the best way to change this situation is through education, notably by providing a new vision of wetlands as a special part of nature.

In Russia, wetlands are now seen as a natural resource, and the main reason for establishing nature reserves e.g. Zapovednik in the Volga River delta in 1919, was to save waterbirds, sturgeon and to provide clean drinking water. Gradually, this approach has been changing, as a result of academic research, to one of conserving biological and landscape diversity, e.g. the Great Arctic Reserve on the Taimyr Peninsula and other protected areas in Russia (Ebbinge *et al.* 2000). This has been largely due to changes in the global view of wetlands, (e.g. UNESCO, which seeks to encourage the identification, and preservation of world heritage sites as irreplaceable sources of life and inspiration). This is embodied in the 1972 UNESCO World Heritage Convention. The World Heritage List contains many wetlands of importance, e.g. Danube Delta in Romania, Everglades National Park in the USA, Greater St Lucia Wetland Park in South Africa, and the Tasmanian Wilderness in Australia. This list has contributed to a new vision for nature and wetlands as a common heritage, rather than just as a natural resource.

Unfortunately, this new recognition has been only by professionals in environmental studies and policy (Mazourov 2002, 2003). In 2003, the 57th Session of the United Nations General Assembly adopted Resolution 57/254 *United Nations Decade of Education for Sustainable Development*. This has helped academics make radical changes to the way they teach ecology to the general public and so to raise ecological culture and heritage awareness.

At Moscow State University, the basic course structure is multi-disciplinary and has been modified to incorporate a wetland theme into a one-term lecture course on heritage studies at the Faculty of Geography with an integrated module 'Wetlands as a natural heritage'. Students study wetland conservation, particularly in areas of natural heritage. Specific wetland issues are studied within the traditional courses of biology, ecology, etc. Students are being trained to work in research and planning institutions, state agencies, government bodies, committees, in secondary schools, private enterprises, and other organizations

involved in analysis, assessment, training and decision-making in the fields of environmental and nature resource management. Students are being taught that wetlands must be considered as unique and important parts of the regional natural heritage, and wise use is essential for sustainable regional development to provide economic and environmental well-being.

In computer related courses such as 'Remote Sensing in Environmental Research', students learn the potential for ecological interpretation of remotely sensed images to assess wetland status. For example the waterlogged landscapes of Meshchera National Park are used as a demonstration and field study area. Peatlands which had been excavated between 1930 and 1990 are now flooded, and are important habitats for many rare species. Students determine conservation or restoration measures on the basis of the current ecological status of habitats. Students learn digital image processing methods and thematic interpretation of Earth Observation data so as to recommend further wetland restoration and wise use.

Post-graduate students participate in international wetland ecology research undertaken by Russian research institutes together with the ALTErra-Green World Institute, DLO-Institute for Forestry and Nature Research (the Netherlands). Field research in the Kola Peninsula is an important component of the training and research for wetland studies. This area holds about 100 000 lakes and 21 000 rivers, with peatlands and swamps occupying 37% of the area.

Wetlands are important for nesting, staging, and wintering waterfowl, but industrial developments have brought significant environmental changes to many. The Lapland State Nature Biosphere Reserve, supporting 190 species of terrestrial and migratory waterbirds, is studied as an area mostly unaffected by anthropogenic changes, where students study habitats of species listed in the Russian Red Data Book. Ecosystem changes are studied in areas exposed to industrial emissions from the Severonickel and Apatit Co. industrial plants, with students carrying out visual observations, satellite imagery, lichen and bryophyte identification, geobotanical and geochemical studies, and hydrological and hydrochemical measurements.

## 6.3 Sustainable waterbird harvest. Workshop Introduction

Niels Kanstrup

Danish Hunters' Association, Molsvej 34, DK-8410 Rønne, Denmark.

Kanstrup, N. 2006. Sustainable waterbird harvest. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 848.

Trapped ducks for sale at Fereydoon Kenar market, Iran. Increasing harvests of waterbirds by growing human populations in many parts of the world challenge waterbird sustainability. Photo: Crawford Prentice.

Waterbird harvest is widespread, long-standing and an important activity for local communities around the world. In many countries the harvest takes place as a primary food source, but sport or recreational hunting is also popular. Waterbird harvesting is a diverse activity and includes a huge variety of methods, and both formal and informal management systems.

Subsistence hunting of waterbirds has a history that stretches back to the dawn of man. In many remote regions (*e.g.* the arctic, central Siberian lowlands, tropical regions), waterbirds are still an important food resource. Local communities (including of indigenous peoples) in these areas have considerable cultural knowledge of trapping techniques, including how to locate species within the landscape, and have considerable emotional links to waterbird populations as an integral component of their environment.

At the same time, sustainable utilization at all levels is regarded as a cornerstone in the conservation of nature. Kanstrup reviews the different components of sustainability, whilst has both ecological and political aspects.

One of the major challenges for waterbird managers is to assess annual harvest levels and to ensure, through regulation, that these are sustainable for the populations concerned. In many countries there is a long tradition of detailed wildlife harvest management including programmes for bag surveys and monitoring of harvest levels. America has a long history of such regulation, and Padding *et al.* and Gobeil outline North American experiences, whilst Bregnballe *et al.* review Danish policies and practices. At the scale of single sites Mondain Monval summarise harvest levels in the Camargue, whilst Sorrenti similarly assesses take in the Po Delta.

In most countries, however, the management of waterbird harvests is poor or completely lacking, and very little information is available on the annual harvest and its impact on populations. In addition, international and flyway based co-ordination is lacking in many regions, and systems need to be developed in order to obtain reliable data on harvest rates in relation to population levels and trends. Despite this, various projects are underway to reduce unsustainable waterbird harvests.

The symposium provided an overview of current waterbird harvest activities and various methods applied; to identify harvest numbers and to review methods of collecting harvest data. It also explored aspects of traditional hunting, such as the use of toxic lead gun-shot that are now known to be unsustainable. Olivier and Kanstrup reviewed Danish and other experiences in moving towards eliminating lead gunshot from waterbird shooting.

Although there are examples of unsustainable harvest practices, there seems to be no reason to believe that harvesting/hunting should inherently be thus. On the contrary, the right to use natural resources can motivate local people – especially hunters – to get involved in conservation. Training, however, is a vital element.

To build capacity at all levels, the workshop concluded that more knowledge is needed in terms of (a) the direct impact of harvest (bag, products) and indirect impact (disturbance); (b) population status and trends at flyway, migration route and population level; (c) mankind and nature, in relation to the processes of sustainable development. To secure the conservation of flyways across borders and across continents world-wide, co-operation is needed at all levels – including that of the hunters.

## Estimating waterfowl harvest in North America

### ABSTRACT

Most of the waterfowl harvested in North America are taken by sport hunters. The United States and Canada monitor the sport harvest through annual surveys of those hunters. Both countries employ sport harvest survey systems that consist of two major mail surveys: a questionnaire survey that asks a large sample of hunters to report their total harvest of ducks and geese for the year, and a parts collection survey that asks a smaller, separate sample of hunters to send in a wing from every duck and the tail feathers from every goose they harvest. The questionnaire survey gives estimates of total duck and goose harvest, whereas the parts collection survey provides estimates of the species, age and sex composition of the waterfowl harvest. These data are used to examine long-term trends in species-specific harvest and demographics that can yield vital information on the status of North American waterfowl populations. Subsistence harvest in Canada is estimated using indirect methods, but in Alaska an intensive specialized survey is used to estimate subsistence harvest.

### INTRODUCTION

Regulating the harvest of waterfowl to ensure that it is commensurate with population status is an important component of waterfowl management in North America. In order to establish appropriate waterfowl hunting regulations each year, both harvest and population size must be monitored (Geis *et al.* 1969, Smith *et al.* 1989). Most of the waterfowl harvest is monitored through surveys of hunters that are conducted annually.

The primary sources of waterfowl harvest in North America are sport hunting in Canada, the United States and Mexico, and subsistence hunting in Alaska and northern Canada. In this paper, we summarize the various methods used in North America to estimate the number of ducks and geese harvested by sport and subsistence hunters. We describe the sample frames of the various surveys, how those sample frames are obtained, and the survey methodologies and estimation procedures that are employed. Then we present the results of those efforts, and discuss how harvest estimates are used to help ensure that the harvest is sustainable.

### METHODS

#### Estimating sport harvest in the United States

In the United States, sport hunters are required to purchase hunting licenses annually. Those hunting licenses are issued by the individual state governments, not by the federal government. The cooperative state-federal Migratory Bird Harvest Information Program uses the states' licensing systems to provide the sample frame for the federal migratory bird harvest survey system. Under this program, state wildlife agencies collect the name and address of each migratory bird hunter who purchases a hunting license. They also ask each of those migra-

tory bird hunters a series of general questions about the species they hunted and their hunting success the previous year. The state wildlife agencies then send those names and addresses to the U.S. Fish and Wildlife Service. Participation in this program is mandatory for migratory bird hunters; thus, the sample frame includes all licensed sport hunters who are legally authorized to hunt migratory game birds. This totals about 3 500 000 sport hunters each year.

The U.S. Fish and Wildlife Service selects samples of hunters from the name and address data that the state wildlife agencies provide. Hunters are stratified by state and by hunting activity and success in the previous year, and stratum-specific sampling rates are selected to increase precision and maximize sampling efficiency. For example, the small group of duck hunters who were very successful in the previous year is sampled at a high rate, the larger group of moderately successful duck hunters is sampled at a lower rate, and the very large group of hunters who rarely if ever hunt ducks is sampled at a very low rate.

At the beginning of the hunting season, each sampled hunter is mailed a hunting diary form and asked to record the date, location and number of ducks and geese taken for each day of waterfowl hunting. After the end of the hunting season, the U.S. Fish and Wildlife Service sends the sample hunters a postcard reminder asking them to complete and mail back their hunting diaries. This mailing is followed by two additional reminders to all sample hunters who still have not responded. Both of those reminder mailings include replacement diary forms.

Hunters' responses are used to estimate the mean number of ducks and geese harvested per hunter for each stratum, and the total harvests of ducks and geese are estimated by expanding the means by the number of active hunters in each stratum. About 60 000 hunters are selected annually for the waterfowl hunting diary survey. Participation is voluntary, and the response rate is 55-60%.

Some hunters are unable to identify to species all of the birds they harvest. Thus the survey described above does not ask participants to report their harvest by species. To obtain species-specific harvest estimates, the U.S. Fish and Wildlife Service selects another sample of waterfowl hunters annually, and asks those hunters to participate in the Waterfowl Parts Collection Survey. Hunters who agree to participate are given special postage-paid "wing envelopes", and are asked to send back a wing from every duck they shoot and the tail feathers of every goose they shoot throughout the hunting season.

Biologists identify the species, age and sex of each duck wing sample and the species and age of each goose tail sample. Thus, the survey yields estimates of the species composition of the duck and goose harvest. Results of this survey are combined with the results of the hunting diary survey to provide species-specific harvest estimates, as well as estimates of age and sex

ratios (Martin & Carney 1977, Geissler 1990). The annual sample size for the Waterfowl Parts Collection Survey is about 90 000 duck wings and 20 000 goose tails (Padding *et al.* 2003).

### Estimating sport harvest in Canada

The Canadian waterfowl harvest survey system was established in 1967 (Cooch *et al.* 1978). All sport hunters who wish to hunt waterfowl in Canada must purchase the Canada Migratory Game Bird Hunting Permit, which was introduced in 1966. This is a national permit that is issued by the federal government, primarily at post offices throughout the country. The permit includes a stub on which the postmaster records the person's name and address, and whether or not that person purchased a permit and hunted the previous year. The postmaster then detaches the completed stub and sends it to the Canadian Wildlife Service. Thus, the sample frame for Canada's harvest survey system consists of all sport hunters who are legally authorized by the Canadian government to hunt migratory game birds. In recent years, this amounts to about 200 000 sport hunters each year.

The Canadian Wildlife Service selects samples of permit buyers, stratified by geographic survey zone, permit renewal status, past hunting success and county of residence (Cooch *et al.* 1978). The permit includes a hunting diary on which hunters are asked to note the date, location, and harvest for each of their hunts. Near the end of the migratory bird hunting season, each sampled hunter is mailed the Harvest Questionnaire Survey, which is a more detailed survey form. Hunters are asked to use their permit diaries to help them report their hunting activity and harvest accurately on the survey form. About two months after the first mailing, the Canadian Wildlife Service sends a second survey form to those who have not responded.

Estimates of mean and total duck and goose harvest are derived in much the same way as they are in the United States (Cooch *et al.* 1978). The Canadian Wildlife Service selects about 45 000 hunters annually for the Harvest Questionnaire Survey. Participation in the survey is voluntary, and the response rate is about 40%.

The Canadian Wildlife Service selects another sample of waterfowl hunters annually and asks those hunters to participate in the Species Composition Survey. This survey is conducted for the same purpose as the Waterfowl Parts Collection Survey in the United States, and employs similar methods. Likewise, Canada's analyses are similar to those used by the United States. The results of the Harvest Questionnaire Survey and the Species Composition Survey are combined to produce species-specific harvest estimates (Cooch *et al.* 1978). The annual sample size for Canada's Species Composition Survey is about 20 000 duck wings and 8 000 goose tails.

### Estimating subsistence harvest in Alaska

The sample frame for the Alaska Subsistence Harvest Survey consists of all households in the parts of Alaska in which subsistence harvesting of birds and eggs is a legal activity. There are about 26 000 such households. The sample frame is stratified by geographic region, by communities within regions, and by previous history of hunting activity for each household. About two thirds of the communities in each region are selected for sampling. In those communities, about 40% of the high-harvest households, 15% of the low-harvest households, and 10% of the no-harvest households are selected to participate in the survey.

The survey covers the subsistence harvest period, April–October, in three increments. Survey workers hand-deliver the first survey forms to sampled households in April, at which time the workers explain how the forms should be filled out. The survey form shows pictures of the various species of birds, and participants are asked to record how many birds and eggs of each species they take. Three months later, the survey workers visit the households again to retrieve the first survey forms and deliver the forms for the second period. Two months after that, the survey workers visit again to pick up forms and deliver the forms for the last period, and at the end of the final period they visit once more to collect the last survey forms.

The analyses used to estimate the harvest are similar to those used to estimate sport harvest in the United States and Canada, except that species-specific estimates are derived directly from household reports rather than from a wing survey. Participation in the survey is voluntary, and the response rate is about 66%.

### Sport harvest in Mexico

There are no annual estimates available for sport harvest in Mexico. However, a study by Kramer *et al.* (1995) gives a good indication of the magnitude and species composition of the annual waterfowl harvest in Mexico. From 1987 to 1992, Kramer *et al.* conducted a census of harvest in all the traditional waterfowl hunting areas of Mexico, visiting each major area in a different year. Then they applied area-specific correction factors to adjust for under-reporting by hunters. Finally, they summed the results for each area across years to obtain estimates of average annual harvest for all of Mexico.

### Subsistence harvest in Canada

The most recent comprehensive assessment of subsistence harvest in Canada was undertaken by Wendt & Dickson in 1994 (unpublished report). They reported harvest estimates for all areas where surveys had been conducted at some time during the previous 20 years. For areas where surveys had not been conducted, they derived indirect estimates of harvest. Their report gives estimates of total duck and goose harvest, but no species-specific estimates are available. The Canadian Wildlife Service is expecting to obtain up-to-date, direct estimates of subsistence harvest for most of Canada in the near future.

## RESULTS

Sport hunting accounts for by far the greatest proportion of the total duck and goose harvest in North America. Of the approximately 15 000 000 ducks harvested in 2002, about 14 000 000 were taken by sport hunters, primarily in the United States (Fig. 1). Similarly, of about 4 850 000 geese harvested in 2002, nearly 4 300 000 were taken by sport hunters in the United States and Canada (Fig. 2). Most of the waterfowl hunting and harvest in Canada occurs in the south-central part of the country (Quebec, Ontario, Manitoba, Saskatchewan and Alberta), whereas comparatively little sport hunting occurs along the coasts and in the far north (Table 1). Similarly, in the United States, about 70% of the waterfowl hunters are in the middle of the country (Mississippi Flyway and Central Flyway); thus most of the duck and goose harvest also occurs there, compared to the east (Atlantic Flyway) and west (Pacific Flyway) coasts (Table 1). In general, more ducks are harvested in southern states (e.g. Arkansas, Louisiana, Texas), whereas more geese are harvested in northern and mid-latitude states (Table 1).

**Table 1.** Estimated sport harvest of ducks and geese and number of waterfowl hunters in Canada and the United States during the 2001 hunting season.

\* Montana, Wyoming, Colorado, and New Mexico are transected by the Central/Pacific Flyway boundary and are therefore listed in both flyways. Estimates are partitioned into their respective flyways.

**Fig. 1.** Distribution of the duck harvest in North America among sport and subsistence hunters during the 2002 waterfowl hunting season.**Fig. 2.** Distribution of the goose harvest in North America among sport and subsistence hunters during the 2002 waterfowl hunting season.

The annual sport harvest is comprised of 33 species of ducks and five species of geese. The species composition of the duck harvest during the 2002 hunting season was typical of recent years. More than 30% of all ducks harvested were Mallard *Anas platyrhynchos*, followed by Green-winged Teal *A. crecca*, Gadwall *A. strepera* and Wood Duck *Aix sponsa* at about 10% each. Ring-necked Duck *Aythya collaris* and Lesser Scaup *A. affinis* were the most commonly harvested diving-ducks. As with ducks, the species composition of the sport harvest of geese during the 2002 hunting season was typical of recent years. About 70% of all geese taken were Canada Geese *Branta canadensis*, followed by Snow Geese *Chen (Anser) caerulescens* at about 20%.

Although most of the waterfowl harvest in North America is due to sport hunting, there are some cases in which subsistence hunting is an important source of mortality, especially for some species of concern. For example, the Emperor Goose *Chen (Anser) canagicus* population numbers only about 75 000 birds. Sport hunting of this species is not allowed, and therefore the only harvest that occurs is subsistence harvest in Alaska. The estimated harvest is 3 200 birds per year, or about 4% of the population. Another species of concern is the Black Brant *Branta bernicla nigricans*, which has a population of about 120 000 birds. Of a total harvest of about 17 000, more than half are taken by subsistence hunters in Alaska. Only 2 000 are taken by sport hunters in the United States and Canada, whereas 5 000 are taken by sport hunters in Mexico.

## DISCUSSION

National sport harvest survey systems have been in place in the United States since 1952 and in Canada since 1967, and subsistence harvest surveys have been conducted in Alaska since 1985. These surveys have provided annual estimates over an extended period of time that enable biologists to evaluate long-term trends in hunter numbers, hunting pressure, harvest, and waterfowl population demographics (e.g. Trost *et al.* 1987). These data in turn help biologists to formulate models of population dynamics that are used to determine harvest management prescriptions for species such as Mallard, Northern Pintail *Anas acuta* and Canvasback *Aythya valisineria*.

Estimates of the annual harvest also help waterfowl managers assess the impacts of hunting regulations on harvest. For example, the results of the harvest surveys described above can be used to predict the effects of changes in season length and bag limits on total duck or goose harvest, or to predict the effects of changes in species-specific bag limits on individual species (Martin & Carney 1977). This helps managers determine the appropriate regulatory actions to take when harvest must be reduced or, if populations are expanding, when it can be allowed to increase.

The estimates of age and sex composition derived from wing surveys can also be valuable, particularly for showing long-term trends in productivity (e.g. Reynolds 1987, Miller 2000). Harvest age ratios can serve as an early warning system that helps identify declining species or populations. For example, age ratios (immature/adult) of Lesser Scaup harvested in the United States have been declining for the last 20 years (Padding *et al.* 2003), suggesting a gradual decline in productivity of the species.

During the same period, the North American breeding population of the species has also undergone a significant decrease (U.S. Fish and Wildlife Service 2003). As a result of these findings, several research efforts to determine the causes of the decline in the Lesser Scaup population are currently underway, and these are focusing on adult female survival and productivity.

## Migratory bird harvest surveys in Canada

Jean-François Gobeil

Canadian Wildlife Service, National Wildlife Research Centre, Ottawa, Ontario, K1A 0H3, Canada.  
(email: jean-francois.gobeil@ec.gc.ca)

Gobeil, J.-F. 2006. Migratory bird harvest surveys in Canada. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 853.

In Canada, the Canadian Wildlife Service (CWS) of Environment Canada is mandated to protect migratory birds under the Migratory Birds Convention Act (MBC Act 1994). This Act and its regulations are the main domestic legal instruments used to implement the Migratory Birds Convention, an international treaty signed with the U.S. in 1916. The MBC Act 1994 and its regulations confer powers to regulate migratory game bird hunting by following guiding principles of conservation such as sustaining healthy migratory bird populations while allowing activities such as harvesting. Science-based management, which involves basing management on sound scientific models, is implemented using a variety of monitoring programs to evaluate and update the models.

For waterfowl, these monitoring programs include breeding ground surveys to estimate population sizes and productivity, banding programs to estimate survival rates and movements, and harvest surveys to estimate the size of the harvest, and assess the impacts of hunting regulations on populations. By combining these data, CWS has the capacity to assess the status of all migratory game birds found in Canada and adjust regulations accordingly.

CWS introduced the Migratory Game Bird Hunting Permit (MGBHP) in 1966 to obtain information about hunters. The following year, a programme entitled the National Harvest Survey (NHS) was initiated, consisting primarily of two annual surveys sent to MGBHP purchasers: the Harvest Questionnaire Survey (HQS) and the Species Composition Survey (SCS).

The HQS consists of a questionnaire mailed to approximately 44 000 hunters to estimate hunting activity and the annual harvest of major groups of birds (e.g. ducks, geese) and other species such as snipe and woodcock. The sample is random stratified; hunters are selected based on permit renewal, region, and residency. Hunting activity data are provided as estimates of numbers of active and successful hunters, and bag sizes. For ducks and geese, specific data are also obtained about hunting locations and the distribution of bags and hunting activity throughout the season (provided by calendars in the questionnaire).

The SCS asks hunters to submit samples of each duck (one wing) and goose (tail feathers and primaries) they harvest. A total of 35 000 hunters are screened prior to each season, and 10 000 participate. The sample (random stratified) takes into account previous responses to the HQS, permit renewal, and past participation. Annually, 25 000 samples are collected and species, age and sex are identified with waterfowl experts confirming the identification. Identification cue cards and posters are used for training and reference, and are being incorporated into an updated, comprehensive Canadian identification guide.

Both the HQS and the SCS provide a wealth of data used mainly for the revision of annual bag and possession limits, and of season dates. However, there are other “indirect” uses of the

data such as the collection of tissue samples for genetic studies and contaminant studies.

CWS also conducts additional “special” surveys such as the Spring Snow Goose Survey. This survey has been running since 1999 to monitor the Spring Snow Goose Hunting Season, a special conservation measure introduced to reduce Snow Goose populations breeding in the Arctic.

Since the 1980s, CWS has also been conducting surveys in Newfoundland and Labrador to monitor harvest and hunting of sea ducks and murre. For these special surveys, methodologies are adjusted based on their particular objectives and the desired results.

The NHS is a large-scale survey and suffers from some limitations. There will always be errors or missing information, for example due to mis-classification of hunters into survey strata, misinterpretation of instructions by hunters, and unidentifiable bird parts. For some species, identification keys are not yet reliable (e.g. scoters). Low participation rates in some areas result in poor estimates at smaller spatial scales, an inevitable trade-off between cost and precision. Furthermore, surveys do not take into account native harvest, illegal hunting and losses from crippling. Some of those pitfalls are currently being addressed.

Some species form a major portion of the total harvest, resulting in a lot of information collected and their harvest being estimated with good precision; other species are poorly sampled. The different level of precision for different species is an inherent property of the sampling procedure. The NHS is redesigned periodically by reallocating the sampling effort, which can generally achieve a reduction of 10-15% in the coefficient of variation (CV) of harvest estimates. Computer models estimate the impact of reallocating survey effort under various scenarios. The objective is to find the allocation that leads to the greatest reduction in the total CV of the harvest for various species and regions, while keeping survey costs the same. Optimal allocations are then derived under all scenarios and the appropriate scenario selected following discussions amongst CWS biologists and managers, allowing for a conscious decision on the optimal trade-off between precision at various scales and for various species.

Despite their limitations, the National Harvest Survey and the special surveys are valuable sources of data for monitoring and managing migratory game birds in Canada and North America. The data are relatively inexpensive to obtain compared with other types of monitoring schemes such as banding. Periodic redesign of the survey helps to maintain its efficiency, although there is a trade-off between reallocating effort and maintaining consistency over time. In some cases, special surveys may be a better approach to deal with specific management issues, rather than reallocating resources within the long-term survey.

## Sustainable hunting of migratory waterbirds: the Danish approach

Bregnballe, T., Noer, H., Christensen, T.K., Clausen, P., Asferg, T., Fox, A.D. & Delany, S. 2006. Sustainable hunting of migratory waterbirds: the Danish approach. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 854-860.

### ABSTRACT

The harvesting of migratory waterbirds continues unmodified on a large scale in many European countries despite increasing calls in several countries and at the EU level to ensure that the take is “sustainable”. Despite widespread and common interest, there is neither consensus in Europe concerning an operational definition of “sustainable harvesting” nor consensus concerning the criteria that should be applied in determining sustainability. Around 700 000 wild waterbirds are killed annually in Denmark where the hunting of migratory waterbirds has a strong tradition. We applied simple assessments combining population trends and size of take to determine whether the current kill of quarry species in Denmark is sustainable or not. We present the national approach taken to determine sustainability and provide examples of how data on bag records and knowledge about specific population sizes have been used as case studies in Denmark.

### INTRODUCTION

Shooting of waterbirds is a widespread and legitimate recreational activity in many parts of the world, including Europe. Over the past century, its role in regulating the size and distribution of waterbird populations has been the focus of much debate, and this has affected the management of hunting in both the USA and Europe. As a result of increasing political unification, enhanced international co-operation and a vast improvement in our knowledge, the legislative management of bird species and hunting activities in Europe has grown increasingly international over the last 30 years. Starting with the Ramsar Convention on Wetlands (1971), followed by the EEC Directive on the Conservation of Wild Birds (“Birds Directive”, 1979), the Convention on Migratory Species of Wild Animals (CMS, 1979) and the African-Eurasian Migratory Waterbird Agreement (AEWA, 1999), both international and national legislation have increasingly emphasised that the harvest of game animals must be “sustainable”. As yet, however, there is no general consensus nor any internationally accepted operational definition of “sustainable harvesting” that can serve as a basis for the scientific assessment of the impact of hunting (see, for example, Sutherland 2001).

Denmark is an important staging and wintering area for migratory waterbirds, and has a strong tradition of waterbird hunting. There are open seasons for 29 species of waterbirds, many of which occur in concentrations that are internationally important according to the 1% criterion of the Ramsar Convention. The present Danish Game Act came into effect in 1994, both confirming international obligations and emphasising the sustainable management of hunting and game species, not only in an ecological sense, but also in an ethical sense (although

we here limit the discussion to ecological rather than ethical considerations).

Responsibility for establishing hunting seasons lies with the Danish Ministry of the Environment and the process of their revision is administered by the Forest and Nature Agency. Under the 1994 Game Act, hunting seasons can be revised at three-year intervals by Government Orders, increasing flexibility considerably over the previous arrangements when, more often than not, Parliament had to pass a new Game Act to change hunting seasons. On a three-year cycle, the National Environmental Research Institute (NERI) undertakes a scientific review of changes in the bags and population sizes and a re-assessment of the effects of hunting on each species. The available estimates of population size for a given species may, for example, indicate that numbers continue to decline, in which case NERI may recommend that the length of the open season be reduced (see Bregnballe *et al.* 2003 for an example of a detailed review). This recommendation is passed on to the Council for Wildlife Management, which is composed of representatives of stakeholders (including the Danish Hunters' Association and Danish Ornithological Society), and their main task is to discuss the options for adjusting current regulations, attempt to reach consensus and pass on their conclusions to the Forest and Nature Agency, i.e. the Minister of the Environment. Based on this and other advice, the Minister will thereafter announce the appropriate new local and national adjustments to the length of open seasons. For the species in decline, the change in the open season may or may not slow down the speed of decline.

It has been impractical to wait for international consensus on definitions of sustainability, and so NERI has had to establish operational pragmatic concepts on a “national” level. In this paper, we present this view of sustainability and use worked examples to exemplify how information on bag records and population trends is used to assess whether or not the take in Denmark is sustainable for three different species of waterbirds.

### METHODS

#### What is sustainability?

Our basic concept of sustainability applied to exploitation is that a renewable resource must not be over-exploited, over-exploitation representing a state where the ability of a resource to renew itself and maintain current distribution and abundance is curtailed. In the long run, such over-exploitation will eventually exterminate the resource.

Much effort has been devoted to obtaining the population data necessary for assessing whether hunted populations are over-exploited (e.g. Sutherland 2001), often based upon information on trends in both reproduction and survival as well as abundance (e.g.

Williams & Nichols 2001). Sutherland (2001) argued that knowledge of growth rates should be provided as a basis for assessing sustainable takes. In the absence of such detailed data for most species, Madsen *et al.* (1996) defined sustainable exploitation by means of combining the size of the take and population trends, the basic idea being that as long as a population is stable or increasing, over short periods, current exploitation can be assessed as sustainable. While this obviously works for large and well-known populations, care has to be taken for small and vulnerable populations (Madsen *et al.* 1996). Since many of the waterbird populations hunted in Denmark are indeed stable or increasing, this definition reduces the task of assessing 29 different species considerably.

The initial definition, however, leaves open the interpretation of cases involving decreasing populations. Though not yet fully resolved, a decreasing population trend is not necessarily evidence of unsustainable hunting. For example, breeding numbers and output may be limited by available breeding habitat. If the extent of this breeding habitat is undergoing reduction, harvest is expected to contribute to the rate of population decrease, but also to reach a sustainable level eventually (though depending on the take), if the population in question stabilizes at a new level (Bregnballe *et al.* 2003). Basically, then, decreasing populations will have to be the focus of closer scrutiny before any assessment as to the sustainability of hunting can be made.

Classifying the hunting of a species as “not sustainable” does not necessarily result in recommending a ban on hunting, in particular if the population decline is moderate and the population continues to be large (see the example of Common Eider *Somateria mollissima* below). In the evaluations made at three-year intervals, we distinguish, as objectively as possible, between “sustainable”, “probably sustainable”, “probably not sustainable”, “not sustainable” and “not possible to judge”.

Compared to the Ramsar Convention and the EC Birds Directive, the Habitats Directive of 1992 (implemented 8-10 years later) introduced a new generation of Directives relating to nature conservation in Europe. Since the Habitats Directive does not concern birds, the legal status of the Birds Directive in Denmark was strengthened in 2001 by giving it the same status as the Habitats Directive by Government Order. This requires that an assessment of the conservation status of a given bird species be provided to the European Commission at regular (six-year) intervals. In order to ensure a unified treatment, Bregnballe *et al.* (2003) substituted the “simple” population trends used by Madsen *et al.* (1996) with an assessment of the conservation status of each individual species/population.

### Information base

In the north-western Palearctic, most flyway populations breed, stage and winter across several member (and non-member) states of the European Union. Data on population trends – vital to our assessment by the definitions given above – are provided by Wetlands International, based on indices generated from the annual mid-winter International Waterbird Census (e.g. Delany *et al.* 1999). For some species, we also use results from other surveys, e.g. those aimed at estimating the size of sub-populations of geese, and results from the monitoring of Danish breeding populations.

Data on Danish hunting are provided through bag return statistics. After each season, all holders of Danish hunting licenses are required to inform the Forest and Nature Agency of the size

and composition of their annual hunting bag. However, the following groups are pooled in these returns: geese (five species), dabbling ducks except Mallard *Anas platyrhynchos* (six species), diving ducks except Common Eider (nine species), snipes (two species) and gulls (three species). Between the mid-1970s and the early 1980s, about 95% of all licence holders reported their annual bags, but after two major changes in the reporting system, the number of respondents dropped, first to 78%, then recently to 58%. Although estimates of the national bag are corrected for this, maintenance of a higher return rate would clearly be preferable. Since 1982/83, hunters have also voluntarily submitted the wings of bagged waterbirds to NERI, enabling assessment of changes in the age and sex ratios of the bagged sample (Clausager 2004 and references therein). Data from this wing survey are used to estimate the species composition amongst the amalgamated groups “geese”, “other dabbling ducks”, “other diving ducks”, “snipes” and “gulls”. The proportion of hunters submitting wings, however, is relatively low, ranging from 3% of those bagging “other dabbling ducks” to 1% of those bagging geese. Because so few wings are received compared with the total bag, uncertainties amongst species in which fewer than 2 000 individuals are bagged are considerable. The wing survey also provides us with an opportunity to estimate the temporal and geographical distribution of the bag, as well as the age and sex composition.

## RESULTS

### The bag of waterbirds in Denmark

The number of holders of hunting licences increased during the 1960s and 1970s, and has subsequently stabilized at 160 000 - 170 000 (Fig. 1), c. 3% of the total Danish population. The annual bag of waterbirds (excluding Mallard) declined from a maximum of 900 000 in the mid-1970s to 350 000 in the mid-1990s, and has changed little since then. The decline was partly caused by the protection in 1982 of divers, grebes, auks (alcids) and some species of waders, followed by the protection in 1994 of Eurasian Curlew *Numenius arquata*, Whimbrel *N. phaeopus*, Black-headed Gull *Larus ridibundus* and Common Gull *L. canus*. For species still subject to an open season, marked reductions in bag sizes have taken place for all species of diving ducks, Common Coot *Fulica atra*, snipes and gulls. The bags of Northern Pintail *Anas acuta* and Northern Shoveler *A. clypeata* have declined, but not those of Eurasian Wigeon *A. penelope* or

Fig. 1. Changes in the number of hunters holding a hunting licence in Denmark during the period 1969/70-2004/05.

**Table 1.** Conservation status, population trend, estimated annual bag (1999/2000-2003/04) and sustainability of hunting for 29 species of waterbirds for which there was an open season in Denmark in 2003/04. Conservation status, population trend (25 year trends up to and including 1996 or later) and sustainability of hunting were assessed by the National Environmental Research Institute in 2002 (Bregnballe *et al.* 2003). The estimated species composition of the bags of geese, ducks (except Mallard and Common Eider), snipes and gulls is somewhat uncertain and therefore given in brackets.

Group/species/sub-population	Conservation status	Population trend	Estimated bag 1999/00-2003/04	Sustainability of hunting
<b>Geese</b>			18 000 – 29 000	
Greylag Goose <i>Anser anser</i>	Favourable	Increasing	(> 12 000)	Sustainable
White-fronted Goose <i>Anser albifrons</i>	Favourable	Increasing	(< 300)	Sustainable
Bean Goose <i>Anser fabalis</i>			(< 400)	
Sub-population A (Finland)	Favourable	Increasing		Sustainable
Sub-population B (Åsele Lapmark, Sweden)	Unfavourable and decreasing	Decreasing		Local ban on hunting
Sub-population C (unknown origin)	Unknown	Stable-decreasing?		Uncertain
Pink-footed Goose <i>Anser brachyrhynchus</i>	Favourable	Increasing	(> 2 000)	Sustainable
Canada Goose <i>Branta canadensis</i>	Favourable	Increasing	(> 1 200)	Sustainable
Mallard <i>Anas platyrhynchos</i>	Favourable	Increasing	554 000 – 731 000 <sup>1</sup>	Probably sustainable
<b>Other dabbling ducks</b>			99 000 – 129 000	
Northern Pintail <i>Anas acuta</i>	Favourable	Stable?	(3 200 – 7 100)	Sustainable
Eurasian Wigeon <i>Anas penelope</i>	Favourable	Increasing	(29 000 – 53 000)	Sustainable
Common Teal <i>Anas crecca</i>	Favourable	Increasing	(59 000 – 82 000)	Sustainable
Garganey <i>Anas querquedula</i>	Uncertain	Decreasing?	(100 – 400)	Sustainable
Northern Shoveler <i>Anas clypeata</i>	Favourable	Stable	(1 300 – 2 700)	Sustainable
Gadwall <i>Anas strepera</i>	Favourable	Increasing	(300 – 1 100)	Sustainable
Common Eider <i>Somateria mollissima</i>	Unfavourable and decreasing	Decreasing	75 000 – 95 000	Uncertain
<b>Other diving ducks</b>			31 000 – 34 000	
Common Pochard <i>Aythya ferina</i>	Favourable	Stable	(700 – 1 700)	Sustainable
Tufted Duck <i>Aythya fuligula</i>	Favourable	Stable	(3 300 – 4 400)	Sustainable
Greater Scaup <i>Aythya marila</i>	Favourable	Stable	(300 – 500)	Sustainable
Common Goldeneye <i>Bucephala clangula</i>	Favourable	Increasing	(11 000 – 18 000)	Sustainable
Long-tailed Duck <i>Clangula hyemalis</i>	Favourable	Stable?	(1 500 – 4 700)	Sustainable
Common Scoter <i>Melanitta nigra</i>	Favourable	Stable	(2 800 – 5 200)	Sustainable
Velvet Scoter <i>Melanitta fusca</i>	Favourable?	Unknown	(1 600 – 2 800)	Sustainable
Goosander <i>Mergus merganser</i>			(800 – 1 900)	
Flyway	Favourable	Stable-increasing		Sustainable
Danish breeding population	Favourable but rare	Slowly increasing		Local ban on hunting
Red-breasted Merganser <i>Mergus serrator</i>	Favourable	Increasing	(2 000 – 3 700)	Sustainable
Common Coot <i>Fulica atra</i>	Favourable	Increasing	17 000 – 20 000	Sustainable
<b>Snipes</b>			15 000 – 24 000	
Common Snipe <i>Gallinago gallinago</i>	Unfavourable	Unknown	(14 000 – 23 000)	Probably sustainable
Jack Snipe <i>Lymnocyrtus minimus</i> <sup>2</sup>	Uncertain	Unknown	(1 100 – 3 500)	Uncertain
Eurasian Woodcock <i>Scolopax rusticola</i>	Favourable	Stable	24 000 – 39 000	Sustainable
<b>Gulls</b>			28 000 – 36 000	
Lesser Black-backed Gull <i>Larus fuscus</i>			(100 – 600)	
Baltic sub-population	Unfavourable and decreasing	Decreasing		Not sustainable
Other sub-populations	Favourable	Increasing		Sustainable
Herring Gull <i>Larus argentatus</i>	Favourable	Increasing	(19 000 – 25 000)	Sustainable
Great Black-backed Gull <i>Larus marinus</i>	Favourable	Increasing	(9 000 – 11 000)	Sustainable

<sup>1</sup> The vast majority were released for shooting.

<sup>2</sup> Hunting of the species has been banned since 2004/05.

Common Teal *A. crecca*. The Mallard bag increased from 350 000 in the mid-1970s to 700 000 in the 1990s, concurrent with an increase in the release of Mallard for shooting, although the bag has recently decreased to 600 000. The bag of geese has more than doubled over the last 10 years, reaching 30 600 in 2004/05, mainly because of an increase in the take of Greylag

Goose *Anser anser*. The bag of Eurasian Woodcock *Scolopax rusticola* has increased since the early 1970s. Table 1 gives the range of the estimated bags during the period 1999/2000 to 2003/04, together with population trends, for most of the 29 species of waterbirds for which there was an open season in 2003/04.

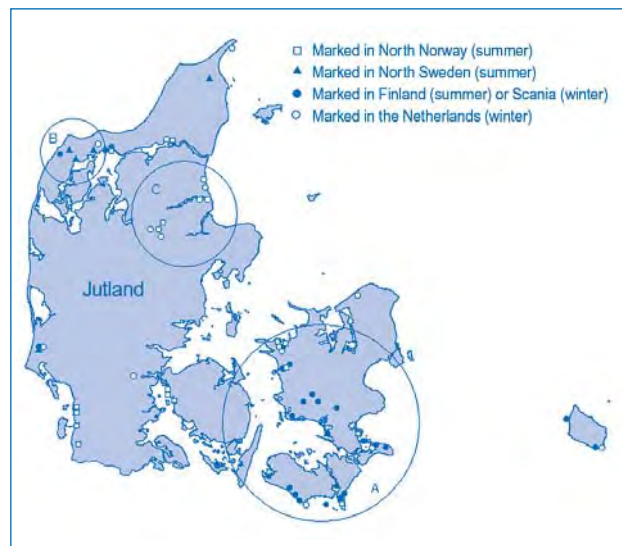

### Small and vulnerable populations: Bean Goose and other populations

The Bean Goose *Anser fabalis* occurs in Denmark during migration and winter. Information from phenology, recoveries and re-sightings of ringed birds suggests that the Taiga Bean Geese *A. f. fabalis* appearing in Denmark belong to at least three partly or entirely separated breeding populations (Madsen *et al.* 1996, Bregnballe *et al.* 2003). Sub-population “A” is large, and is composed of birds that breed in Finland and migrate to wintering areas in southern Sweden, south-eastern Denmark (Fig. 2) and The Netherlands. Sub-population “B” is small, breeds in central Sweden (Åsele Lapmark), and migrates to north-western Jutland (Thy; Fig. 2), with some birds continuing on to eastern England (Yare Valley) during the winter (Parslow-Otsu & Kjeldsen 1992). Sub-population “C” has unknown breeding origins and winters in north-eastern Jutland (Tjele near Viborg and Lille Vildmose; Fig. 2). These “C” birds have a different phenology from those occurring in north-western Jutland, and recovery and re-sighting data indicate that some of them winter in The Netherlands. A possible breeding area for the “C” birds is the border region between Norway, Finland and Russia. It is, however, puzzling that most birds ringed in northern Norway have been recovered in the same region as Finnish ringed birds, and that no Finnish and few Norwegian ringed birds have been recovered in the “C” bird region of Denmark (Fig. 2).

The Finnish breeding population (sub-population “A”) increased during the 1970s and 1980s and probably stabilized thereafter (Nilsson *et al.* 1999). The conservation status of this population is therefore judged as favourable (Table 1). The two other sub-populations do not, however, appear to have a favourable conservation status. Winter counts in northern Jutland show a decline over the last 30-40 years from 3 000-4 000 birds to fewer than 1 500 birds at present. During the 1990s, mid-winter counts for northern Jutland and the Yare Valley combined have never exceeded 2 000 birds. Based on such pieces of information, we judged the conservation status of sub-population “B” as unfavourable-declining and of sub-population “C” as uncertain.

The change in the size of the Bean Goose bag in Denmark is not known in detail because the hunters do not distinguish between species when reporting their kill of geese. Furthermore, the number of goose wings received from hunters in relation to the total bag of geese has declined from 4-5% in the second half of the 1980s to 1% in the second half of the 1990s. A study of the species composition of the bag of geese in the 1960s suggested that c. 1 100 Bean Geese were bagged annually in Denmark. Based on the wing survey, it was estimated that the annual bag amounted to c. 500 in the early 1990s. It is unknown what proportion of these birds belonged to the different sub-populations. Uncertainty about the effects of hunting on sub-population “B” in the early 1990s led to a regional ban on Bean Goose hunting in parts of northern Jutland in 1994/95. This regional hunting ban probably led to a further decline in the annual bag of Bean Geese.

In 2002, we assessed the effect of hunting as sustainable for sub-population “A” and uncertain for sub-population “C”. Based on the uncertainty of the effect on hunting on sub-population “C” and the unfavourable-declining conservation status of sub-population “B”, we recommended that the regional hunting ban

**Fig. 2.** Distribution of the three sub-populations of Taiga Bean Goose *Anser fabalis fabalis* in Denmark, based on ringing recoveries. Each sub-population has a different phenology, conservation status and breeding origin. Circle “A” indicates birds believed to belong to a population breeding in Finland and wintering mainly in southern Sweden (Scania). Circle “B” indicates birds from a small breeding population in northern Sweden. (In addition to the recoveries shown, neck-bands of 29 different individuals from the northern Swedish breeding range have been reported from this area). Circle “C” indicates a small population of unknown breeding origin which winters in north-east Jutland and apparently also in The Netherlands. Recoveries from outside these three areas indicate birds that were shot on migration or at staging areas that were used in the past. Map redrawn from Bregnballe *et al.* (2003) and updated with data from Bønlokke *et al.* (in press).

for Bean Goose (covering parts of northern Jutland) be expanded to include all areas in northern Jutland where the Bean Goose was known to occur. Following this recommendation, the Bean Goose was protected in Jutland by the 2004 Government Order.

Similar regional hunting bans have been used for a few other species of waterbirds in Denmark, e.g. hunting of gulls was banned south of latitude 55°40'N in order to increase the protection of the now threatened and declining nominate (Baltic) subspecies of the Lesser Black-backed Gull *Larus fuscus*. Also, as a result of representations to the Council for Wildlife Management, the Goosander *Mergus merganser* was protected south of 55°40'N in order to assist the establishment of a breeding population in Denmark (presently <30 pairs). Because of the problem of “look-alike species”, the Red-breasted Merganser *M. serrator* was also protected within this area.

### Eurasian Wigeon

Eurasian Wigeon breeding in Scandinavia, Finland, Russia and Siberia occur in Denmark during August-November. Based on January counts, the estimated North-west European population of the Eurasian Wigeon increased three-fold between 1987 and 1996 (Delany *et al.* 1999), and subsequently declined to a lower level (Fig. 3). The decline in estimated population size was probably partly an effect of very poor breeding success in 1994 and in several of the subsequent years (Clausager 2004; Fig. 4).

The open season for Eurasian Wigeon is the same as that for all dabbling ducks in Denmark, i.e. 1 September – 31 December.

**Fig. 3.** Population trend of Eurasian Wigeon *Anas penelope* in North-west Europe during the period 1974-2002, estimated by Wetlands International from annual mid-winter counts (Wetlands International, unpubl. data). Points indicate index values  $\pm$  SE using TRIM methods to estimate values (Pannekoek & van Strien 1998).

**Fig. 4.** Proportion of juveniles among Eurasian Wigeon *Anas penelope* bagged in Denmark during the hunting seasons 1982/83-2005/06. The proportion of juveniles is given as the number of juveniles of both sexes per adult female. The two solid horizontal lines give the means for the periods 1982/83-1991/92 and 1992/93-2005/06, respectively.

**Fig. 5.** Danish bag of Eurasian Wigeon *Anas penelope* during the period 1969/70-2003/04.

**Fig. 6.** Relationship between the annual bag of Eurasian Wigeon *Anas penelope* in Denmark and the estimated population size for North-west Europe during the periods 1982/83-1995/96 and 1996/97-2001/02.

The Danish bag of Eurasian Wigeon increased until 1995/96 (Fig. 5) simultaneously with an increase in the size of the population (Fig. 6). After 1995/96, the bag decreased markedly to a lower level than expected from the relationship between bag size and population size in the preceding years (Fig. 6). The seasons 2000/01 and 2001/02 had a higher bag than in former and subsequent years, probably because of a relatively high breeding success (Fig. 4).

Our interpretation in 2002 was that there had been no further decline in the size of the flyway population and that the species had a favourable conservation status. Furthermore, the take in Denmark in proportion to the size of the flyway was low in most seasons after 1995/96. Consequently, we judged the take in Denmark as sustainable.

#### Common Eider: first steps towards adaptive management?

Common Eiders breeding in Denmark, southern Norway, the west coast of Sweden and the Baltic moult, stage and winter in Danish waters. These populations all increased substantially throughout the twentieth century, but from the mid-1990s, the population trend was reversed, with overall peak numbers of at least 2 000 000 apparently decreasing by 30-50% in less than a decade (Desholm *et al.* 2002). This decline has been further aggravated by a change in the sex ratio over the same period from 60:40 (males to females) to 70:30 at present. The decline in the Baltic Sea/Wadden Sea flyway of Common Eiders is probably, to some extent, a result of the combined effects of avian cholera (causing mass mortality of incubating females), parasites and viral infections (causing low duckling survival), and poor feeding conditions in parts of the wintering area causing mass mortality, e.g. 25 000 Common Eiders were found dead in the Dutch-German part of the Wadden Sea in 1999/2000 (Desholm *et al.* 2002).

The annual bag in Denmark has partly reflected population trends, increasing to c. 140 000 in 1970, after which it fluctuated until the 1990s and then declined to 69 000 in 2004/05 (Fig. 7). It is likely, however, that the decline in annual bags reflects the declining interest of hunters in seaducks, as the number of hunters

**Fig. 7.** Danish bag of Common Eider *Somateria mollissima* during the period 1958/59–2004/05, and the number of hunters that bagged Common Eiders during the period 1980/81–2004/05.

bagging Common Eiders decreased from c. 14 000 in 1980 to 6 000 in 2001/02 (Fig. 7, Christensen 2005). For many years, the open season for eiders in Denmark was 1 October – 29 February, but since 1994, hunting in February has not been permitted in EU Special Protection Areas.

In 2002, we assessed the conservation status of the Baltic Sea/Wadden Sea population of the Common Eider as

Shooting seaducks from punts in the shallow waters around Denmark is highly traditional. Photo: Niels Søndergaard

**Fig. 8.** Number of adult male Common Eiders *Somateria mollissima* per female based on the wing survey in 1982/83–2004/05 and on birds found dead during oiling accidents in 1982/83 and 2004/05.

unfavourable–declining and the effect of hunting as uncertain. Our interpretation of the available information was that the overall impact of hunting on the population had probably changed from reducing the rate of annual increase to potentially adding directly to the decline in breeding numbers. By 2002, the declines led NERI to consider means to limit the take, particularly of females. Consequently, we recommended differentiating between the two sexes, with the open season for females closing on 15 January and that for males on 15 February. At the same time, the open season for Common Scoter *Melanitta nigra*, Velvet Scoter *M. fusca* and Long-tailed Duck *Clangula hyemalis* was extended from 31 January to 15 February. This proposal was accepted, and although the data are still limited, they suggest a shifting sex ratio in the bag of eiders (see 2004/05 in Fig. 8), with the harvest of females being reduced by approximately 8 800 per year, of which 7 500 would belong to the Baltic population breeding to the east of Denmark.

## DISCUSSION

### Sustainability of hunting

Strategies for achieving and developing sustainable hunting differ widely. In general, researchers have sought to develop highly sophisticated systems of adaptive management based on collection of data, not only on population trends but also on reproduction and survival rates and habitat conditions, which coupled with advanced modelling lead to adaptive management through the introduction of bag limits and variations in annual open seasons. In our case, we have been forced by temporal and financial constraints to develop much more pragmatic systems based on the best information available.

Although most scientists would probably agree that improved data sets are always needed to inform changes in hunting regulation, we note that given an inventory of 29 hunt-able waterbird species, a considerable subset will always be scarcer, and that abundant species may be split into sub-populations, some of which may be small. By definition, these species and populations will be more vulnerable. The obvious solution – to protect them because they are of limited hunting interest – is often difficult because of “look-alike” issues; for example, it is hardly practicable to protect the Garganey *Anas querquedula*

efficiently while maintaining an open season for the Common Teal. While over-exploitation of common and abundant species leaves time to carry out needed adjustments in case of population declines, the quest for sustainability may indeed be more challenging for scarce populations or sub-populations.

In our case, the continuing development of simple systems is based on the political desire for simplicity of management. So far, the specific objective for providing guidelines for Danish hunting management has been the desire for simple rules.

While the tools for assessing sustainability of hunting are undoubtedly in need of further refinement, we note that the need for assessing the impact of hunting on other aspects of waterbird populations based on factors other than population size are increasing. The recent demands for improved information relating to the timing of breeding seasons and the onset of spring migration under the Sustainable Hunting Initiative launched by the European Commission emphasise that hunting should not take place after birds commence their prenuptial migration. Combined with the demands for ethical sustainability, such new initiatives are likely to prolong the period necessary to harmonize general definitions of sustainability at international level.

### Improvement of the information base

Compared to many other countries, Denmark has a unique and fairly reliable system for monitoring its bag of migratory waterbirds. Nevertheless, challenges remain to improve the system: two major current problems are that the proportion of hunters reporting their bag has dropped to 58%, and that the estimated bag for most species is based on the wing survey, which is subject to bias. Steps have now been taken to ensure that reporting rates will increase again, but as long as wings are received from only 1-3% of the migratory waterbirds harvested, we face problems of scaling up from such samples. For example, the Eurasian Wigeon bag may be underestimated if the proportion of hunters contributing to the wing survey is low in that part of the country where most wigeon are bagged. This scaling-up problem could largely be avoided if hunters were required to report their entire bag at species level.

At present, it is possible for a few species to give a rough estimate of the proportion of the total bag in the flyway that is taken in Denmark. However, for most species we lack precise information on bag sizes along the remainder of the flyway. It would be useful if, for example, all Member States of the EU were obliged to publish their annual bag statistics, preferably within a year to permit effective feedback to flyway management.

With the present definition of sustainable hunting applied in Denmark, we rely heavily on the best available information from a variety of sources, such as estimates of population trends. It is therefore most unfortunate that trends have been updated only after a delay of several years because of insufficient resources for the International Waterbird Census, co-ordinated by Wetlands International. For a number of species, the available information on population size and geographical extent of populations and sub-populations is insufficient or unreliable. As a consequence, information on the conservation status of the populations we are harvesting may be outdated or inaccurate. We must continually strive to improve this situation, especially at the international level.

### ACKNOWLEDGEMENTS

We thank Ib Clausager for his long-term commitment in running the Danish wing survey. The estimation of waterbird trends would not be possible without the contribution, freely given every year, of thousands of voluntary waterbird counters.

## Non-toxic shot – Danish experiences

Niels Kanstrup

Danish Hunters' Association, Molsvej 34, DK-8410 Rønne, Denmark. (email: nk@jaegerne.dk)

Kanstrup, N. 2006. Non-toxic shot – Danish experiences. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 861.

Lead poisoning of waterbirds as a consequence hunters' use of lead shot is an issue which needs to be addressed internationally, since migratory waterbirds cross many borders during their migrations. Hence management practices - such as whether the use of lead shot is, or is not, permitted - in one country has consequences for the conservation of waterbirds in all countries on their flyways. The issue is also one of public relations and the image of hunting, and both hunters' and national and local government administrations can benefit from international co-operation and the exchange of knowledge and experience. To phase out lead shot, suitable alternatives must be available, and the research and development of alternatives and analysis of the market for their sale facilitated through international co-operation.

In Denmark, when the use of lead shot was first regulated in 1985, the hunters themselves initiated the use of alternative shot. The successful introduction of steel shot for clay pigeon shooting allayed the concerns of many hunters by showing that steel shot cartridges were not dangerous to fire and that the price of steel shot cartridges was still acceptable. Research by the Hunters Association also demonstrated that steel shot was just as effective as lead shot for killing birds.

Denmark enforced a total ban on the use of lead shot in 1996. However, this led to problems not for hunting in wetlands but in forests, since the use steel shot was unacceptable to foresters because of its hardness and the consequent risk of damage to machinery used in the timber industry from steel shot embedded in trees. This led to pressure to develop softer shot alternatives such as bismuth, tin and wolfram products. Five such alternatives have now been introduced and have proved to be popular, even though the prices of these cartridges are significantly higher than those of lead or steel shot.

Many Danish hunters were concerned the phasing out of lead shot would lead to the phasing out of hunting, but this has not been the case and the number of hunters and the annual bag has not changed significantly. In addition, the hunters' initial main concern, that there was increased risk of guns exploding or being damaged by steel shot, proved groundless.

The efficiency of alternative shot has been investigated in several scientific studies and more popular programmes, with results showing that efficiency is more related to hunters' experience and their shooting distances rather than to the performance of the cartridge; and in turn that the performance of the cartridge (its velocity generated, conformity etc.) is more critical than the shot material itself. Although lead is still regarded as an ideal shot material due to its ballistic qualities, there have been many examples of lead shot cartridges operating far less efficiently than cartridges containing alternative shot material.

Concerns by Danish hunters about the consequences of changing from lead to non-toxic shots have proved groundless. Photo: Else Ammentorp, Danmarks Jægerforbund/Danish Hunters Association.

The phasing out of lead shot has now led to more focus on the efficiency and effectiveness of hunting techniques. Steel shot has, to some extent, taught hunters to be more cautious, by shortening their shooting distances to quarry. This seems to have caused an increase in the efficiency of the hunting since shortening the quarry distance will markedly increase the probability of cleanly striking the birds.

Addressing the problems of lead poisoning of waterbirds caused by hunting with lead shot may seem a less important issue in many countries than addressing other pressures on wetland conservation such as safeguarding the future existence of ecosystems such as wetlands themselves. But maintaining and restoring the quality of wetlands, including reducing pollution levels such as from toxic lead, is an important component of their conservation. The Danish example of a total ban on lead for hunting has demonstrated that this can be achieved, and to inspire and motivate the process there is a clear need for a constructive dialogue at both national and international level between governments, nature conservationists and hunters – all of whom share the objective of maintaining wetlands for waterbirds. Such co-operation is a precondition for continuing the momentum and progress towards flyway-wide phasing out the use of lead shot in wetlands.

## The monitoring of hunting bags and hunting effort in the Camargue, France

Mondain-Monval, J.-Y., Defos du Rau, P., Mathon, N., Olivier, A. & Desnouhes, L. 2006. The monitoring of hunting bags and hunting effort in the Camargue, France. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 862-863.

The Camargue, in the Rhone river delta, is the most extensive wetland area in France, covering about 150 000 hectares of natural, semi-natural and agricultural habitats, and is a wetland of international importance. It is the most important wintering site in France for Anatidae species and for Coot *Fulica atra*. The numbers of ducks and coots in mid-winter amount, on average, to 10-20% of the numbers wintering in France. The Camargue is also one of the most important places for wildfowling in the country. Despite its ecological, cultural and economic impact on habitats, hunting activity has received little attention (Mathevet *et al.* 2002). Several research projects in the area aim to achieve a better understanding of population dynamics of game species, such as Teal *Anas crecca*, a very popular quarry species in Europe (Devineau 2003, Guillemain *et al.* 2002). However, precise data on mortality through hunting, recognised as vital information (Aebischer *et al.* 1999), is still missing. The aims of this work were to provide preliminary figures about the recent/latest hunting bag trend and composition, and to encourage hunters to set up an efficient monitoring scheme of their bag and hunting effort.

About 205 private hunting estates and 23 hunters' associations shoot on public land or extensive private estates. For many estate managers, there is a strong tradition of recording annual hunting bags. However, long-term data are not always available because of the high turnover of managers. Managers were contacted first at random, then by acquaintance, focusing on the most important in terms of annual bag or managed area. Therefore, this sample cannot be considered as truly randomly selected, although the intention in the medium-term is to sample most of the total hunted area throughout the Camargue. Bag statistics for about 50 estates were collected, covering very different periods of time (from one year, to 90 years). For 15 estates, bag data are available for a recent 12 year period. However, data from hunters' shooting on common/public land are totally missing as there is no organised scheme to collect this type of data.

Mallard *Anas platyrhynchos* and Teal amount to two-thirds of the Anatidae bag (Fig 1). The Mallard proportion has increased from 29% to 46% over the 1988 to 1999 period. The Simpson index for diversity (Fig. 2) shows a non significant tendency of decline ( $R^2=0.23$   $p=0.114$   $N=12$ ), possibly due to increasing dominance of annually released mallards.

A TRIM index (Pannekoek & Van Strien 1998) for raw bag data and an index adjusted to hunting effort were compared (Figs. 3 & 4) with a count index obtained from aerial counts (Tamisier 2003) to examine bag trends.

There was no significant linear relationship between the adjusted bag index and count index (Teal  $R^2=0.013$   $p=0.725$   $n=12$ ; Mallard  $R^2=0.176$   $P=0.175$   $N=12$ ).

Fig. 1. Species composition of the bag sample of ducks between 1988-1999.

Fig. 2. Trends in the Simpson Index of diversity for the bag sample of ducks 1988-1999.

The main current technical challenges are that:

- a longer-term dataset seems necessary to reach more robust conclusions on trends, if any exist;
- raising awareness of the crucial importance of monitoring hunting effort as well as hunting bags for both individual hunters and estate managers is urgent;
- improving the representativeness of wildfowling areas in the analysis seems a necessary step but is likely to add major costs in data collection, as randomly sampled hunting managers might be reluctant to cooperate; and

**Fig. 3.** Trends (TRIM index) in the bag and count indices for Teal *Anas crecca* 1988-1999.

**Fig. 4.** Trends (TRIM index) in the bag and count indices for Mallard *Anas platyrhynchos* 1988-1999.

- hunting bag collection in this area is very time consuming, as hunters very rarely answer mailed questionnaires and often want to be met personally before participating.

It is therefore time to discuss opportunities, strategies and issues to increase monitoring effort and capacities; and the re-launching of a new monitoring program of hunting activity in the area.

If hunting statistics were to be collected at a broader scale, for example at a flyway level, it is absolutely vital to fully consider local, national and international hunting organisations as key partners for this type of survey.

Sorrenti, M., Carnacina, L., Radice, D. & Costato, A. 2006. Duck harvest in the Po delta, Italy. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 864-865.

Estimates of waterfowl hunting bags are the main research activity of the Associazione Cacciatori Migratori Acquatici (ACMA). These data are necessary for good species management, and are also a tool to provide an objective basis for public debate on hunting. The main objective is to create a monitoring scheme that allows the organisation to estimate, for each hunting season, the total bag in Italy (Sorrenti *et al.* 1999).

This short note provides the results obtained from public (ATC – Italian Hunting Association) and private (Aziende Faunistico Venatorie, AFV) shooting areas in the Po river delta, situated in the Rovigo district of the Veneto region, for the duck hunting season of 2002/03. This area is an important wintering site for many species, both at national and international level (Verza 2003, Baccetti *et al.* 2002).

The Rovigo District Administration worked with ACMA, in cooperation with the local hunting association, ATC Delta del Po, to estimate the waterfowl harvest in public shooting areas. ATC collected sheets compiled by waterfowl hunters and generalist hunters which gave the total number of hunters of each category and the total number of fixed hunting hides in the area. Rovigo District Administration provided reports of official bags from private shooting areas. A sample from the public area records were elaborated to expand the results to a wider area, using a Poisson distribution with 95% confidence interval.

The results from waterfowl hunters are provided in Table 1, and those of generalist hunters in Table 2. Table 3 reports the declared bag of the AFV. The total estimate of the duck harvest

**Table 1.** Estimates of bag totals of waterfowl shot by specialized waterfowl hunters 2002/03 public area.

Species	n	Total species estimates					
		95% confidence interval			95% confidence interval		
		Mean	Lower	Upper	Mean	Lower	Upper
Teal <i>Anas crecca</i>	35	27	25	29	7 679	7 198	8 183

Gadwall <i>Anas strepera</i>	16	1	0	1	225	103	427
Pochard <i>Aythya ferina</i>	16	1	0	1	250	120	460
Tufted Duck <i>Aythya fuligula</i>	16	0	0	1	150	55	326
Total	16	12	10	14	4 775	4 122	5 502

in the Po delta is presented in Table 4 as a sum of the averages of Tables 1 and 2 and data from Table 3. However, the declared harvest of the AFV is considered an underestimation of the real numbers. A further 8 000-10 000 ducks should be added to the AFV declared bag, bringing the total duck harvest in this study area for the 2002/03 season to an estimated c. 70 000 birds. Based on the results from Table 4, the most common species of ducks shot were: Mallard *Anas platyrhynchos* (38%), Wigeon *Anas penelope* (22%), Teal *Anas crecca* (21%), Pochard *Aythya ferina* (6%) and Gadwall *Anas strepera* (3%).

**Table 3.** The declared waterfowl hunting bag in private shooting areas (AFV) in 2002/03.

## Considerations on the use of lead shot over wetlands

Guy-Noël Olivier

OMPO Secretary General, 5, ave des Chasseurs 75017 Paris, France. (email: ompo@ompo.org)

Olivier, G.-N. 2006. Considerations on the use of lead shot over wetlands. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 866-867.

### ABSTRACT

OMPO (Migratory Birds of the Western Palearctic) was created some 20 years ago, and is committed to the conservation and sustainable use of Western Palearctic wetlands and the migratory waterbirds that inhabit them. OMPO has focussed its efforts on safeguarding wetlands from drainage and other detrimental activities within the framework of the Ramsar Convention on Wetlands, and has strong links with this Convention in Europe and Africa. OMPO was aware of the pollution caused by the use of lead shot in wetlands over 10 years ago, but at that time, the alternatives to lead shot were of poor quality and could not be recommended to hunters. Further studies on the effects of lead poisoning on waterbirds were conducted in France in the 1990s. These studies were financed by the hunting community and supervised by the Ministry of Environment, with the participation of OMPO. The conclusions, published in April 2001, reinforced the results of previous studies regarding the consequences of lead poisoning on reproductive success. OMPO is now strongly recommending to its network of partners throughout the Western Palearctic region that they abandon lead shot in hunting over wetlands and replace it with non-toxic substitutes. The additional mortality caused by lead poisoning is unacceptable for both conservationists and hunters, and is contrary to the long tradition of hunting to which OMPO is strongly attached.

### INTRODUCTION

OMPO (Migratory Birds of the Western Palearctic) was created some 20 years ago, and has committed itself to the conservation of migratory waterbird species inhabiting Palearctic wetlands for breeding, staging or wintering. OMPO is also committed to the principle of sustainable use of these renewable natural resources through the management of wetlands and bird populations. This avoids any waste of this international wealth.

In the past, OMPO was well aware of the damage caused by the intensive use of lead shot over wetlands and some of the consequences for wildlife (Bellrose 1959, Sanderson & Bellrose 1986, Roster 2002). Regrettably, however, this was by no means the only source of pollution having a negative impact on wetlands. Chemical residues and poisons of all kinds used in intensive agriculture and industry, as well as domestic garbage, were all going directly or indirectly into hydrological systems and consequently wetlands, where they were poisoning waterbirds and their predators.

The first studies of lead poisoning in waterbirds were conducted in the USA in 1959 (Bellrose 1959). In 1990, the results of French studies conducted in the Camargue were convincing for ornithologists but quite difficult to interpret for millions of hunters and still more so for the many millions of other polluters (Beck *et al.* 1995, Beck & Olivier 1998, Pain 1991a, 1991b, Pain *et al.* 1992). Furthermore, at that time, the alternatives to lead shot were of poor quality, and their efficiency

was so uncertain that they could not be recommended to hunters. This is why, from 1985, OMPO gave priority to fighting the causes of wetland loss, i.e. to making every possible effort to save wetlands from various types of drainage caused by agriculture, industry, expansion of urban areas and development of infrastructure.

The safeguarding of wetlands appeared to OMPO to be more efficient and essential than to reduce specific forms of pollution. An international conservationist NGO with a small staff and limited budget must make choices. Thanks to the stimulus provided by the international convention on wetlands signed in Ramsar, Iran, in 1971 (the Ramsar Convention on Wetlands), OMPO pressed ahead with its programme. Of the many projects subsequently carried out by OMPO, we give simply two examples:

- 1 The Ndiel Bowl, covering 10 000 hectares in the delta of the Senegal River, has been listed as a Wetland of International Importance under the Ramsar Convention since July 1977, but was drained in 1989 as a result of construction works. In 1991/1992, OMPO decided to restore the site to its former importance for birds. A feasibility study was carried out by the National Centre for Scientific Research (CNRS), and in 1994, work began on the digging of a 10 km long canal that would eventually replenish the site with water.
- 2 OMPO provided the financing for studies relating to the first three Ramsar sites in Latvia, including the renowned Lake Engure.

### LEAD POISONING IN WATERBIRDS AND A CALL FOR A BAN ON LEAD SHOT

In the 1990s, various scientific studies were conducted in France on lead pollution in wetlands and the possible consequences of direct or indirect lead poisoning affecting waterbirds. The purpose of these studies was to build upon previous studies undertaken in 1959 and 1990, to identify the collateral effects of this poisoning. These studies, conducted by the Laboratory of Chemistry and Toxicology at the National Veterinary School of Nantes, took over six years (Pinault 1996, Mézières 1999). They were financed by hunters' organizations and supervised by the Ministry of Environment, with the active co-operation of OMPO. The conclusions were made available in April 2001 (Baron 2001), and reinforced the results of previous studies concerning the consequences of the use of lead shot over wetlands and the ingestion of this poisonous heavy metal by birds, e.g.:

- death of birds that have ingested more than two pellets;
- weakness of contaminated birds and consequently increased predation;
- alteration of energy requirements and consequently a handicap for birds on migration;

- reduction in clutch size; and
- risk of eggshell and embryo malformations.

Most of these toxicological studies were conducted on species of ducks and swans. Thus, it appeared interesting to OMPO, the Office National de la Chasse et de la Faune sauvage (ONCFS), the Biological Station of Tour du Valat and the International Snipe Hunters' Club (CICB) to investigate if lead poisoning could have a similar effect on waders. Studies were conducted on two species: Common Snipe *Gallinago gallinago* (Beck *et al.* 1995, Veiga 1984) and Jack Snipe *Lymnocyptes minimus* (Beck & Olivier 1998, Veiga 1985). A sample of 269 Common Snipe revealed an ingestion rate of 15.6%, whereas a sample of 178 Jack Snipe revealed an ingestion rate of 6.5%. It was concluded that lead poisoning also affects waders and to a similar extent to that found in ducks, thus confirming previous studies.

A French Ministerial Order signed on 21 March 2002 by the Minister of Environment stipulated that from the opening day of the 2005 hunting season on migratory waterbirds, the use of lead shot would be forbidden in France on the following wetlands: coastal and inshore areas, permanent wetlands, rivers, canals, reservoirs, lakes, ponds and stretches of water.

For the past three years, OMPO has been associated, as a corresponding member, with the work undertaken by the Technical Committee of the African-Eurasian Waterbird Agreement (AEWA). OMPO used its influence to persuade the French Government to ratify the Agreement as quickly as possible, and this was achieved in July 2003, when a new hunting law including the ratification of the Agreement was approved by parliament. OMPO has also been accredited to promote the AEWA in those states covered by its network of partners, and to encourage them to join the Agreement.

OMPO is particularly sensitive to the need to promote sustainable hunting, as this provides a highly appreciated - and sometimes even essential - argument for the conservation of waterbirds, particularly in Africa and Eastern Europe where hunting is strongly anchored in local traditions. At the same time, OMPO is well aware of the negative impact of lead poisoning on waterbird populations as a result of the use of lead shot over wetlands. Therefore, in accordance with the Convention on the Conservation of European Wetlands and Natural Habitats (Bern Convention) and the AEWA, OMPO recommends to its international network of partners throughout the Western Palearctic region that consideration be given to abandoning the use of lead shot over wetlands.

Additional mortality of waterbirds due to all types of poisoning, including lead poisoning, is unacceptable for both conservationists and hunters. As the primary concern of hunters is to ensure that hunting opportunities persist into the future, it seems obvious that a decision should be made to abandon the use of lead shot so that the conservation status of those species that may be hunted remains in a favourable condition.

## CONCLUSION

It seems clear that the use of lead shot over wetlands should come to an end and appropriate substitutes used instead. This will take some time, given not only that it is an international

political issue, but also that it requires the technical adaptation of guns and ammunition, especially in a number of countries located mostly in south-western Europe. It is in these countries, where hunters are strongly attached to their old traditions, that lead shot is most widely used and remains the most popular. OMPO is therefore making a strong recommendation to hunters to adopt a positive attitude in this regard, to avoid further wastage of a natural resource which is so valuable to them.

## Harvesting status of migratory waterfowl in northern Iran: a case study from Gilan Province

Behnam Balmaki<sup>1</sup> & Ahmad Barati<sup>2</sup>

<sup>1</sup> Department of Environmental Sciences, Azad University of Arak, Iran

<sup>2</sup> Department of Environmental Sciences, Higher Education Complex of Malayer, Iran. (email: abarati@basu.ac.ir)

Balmaki, B. & Barati, A. 2006. Harvesting status of migratory waterfowl in northern Iran: a case study from Gilan Province. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 868-869.

Commercial and recreational waterfowl hunting is a well established part of the culture of northern Iran and migratory waterbirds have an important role in the economic and social development of this area. This survey was carried out to determine the abundance and diversity of hunted waterfowl in Gilan province, northern Iran, from November 2001 to February 2002. The results showed that 393 693 individual birds from 49 species and eight families were harvested from the aquatic ecosystems of Gilan province during the study period (Table 1). Anatidae were the most abundantly hunted group of species.

Due to its ecology and geographical situation, northern Iran is an important key wintering area for waterbirds in the Middle-East (Mansori 1984). It contains diverse habitats which attract many different species. Gilan province (36°02'- 38°27'N and

48°30'-50°30'E) covers 14 711 km<sup>2</sup>, has three Ramsar sites and numerous other aquatic ecosystems making this area a key site for wintering migratory waterbirds. The legal and illegal harvesting of these migratory waterbirds is an important source of income for the indigenous people of this state.

Surveys found that the main local markets for hunted birds are in the cities of Rashat, Anzali and Langrud. In order to determine the number of birds harvested, counting was carried out during the four months of November, December, January and February in these three cities. Each week data was collected on the diversity and numbers of species in the bird markets of these cities.

From November 2001 to February 2002 a total of 393 693 waterbirds were harvested. Comparison of the three main cities suggested that the harvesting rate in Anzali was the highest, about 39% of all hunted birds (Fig. 1). The highest number of birds was recorded in January, with a total of 160 514 birds (Fig. 2).

Commercial and recreational waterbird hunting is a well established part of the culture of northern Iran. It is recognized

<b>Total</b>		<b>122 662</b>	<b>160 514</b>	<b>80 826</b>	<b>29 691</b>

as a legitimate activity within the context of sustainability but requires management. Harvesting of these species by recreational hunters is minimal. The management of commercial harvesting is achieved through the declaration of an annual waterbird hunting season with regulation of the length of each

season, setting of daily opening and closing times and the setting of daily bag limits and total possession limits. Estimates of total waterbird populations are used to vary these parameters in order to restrict the harvest to sustainable levels (Balmaki 2002). The standard waterbird hunting season lasts three months but may be extended in 'good' years and reduced in 'bad' years.

Surveys showed that 83 Pygmy Cormorant *Phalacrocorax pygmaeus* and 130 Ferruginous Duck *Aythya nyroca* were hunted during this period. These species are listed as threatened in the IUCN Red List (BirdLife International 2000). The presence of these species in the bird markets indicates that management of the traditional harvest is extremely difficult due to cultural constraints in Gilan, and is not being fully implemented at present.

The most abundant group of harvested waterbird in this region was the Anatidae family with the Eurasian Coot *Fulica atra* the most popular prey for hunters.

## Harvest of migratory geese *Chloephaga* spp. in Argentina: an overview of the present situation

Daniel E. Blanco & Victoria M. de la Balze

Wetlands International, 25 de Mayo 758 10° I (1002) Buenos Aires, Argentina. (email: deblanco@wamani.apc.org)

Blanco, D.E. & de la Balze, V.M. 2006. Harvest of migratory geese *Chloephaga* spp. in Argentina: an overview of the present situation. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 870-873.

### ABSTRACT

Austral geese (*Chloephaga* spp.) are endemic to South America. Four species are migratory and occur in Argentina and Chile. One of these, the Ruddy-headed Goose *Chloephaga rubidiceps*, is endangered on the mainland of South America, where the population is estimated at only about 1 000 individuals. During the migration periods and in winter, austral geese are threatened by recreational hunting and hunting to control crop damage. Recreational hunting is a common activity in Argentina, and attracts many foreign hunters from Europe and North America. Despite the fact that large numbers of geese are killed each year, no information exists on the impact of this hunting on their populations. The aims of the present study were to make an assessment of the hunting of austral geese in Argentina, and to evaluate the potential consequences of hunting for the conservation of these species. The assessment was based on an intensive literature search, an analysis of current hunting regulations, questionnaires to waterfowl hunters, and interviews with wildlife authorities and key specialists. Issues addressed include the status of the geese, hunting practices, hunting regulations, and implications for conservation. The results are discussed in the context of the current situation, and monitoring and management needs are formulated in order to contribute to the conservation of migratory geese in southern South America.

### INTRODUCTION

The five species of austral geese (*Chloephaga* spp.) are endemic to South America. Four of the species occur on the mainland of southern South America (including Tierra del Fuego) and also have separate subspecies or populations in the Malvinas Falkland Islands (Canevari 1996). The mainland populations of the Upland Goose *Chloephaga picta*, Ashy-headed Goose *C. poliocephala* and Ruddy-headed Goose *C. rubidiceps* are migratory (Canevari 1996). Their breeding grounds are located in southern Patagonia and Tierra del Fuego (Argentina and Chile), while their wintering areas are in northern Patagonia and the southern pampas of Buenos Aires Province (Argentina).

The mainland and Tierra del Fuego population of the Ruddy-headed Goose has a very restricted distribution. Breeding pairs concentrate in the surroundings of Punta Arenas (southern Chile) and in the northern portion of Tierra del Fuego island (Madsen *et al.* 2003), while during the winter, the birds concentrate in a small area in southern Buenos Aires Province (Blanco *et al.* 2003a). This population has declined steeply since the 1950s, and is now considered in danger of extinction in both Argentina and Chile (García Fernández *et al.* 1997, Glade 1993, de la Balze & Blanco 2002). The size of this population is currently estimated at around 1 000 individuals (Madsen *et al.* 2003, Blanco *et al.* 2003b).

The available information suggests a decreasing trend not only for the Ruddy-headed Goose but also for the other two migratory species (Canevari 1996, Wetlands International 2002).

**Table 1.** Status of the subspecies (s) or populations (p) of three species of austral geese (*Chloephaga* spp.) on the mainland of South America.

Species	Common name	Estimate	Trend
<i>Chloephaga picta picta</i> (s)	Upland Goose	D	DEC
<i>Chloephaga poliocephala</i> (p)	Ashy-headed Goose	C/D	DEC
<i>Chloephaga rubidiceps</i> (p)	Ruddy-headed Goose	900-1 178	DEC

C = 25 000-100 000 individuals; D = 100 000-1 000 000 individuals; DEC = decreasing trend.

(Table 1). Recent observations of reduced numbers both in mainland South America and in Tierra del Fuego (Blanco *et al.* 2003b, N. Loekemeyer pers. comm., J. Veiga pers. comm.) point in the same direction. Population declines appear to have been caused by the combined effects of various factors.

The hunting of austral geese is a common activity in Argentina and Chile, and is legally restricted to two species, the Upland Goose and Ashy-headed Goose (Canevari 1996, Servicio Agrícola y Ganadero 1999, Blanco *et al.* 2002). In Argentina, hunting affects goose populations during the autumn migration season and in winter, mainly in the northern portion of their ranges. The aims of the present study were to undertake an assessment of the hunting of austral geese in Argentina, including a review of the provincial regulations, and to consider the implications for conservation.

### STUDY AREA AND METHODS

Argentina is a federal country with 23 provincial jurisdictions. Provinces are responsible for the management of natural resources within their territories, including wildlife. This assessment was restricted to the provinces of Buenos Aires, Neuquén, Río Negro, Chubut, Santa Cruz and Tierra del Fuego, which encompass the main distribution of austral geese in Argentina (Fig. 1).

The assessment was based on the following sources of information: 1) an intensive search of the literature concerning the harvesting of austral geese; 2) an analysis of hunting regulations in each province; 3) questionnaires to waterfowl hunters; and 4) interviews with wildlife authorities and key specialists.

### RESULTS AND DISCUSSION

Waterfowl are hunted for recreation (sport hunting), as a subsistence harvest and for the control of crop damage (Ojasti 2000). Many South American species of waterfowl are threatened by intensive hunting because of insufficient regulations; most of the regulations that do exist relate to those species with a critical conservation status (Menegheti *et al.* 1990).

**Fig. 1.** The study area in southern Argentina, indicating provincial jurisdictions and the northern limit of austral goose migration.

Austral geese are amongst the most commonly hunted species of waterfowl in Argentina. The hunting of Upland and Ashy-headed Geese is permitted in various provinces, while the Ruddy-headed Goose is protected by national and provincial laws. However, the difficulty in distinguishing Ruddy-headed Geese from female Upland Geese poses a serious threat to the former species, as the geese form mixed flocks during migration and in winter.

#### Sport hunting

The hunting of austral geese is common in several provinces of Argentina, although local hunters generally prefer terrestrial game species such as the Spotted Nothura *Nothura maculosa* and European Hare *Lepus capensis* (Blanco *et al.* 2002). In Buenos Aires Province, for example, only about 18% of the hunters interviewed expressed a preference for waterfowl (Parisi 1998).

Goose hunting is permitted throughout the entire range of

**Table 2.** Hunting regulations and bag limits (geese per hunter per day) for the Upland Goose *Chloephaga picta* (CHLPI) and Ashy-headed Goose *C. poliocephala* (CHLPO) in Argentina.

Province	Bag limits		Season	Maximum per season
	CHLPI	CHLPO		
Buenos Aires	No limit		Whole year	No limit
Río Negro	12	12	1 May – 30 September	48
Neuquén	6	6	1 May – 31 July	24 / 36
Chubut	5	5	1 May – 31 July	?
Santa Cruz	2	0*	1 April – 31 August	2
Tierra del Fuego	Prohibited		—	—

\* The hunting of Ashy-headed Geese is prohibited in Santa Cruz Province.

the geese, with the exception of Tierra del Fuego, and takes place mainly during the autumn migration and in winter. It is practised mainly by foreign hunters who consider the austral geese as overlooked game species. In recent years, goose hunting has become more popular not only in Buenos Aires (F. Moschione pers. comm.), but also in the Patagonian provinces (A. Contreras pers. comm.).

The limited information available suggests that the contribution of sport hunting to the total number of geese killed per year in Argentina varies between provinces. In Chubut Province, for example, about 80% of the goose harvest results from recreational hunting and only 20% from hunting to control the numbers of geese which utilize agricultural land in the river valleys as staging areas during their migrations (A. Contreras pers. comm.). Bag limits for Upland and Ashy-headed Geese also differ between provinces, ranging from “unlimited hunting” in Buenos Aires Province (a wintering area) to total prohibition in Tierra del Fuego (a breeding area) (Table 2).

### Hunting to control numbers

Hunting to control the numbers of geese is more common in the northern portion of their range than in the south. In northern Patagonia and the southern Pampas, geese have traditionally been persecuted by local farmers because they feed on crops (mainly wheat) and pastures during the migration seasons and in winter. In the past, geese were also considered to compete with sheep in southern Patagonia, where they were chased and killed by ranchers (N. Loekemeyer pers. comm.).

In 1931, austral geese were officially declared “agricultural pests” (Pergolani de Costa 1955), but the Ruddy-headed Goose was later excluded from the list of “pest species” because of its remarkable fall in numbers (Rumboll 1975). More recently, Tracanna & Ferreira (1984) and Martin *et al.* (1986) questioned the real magnitude of wheat losses caused by grazing geese, and pointed out that situations in which austral geese come into conflict with agriculture are relatively few. In some areas of Buenos Aires Province, where geese are still considered harmful by local farmers, aircraft are used to scare them away from wheat fields (R. Scofield pers. comm.). Furthermore, some farmers welcome foreign hunters to kill as many geese as they want in return for a payment of just US\$ 10 per hunter per day.

### Is sustainable harvest possible?

The hunting of austral geese in Argentina lacks an adequate regulatory framework to guarantee the sustainable use of the resource. In Buenos Aires Province, the hunting of Upland and

Ashy-headed Geese is allowed without limits throughout the whole year (Blanco *et al.* 2002). This decision, which is not based on population data, allows geese to be killed on a massive scale without any governmental control.

According to Zaccagnini (2002), a programme aimed at ensuring the sustainable use of waterfowl populations should include at least the following components: 1) biological (monitoring of populations and basic ecological research); 2) use/harvest (monitoring the harvest by working with hunters); 3) conservation and education (training and outreach materials such as brochures, field guides etc.); and 4) financial (fundraising for implementation of actions under components 1, 2 and 3).

Some of these components and activities are mentioned briefly in the provincial regulations, but are rarely put into practice. The main gaps that we identified if sustainable management of the resource is to be achieved are the lack of:

- accurate population estimates and trend data for the Upland Goose and Ashy-headed Goose;
- data on the geese hunted per season in each province (species, numbers, sex ratio, age composition);
- Specific actions to protect the Ruddy-headed Goose from illegal hunting;
- co-ordination between the provinces with respect to hunting regulations and the setting of bag limits within Patagonia;
- education/awareness campaigns directed at farmers, outfitters and hunters, with an emphasis on conservation of the Ruddy-headed Goose;
- funding support to keep the programme functioning.

Our main recommendations are as follows:

- organization of a National Austral Goose Monitoring Programme with the participation of the federal government and provinces, based on “survey stations” distributed throughout the migration and wintering ranges of the geese;
- organization of a harvest monitoring programme in each province involving the local hunting associations;
- prohibition of goose hunting within the main breeding and wintering areas of the Ruddy-headed Goose, as well as along its migration route (e.g. Chubut Province has recently prohibited goose hunting in the coastal departments along the migration route of the Ruddy-headed Goose);
- promotion of inter-provincial co-ordination concerning goose management and conservation within the framework of the Patagonian Wildlife Advisory Council (CARPFS).

## FINAL REMARKS

The conservation and management of migratory species which are shared by two or more countries require international co-operation. Furthermore, under a federal system of natural resource management such as that found in Argentina, co-ordination is required between provinces in their efforts to manage shared species such as the austral geese.

As in many other parts of the world, geese are considered simultaneously to be pests on agriculture and to be overlooked game species. In Argentina, austral geese are hunted without there being an adequate framework for the sustainable use of the resource. As in the case of the globally threatened Lesser White-fronted Goose *Anser erythropus*, the Ruddy-headed Goose is today seriously threatened by illegal hunting during the autumn migration season and in winter, as farmers and hunters do not distinguish it from other very similar goose species. Immediate action is required to bring the mainland population of the Ruddy-headed Goose to a favourable conservation status.

## ACKNOWLEDGEMENTS

This assessment is based on data compiled under the "Waterbird harvest in the Pampas wetlands" project funded by The Netherlands Ministry of Foreign Affairs (DGIS), as well as information gathered by the Ruddy-headed Goose Project funded by the Convention on the Conservation of Migratory Species of Wild Animals (CMS-UNEP). We would also like to give special thanks to Rosemary Scoffield, Flavio Moschione, Nora Loekemeyer, Luis Benegas, Jorge Veiga and Adrián Contreras for their valuable contributions.

## The Wetlands International Waterbird Harvest Specialist Group: challenges and objectives

Gilles Deplanque<sup>1</sup> & Tunde Ojei<sup>2</sup>

<sup>1</sup>ANCCE c/o OMPO, 5 avenue des Chasseurs, 75017 Paris, France. (email: gillesdeplanque@nordnet.fr)

<sup>2</sup>Capacity Building Officer, Wetlands International, PO Box 471, 6700 AA Wageningen, The Netherlands.

Deplanque, G. & Ojei, T. 2006. The Wetlands International Waterbird Harvest Specialist Group: challenges and objectives. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 874-875.

An IWRB "Hunting Research Group" was originally established in 1969, and was subsequently renamed the Wetlands International "Waterbird Hunting Specialist Group". However, for a number of reasons, not least the reluctance of the hunting world to provide information on the size and composition of hunting bags, since the mid-1990s the group found it increasingly difficult to operate effectively so as to contribute assessment of patterns of waterbird hunting in different parts of the world.

In 2001, Wetlands International and other relevant bodies including OMPO - Migratory Birds of Western Palearctic and other organisations concerned with waterbird harvesting reviewed the situation, and agreed to redevelop the Specialist Group. The Group has now been renamed the "Waterbird Harvest Specialist Group" (WHSG), in recognition of a widened scope that now covers other forms of waterbird harvest beyond direct hunting harvest. Its overall objectives are:

- i. to use waterbird harvest data to improve population estimates of waterbird species which are too widespread and dispersed for estimates to be made from site-based censuses such as the International Waterbird Census; and
- ii. to assess the hunting pressure on huntable waterbird populations, so as to establish whether or not it is sustainable.

Concerning objective i., waterbird harvest data has already been used to improve the biogeographic population estimates for some waterbird species, notably for Jack Snipe *Lymnocyptes minimus* in Europe which has led to a major correction to previous underestimates in the latest editions of Wetlands International's *Waterbird Population Estimates*.

The Group's working basis is that sustainable use is the harvesting, whatever its nature, of a species with due consideration for its conservation status, whether its demographic trend is

stable or increasing. To better understand and assess the extent of sustainability of waterbird harvests there is a need to combine and compare different parameters such as population estimate, productivity rate, natural mortality, hunting harvest assessment, other human harvest and other human causes of mortality.

The new Group held its first meeting during the Edinburgh Global Flyways Conference, and identified three initial challenges in developing its work. These are: defining the Group's scope of activity within the field of waterbird harvests; developing a strong global network with a good balance between developed and developing countries; and defining a strategy, objectives and priorities for developing work on the different aspects of the Group's scope.

### The Harvest Group's scope of activity

The Group's work will cover:

- i. Waterbird harvests by hunting and hunting trade exploitation;
- ii. Intentional non-hunting waterbird harvests for food or trade purposes; and
- iii. Unintentional waterbird harvests (anthropogenic mortality) which are directly caused by other human activities such as marine oil pollution, all types of collisions (wires, land and air transportation, glass-facades of buildings, installation of wind turbines on migratory corridors etc.), various poisoning (hunting lead, agricultural pesticides or insecticides), proliferation and straying of pets, and introduced predators (especially cats).

The Harvest Group will not be dealing with indirect waterbird mortality or disappearance resulting from human activities such as wetland degradation, urbanisation and coastal development.

### Establishing a global network

A strong membership network of motivated and competent people in each of the three main areas of the Group's scope, and good regional spread of expertise and activity, will be crucial for the group to be meet its objectives. The initial membership of the Group was over 30 people from 21 countries and several continents, and this has now grown and widened following the discussions at the Global Flyways Conference. However, there remains a gap in good regional coverage, with most of the membership still being European-based.

### Defining a strategy, objectives and priorities

The Group recognises that there is a real need for better knowledge of hunting harvests on waterbird species. The majority of the Group's members have expertise in this aspect of waterbird harvest: many are members of hunting societies while others live in communities where waterbirds are hunted for food. Although waterbird hunting assessment will therefore be a strong priority for the Group, other harvest sectors will not be neglected.

Teal *Anas crecca* decoys. Photo: Else Ammentorp, Danmarks Jægerforbund/Danish Hunters Association.

### Waterbird hunting harvests

On the basis of available data, some countries monitor, or seek to monitor, the waterbird hunting harvests, but on the whole the effort is inconsistent: some countries have harvest monitoring schemes for all hunted waterbirds, but others monitoring only for particular species (e.g. Woodcock *Scolopax rusticola* or Mallard *Anas platyrhynchos*) or have data only by species group (e.g. geese, ducks, sea ducks, waders). In addition, the methods used for the monitoring also differ greatly between countries for technical, cultural or sometimes political reasons.

The Group identified the major potential for comparing the results of different monitoring methods as a way forwards to avoid long debates about the use and accuracy of different methodologies. For example, in France two different monitoring methods, exhaustive and statistical, have been applied simultaneously for Jack Snipe. Both methods provided the same result, with an estimate of a little less than 50 000 birds harvested annually. Such similarity is quite remarkable, and such comparisons suggest that at least in some cases, the results of different methods used in different countries may be comparable. This will be helpful in compiling multi-county harvest assessments, since some countries have long-established methods which they do not wish to change. It may also be helpful in recommending appropriate methodologies to countries which do not yet undertake harvest monitoring.

The key approach, regardless of what method is used, is to collect the data at the species level. This is essential so as to

allow for comparisons between species, to use the results in improving waterbird population estimates, and to use the data in assessments of sustainable use.

### Intentional non-hunting harvests

This aspect of the group's work will focus on:

- i. Estimates of seabird harvest from fishery activities (nets and long-lines); and
- ii. An awareness campaign aimed at public authorities, through providing mortality or productivity decrease estimates resulting from lead-shot and lead-weights from fishing in wetlands; and recommending, without delay, further research effort on substitute materials.

### Unintentional harvests directly linked to human activities

Here the priority will be to assess the anthropogenic mortality of seabirds from oil-spills, both from shipwrecks, and from dumping of oil at sea which is believed to cause heavy annual mortality of seabirds, as the basis for encouraging the reinforcement of security norms and international controls, especially for degraded ships.

All those involved in waterbird harvest assessment worldwide are encouraged to join the WHSG, so as to strengthen and broaden its capacity to undertake its priority work.

As well as exploring direct harvests, the Harvest Specialist Group will also review unintentional waterbird mortality as a result of collisions with man-made structures such as wind-turbines. Photo: Tom Stroud.

## 6.4 Financing global flyway conservation: innovation, linkages, options. Workshop Introduction

Milton, R. & Swerdfager, T. 2006. Financing global flyway conservation: innovation, linkages, options. Workshop Introduction. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 876-877.

It is rare for banks to directly raise awareness of waterbirds, but the States of Jersey have highlighted Light-bellied Brent Geese *Branta bernicla hrota* on their currency, providing a good return for migratory species conservation. Copyright: The States of Jersey.

Funding for migratory bird and flyway conservation is not expected to increase and new approaches are required to meet identified needs. Programs must become inclusive and collaborative, and be broadened through partnerships and networking to include working landscapes where goals can be integrated into general operating procedures of those who influence practices on the land. Financing global flyway conservation must become more than birds. Migratory flyways need to be internalized within the biodiversity and sustainable development context of human well-being and poverty reduction.

Programs for flyway conservation are multi-faceted and delivered by numerous organizations at different spatial scales. A commonality to all is a reliance on government directed and supported funding mechanisms that have bird or habitat conservation as their primary objectives. To respond to increasing and competing demands for limited human and fiscal resources, financing global flyway conservation must become more creative, innovative and inclusive.

Flyway based conservation programs in the North American (Swerdfager) and Asia-Pacific (Watkins & Mundkur) regions were presented alongside an examination of Global Environment Facility (Castro) supported programs. Symposium participants

were challenged to identify and respond to the linkages and opportunities that exist between financing mechanisms and conservation's other "cost elements". These were interpreted to include multi-lateral agreements and conventions, regional and national supporting infrastructure, effective delivery mechanisms and evaluation processes. Speakers identified how these elements (globally or on a flyway basis) contribute to leverage financial and human resources from national and international (government, non-government and business) organizations in support of flyway conservation activities. This symposium explored innovative approaches, opportunities to expand conservation networks, options to refocus and enhance the delivery of conservation activities and access a wider range of funding mechanisms

Although based on different experiences, common themes emerged from the presentations and discussion. Central to the symposium is a recognition that migratory bird and flyway conservation have unmet financial needs. However, budgetary pressures in many developed countries will severely limit their ability to directly target additional fiscal resources to meet this need. Moreover, the increases in funding delivered by development agencies through bilateral and multilateral agreements

during the 1980s and 1990s appear to have reached a stable plateau. The conservation community must apply the synergy that results from greater collaboration among governments, public and private agencies, businesses, and NGOs, through sharing of information and pooling of expertise and resources, and a combining of forces to support specific conservation finance mechanisms on-the-ground.

To achieve this synergy, changes must occur in how we ‘package and deliver’ conservation programs to include solid biological and socioeconomic planning and measurable objectives. This may require organizations to identify and incorporate new ‘skill sets’ into their program development mix. The base of support must broaden to be inclusive and less restrictive to participation by a sometimes diverse stakeholder community.

Flyway conservation initiatives have traditionally focussed on increasing the network of protected areas. Opportunities for new protected areas still exist, but there is also great potential to become actively involved with the ‘working landscape’. Partnerships and networking to engage local communities will build local capacity, heighten awareness and knowledge, and influence how activities are undertaken in working landscapes. By building upon common interests and developing trust among engaging organizations, it is often possible to extend the influence of the project beyond the negotiating table. Program goals can become integrated into general operating procedures of

companies and government agencies, by becoming collaborative partners rather than competing interests.

The financing of global flyway conservation must move beyond seeking funds for migratory birds to become more inclusive of all birds and refocus to embrace the local dimension. A reassessment of program goals should seek to refine priorities in-line with key funding sources such as the GEF, World Bank, and national and international development agencies. The Convention on Biological Diversity (CBD) and World Summit on Sustainable Development have defined the key deliverables (human well being and poverty reduction) within which the financing of global flyway and migratory bird conservation could be structured.

Migratory flyways need to be internalized within the broader agendas of biodiversity conservation and issues of sustainable development. We must be able to bridge the needs of migratory birds by responding to the needs and aspirations of society for poverty alleviation, and sustainable development in a growing and diversified economy which includes biodiversity conservation as an integral component of production systems. We need to respond to the CBD and other conventions by shifting our focus to mainstream biodiversity conservation into developing projects which promote poverty alleviation — tackling the cause rather than the symptoms. By addressing the needs of people we will produce an environmental dividend in the conservation of migratory birds.

Castro, G. 2006. Conservation finance for waterbird flyways: key issues and emerging opportunities. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 878-880.

### ABSTRACT

This paper includes data on trends in global financing for conservation, a discussion on the special conservation needs of migratory waterbirds, and a set of concrete recommendations for future financing of waterbird flyways. Trends in global financing for conservation show a large financing gap that is likely to grow as competing international societal demands for other issues including health, education, security, and poverty alleviation become more acute. In addition, the conservation financing needs of migratory species and their flyways present special challenges. Because migratory species represent a pure “global common,” their conservation requires the concerted cooperation of the countries that host them throughout their life cycles. Furthermore, because the stopover sites used by migratory birds may not always coincide with national conservation priorities, many critical sites may be left out of national-level conservation efforts. There are successful examples of international financing of migratory flyways. Because of strong competition for resources with other priorities and the pressure to find sustainable financing sources, these examples cannot be extrapolated to all flyways. Instead, over the long term and to be successful, advocates for the conservation of migratory species need to develop strong scientific and political scenarios to find a space within the broader conservation and development processes that determine the configuration of land uses at any given location, and the political processes that support these decisions. In the long term, financing shortcomings can only be met through the mainstreaming of biodiversity conservation within economic sectors in production landscapes, as well as through the development of sustainable funding sources based on market approaches.

### INTRODUCTION

To be successful, conservation of nature cannot occur in a vacuum. Sustainable conservation requires continuous support from societies, the political processes responsible for allocating resources to economic priorities, and must be anchored on mainstreamed, market-based mechanisms that promote individual behaviours that are compatible with conservation.

Migratory species, however, present additional challenges to conservationists; their lives take place in habitats that are very often located in different countries, and thus their conservation depends on maintaining the integrity of each and every habitat or stopover needed for their survival. As with any chain, the strength of this migratory chain of stopovers is only as strong as its weakest link (Myers *et al.* 1987).

Further adding to the challenge of conserving migratory species, there is currently a large financial gap for conservation of biodiversity that is unlikely to be met in the short or mid-term through public funds, whether national or international.

In this paper, I review current funding trends for biodiversity conservation, discuss the unique conservation needs of migratory bird species and their flyways, and propose a set of principles that can enhance the availability of financial resources for the conservation of migratory species by placing their special needs in the context of current financing trends for conservation and environment.

### CURRENT FINANCING TRENDS FOR CONSERVATION AND ENVIRONMENT

Accurate information on conservation financing is largely unavailable, and its collection presents methodological challenges because of lack of standard definitions and methods of data collection and maintenance by funding bodies. Accurate data have only been compiled for the Latin American and Caribbean region, covering the period 1990-1998 (Castro & Locker 2000).

In that survey, the authors relied on questionnaires sent to 118 funding bodies, of which 65 responded. These responses, however, included all known major funding bodies and thus it is likely that the study captured most funding that was actually available during the period. From these sources, the total cumulative funding over the nine-year period was US\$3.26 billion, representing 3 489 projects. The great majority of these funds (90%) was provided by multilateral and bilateral sources, followed by NGOs (5.8%) and private foundations (3.8%). Most funds were allocated to protected areas (36%), followed by biodiversity conservation within natural resources management (35%), policy (8%), research (5%), and capacity building (4%).

Over time, and when compared with a previous study that covered the period 1987-1989 (Abramovitz 1989, 1991), there

Fig. 1. International funding for conservation projects in Latin America and the Caribbean: 1987-1997. In millions of US dollars. Sources: Abramovitz 1989 (1987-1989); Castro & Locker 2000 (1990-1997).

was a significant jump in funding. Funding grew from an average of c. US\$50 million per year in the late 1980s to c. US\$350 million per year in the 1990s. Nevertheless, the trends during the 1990s remained flat and without a clear increase during the period (Fig. 1). These trends have continued until today, and are due to various reasons, primarily the emergence of new priorities for development assistance that are more focused on poverty alleviation and related issues (Lapham & Livermore 2003).

Global trends for development assistance confirm these results. The international community has refocused its efforts towards achieving the Millennium Development Goals, a set of priorities agreed at the 2002 United Nations Conference on Environment and Development (UNCED) in Johannesburg. These goals are the following:

- Reduce extreme poverty and hunger.
- Achieve universal primary education.
- Promote gender equality.
- Reduce infant mortality.
- Improve maternal health.
- Fight AIDS and other diseases.
- Promote sustainable development.
- Promote global development.

It is clear that most of these goals focus on social needs and poverty alleviation, legitimate societal priorities that compete with resource allocation for environment (goal 7) at national and international levels. Further complicating this difficult outlook for environmental financial resources, there is an overall shortage of funds for all development issues. Since the 1990s, the total amount of overseas development assistance (ODA) has remained constant in US dollar terms at about US\$60 billion (Fig. 2), but when expressed as a percentage of GDP, it has decreased steadily over the last 15 years and it is still very far away from the target of 0.7% of GDP agreed in the 1970s (World Bank unpubl. data). Finally, new international priorities have emerged in the last few years, related to security and war, and these urgent issues have drained additional resources away from development funds.

The funding picture from international sources for waterbird flyway conservation is therefore bleak. As we have seen, most

The Millennium Development Goals are increasingly driving international assistance and development policies. Photo: David Stroud.

Fig. 2. Overseas development assistance (ODA) available world-wide: 1960-2000. In millions of US dollars.

current funding sources for development and environment are provided by multilateral and bilateral sources, but the magnitude of ODA since the early 1990s has not grown. Within this flat international funding picture, environment now competes with other social issues that receive higher priorities. Therefore, advocates for migratory species conservation face a total “pie” that has not grown, and a slice within it (environment) that is shrinking.

The picture is complicated even further by the fact that the financial needs of most other conservation issues, many of which are widely considered to be higher priorities, are not currently being adequately met. Even for an issue such as protected areas, commonly considered a top conservation priority and one that receives most conservation funds, current financial flows only cover about 30% of the needs (Brunner *et al.* 2004). How can migratory species receive the funding that not even top priority issues such as protected areas receive today?

### SPECIAL NEEDS OF MIGRATORY SPECIES

As has been documented earlier, the conservation needs of migratory species present special challenges to conservationists. An important characteristic of many migratory waterbirds is that they concentrate in large numbers during migration. This concentration means that very large proportions of entire populations can be found at key locations and at the same time, thus making them extremely vulnerable to local conditions during migration. Many species that migrate long distances rely on a series of these migratory stopover sites, and the loss of just one of these sites could result in catastrophic disruptions to their life cycles and even survival (Myers *et al.* 1987).

Migratory species conservation thus requires concerted international efforts, including the identification and protection of these key sites. Major challenges, however, emerge. Are all such sites well known? Do these sites always coincide with national conservation priorities? Where can the funding be found for sites that do not coincide with national priorities? Are all sites properly conserved and managed? Clearly, the conservation needs of migratory waterbirds present additional challenges to conservationists, over and above existing efforts to conserve biodiversity.

## PERSPECTIVES AND RECOMMENDATIONS

Successful examples exist of conservation efforts that have addressed the challenges of conserving migratory waterbirds. Among them, the establishment of the Western Hemisphere Shorebird Reserve Network by J.P. Myers and collaborators in the mid-1980s represented a milestone that has been emulated in other parts of the world. Other efforts have included the establishment of international conservation agreements under the umbrella of the Convention on Migratory Species (CMS), and the support of several projects with funding provided by the Global Environment Facility and with the support of international NGOs (notably BirdLife International) and countries, to conserve migratory flyways in Africa, Europe and parts of Asia. These efforts, however, cannot be replicated on a scale that would satisfy the needs of all migratory flyways, because resources of such magnitude are simply not available. Furthermore, such approaches are not sustainable because in the absence of sustainable financing mechanisms, they are vulnerable to changes in international financing trends. Instead, these pilot experiences can simply be taken as experiments that have provided important lessons for future work in flyway conservation.

Clearly, these examples are not sufficient, and it is unlikely that they can be replicated at scales sufficiently large and in a timely manner to address all conservation needs of migratory waterbirds. Clearly, additional steps are required. The following is a list of four proposed steps:

1. Build public support. Over the long term, conservation can only succeed to the extent that societies understand its importance and exert pressure over policy-makers to allocate the necessary resources to achieve it. Bird migration is one of the most fascinating spectacles in nature. Therefore, advocates of migratory waterbird conservation must step up efforts to build public support, at all levels, and in all countries.
2. Strengthen the scientific basis of conservation decisions. To be credible, conservation needs to be based on solid scientific data. Information on flyways, stopovers, and resilience of migratory populations to disruptions are key elements to sharpen strategies for migratory waterbirds.
3. Support broader conservation efforts. The conservation of migratory waterbirds is just a “subset” of broader conservation efforts. Its long-term success in developing countries strongly depends upon the ability to achieve broader conservation goals in these countries, including building the necessary local capacity, institutions and policies that support conservation. Advocates of migratory waterbird conservation need to avoid the perception that they represent a “special interest group,” but rather, support broader conservation efforts at national levels.
4. Bring conservation into the mainstream of broader development issues and utilize market-based mechanisms.

Conservation must be perceived as relevant to society’s well-being. Given existing severe financial shortcomings, stand-alone conservation efforts will not succeed and will not attract sufficient funding to address this issue. Therefore, and in addition to continued efforts to increase overall funding for conservation at all levels, it is important to promote development actions that have the potential to generate conservation benefits. There are numerous examples of successful efforts of such “piggy-backing” or “mainstreaming”. For example, coffee grown in the shade and certified as biodiversity friendly commands better prices in the international specialized markets, and provides direct economic incentives to local farmers to maintain forest cover in areas of high biodiversity. Market-based schemes of payments for environmental services have been successfully established in Costa Rica and other countries in Latin America.

In the case of migratory waterbirds, there are numerous opportunities for such “mainstreaming”, for example: (i) with the tourism sector, given the strong overlap between migratory stopovers and coastal areas with high tourism potential; (ii) with the agricultural sector, when crops can be grown in ways that provide habitat for waterbirds, as in the case of rice; and (iii) with the infrastructure sector, finding ways to incorporate the conservation of migratory stopovers within broader regional development schemes.

As with most other conservation issues, there is no single-bullet solution that can address all challenges at the same time. Success will require sustained efforts, creativity, and the willingness to innovate and involve all sectors of society in the conservation of nature.

Nova Scotia's coastal waters support regional and global waterbird populations. With most of the province and its coastline in private ownership, the conservation of waterbird habitat is a shared responsibility. This paper examines different forms of partnering to help deliver flyway conservation activities at a local level.

Nova Scotia's coastal habitats, located in the North American Atlantic Flyway, support regionally and globally significant numbers of migrating, staging, and wintering waterbirds. However, approximately 75% of the province and 95% of its coastline is in private ownership. Provincial and federal governments have historically applied provisions under legislation (e.g. sanctuaries and management areas) or listed areas under international agreements (e.g. Ramsar Convention) to regulate or influence activities that may directly impact waterbirds or their habitats. Although the Southern Bight Minas Basin Ramsar site has overlapping designation with the Western Hemispheric Shorebird Reserve Network (WHSRN), it receives no legislated habitat protection.

Since 1989 the Eastern Habitat Joint Venture (EHJV) partnership has delivered the North American Waterfowl Management Plan (NAWMP) to reduce/ reverse wetland loss and to restore waterfowl populations in Eastern Canada. Government agencies on the EHJV Management Board in 2002 identified the partnership as the principle delivery mechanism for bird habitat conservation under the North American Bird Conservation Initiative (NABCI). This decision by the North American Wetlands Conservation Council (NAWCC-Canada) to support NABCI objectives provided an opportunity to address threats to the waterbirds and habitat of the Southern Bight Minas Basin Ramsar and WHSRN site.

The Southern Bight Minas Basin is located in the upper reaches of the Bay of Fundy. Beginning in late July, 50-95% of the world population of Semipalmated Sandpiper *Calidris pusilla* migrates south through the upper bay. To complete the non-stop 5 000 km transoceanic flight to wintering grounds in South and Central America, the birds depend upon high quality foraging and undisturbed resting (roosting) habitat. An estimated 400 000 Semipalmated Sandpipers and 10 000 Least Sandpipers *Calidris minutilla* stop in the Southern Bight to feed on the high densities of mud shrimp *Corophium volutator* exposed at low tide in the extensive mud flats. During high tide, shorebirds will roost on the upper beach in flocks numbering tens or hundreds of thousands - a key roosting area that is a popular tourism destination where public ownership is limited.

Major threats to the birds and habitat are bloodworm *Glycera dibranchiata* harvesting, agricultural impacts, cottage development and tourism and recreation. To address these

threats, a multi-faceted conservation initiative builds upon a science base, legislation, and stewardship. Stewardship is the wise and ethical management of natural resources by stakeholders who share a common interest in the sustainable management of all resources that occur in the natural environment. Stewardship activities involving governments, landowners, interest groups and/or the general public are voluntary and promote cooperative partnerships.

Unregulated bloodworm harvesting was shown to occur at levels likely to exceed the population's replacement capacity, and the activity had a detrimental effect on populations of *Corophium*, the primary prey of most migrating shorebirds. The demand for bloodworms has led to conflicts between harvesters wishing to exploit the resource.

Research results presented to provincial and federal managers, harvesters, and the local community increased interest in the effects of bloodworm harvesting on the intertidal ecosystem. Uncertainties in federal and provincial legislative jurisdiction hampered introduction of regulatory controls on the industry, but efforts by the provincial government to work cooperatively with bloodworm harvesters yielded positive early results. Local harvesters formed an association and worked with the provincial government to develop conservation guidelines in the Ramsar/WHSRN site. Voluntary guidelines served a useful role for several years until conflict with outside harvesters resulted in active involvement by the federal government. Harvesters are now organized and regional representatives participate on a Marine Advisory Committee with federal and provincial counterparts to manage the resource and minimize impacts. In a period of ten years, an unregulated harvest moved to voluntary guidelines and a formal licensing and zoning system encompassing size restrictions allowing sexually mature worms to spawn.

Nova Scotia agriculture has declined in numbers but increased in the size of operations. For livestock producers, a limited landbase upon which to apply manure has predictable impacts on ground and surface water quality. Moreover, riparian areas and wetlands have been impacted by activities that have negatively affected wildlife habitat and water quality. High levels of nutrients flow into the Southern Bight from rivers draining the most intensively farmed agricultural regions in Nova Scotia.

The Kings County Agricultural Landscape Habitat Conservation Project is conserving wildlife habitats and improving water quality through partnerships with municipal governments, local conservation organizations and private landowners. This project forges alliances with new partners within the agricultural community, develops and distributes wildlife habitat information/education packages to a multitude of

stakeholders, negotiates and signs binding habitat conservation agreements, and jointly funds habitat conservation projects (e.g. riparian fencing and watering ponds, small marsh restoration, and wetland wastewater treatment systems). This project is strongly supported by agricultural and wildlife communities; and builds upon conservation and biodiversity components using Best Management Practices within the recently signed federal/provincial Agricultural Policy Framework (APF) Implementation Agreement.

Cottages and recreational areas line many sensitive shorelines that serve as roost sites, and human recreational and development activity frequently disturbs roosting flocks, while shoreline integrity is compromised through lack of protection on privately owned beaches. With a focus on the Southern Bight Minas Basin, the *Bay of Fundy Shorebird Project* (BoFSP) was initiated in 2001 with four objectives to address concerns related to disturbance of roosting shorebirds:

- Inform coastal landowners and other users about shorebird ecology and the potential effects of human activities to wildlife;
- Develop and implement stewardship initiatives to conserve the habitat of migratory shorebirds & other coastal wildlife;
- Produce educational materials and establish interpretive facilities to promote shorebird conservation;
- Secure key shorebird roosting habitat, through purchase, conservation easements and agreements.

The BoFSP has strong stewardship, educational and public awareness components. In cooperation with the Nova Scotia Nature Trust, a program was begun to cultivate a community-based stewardship ethic: landowners were provided with material on shorebirds and the site's sensitivity, and how to assist in conservation that could include a stewardship agreement. Community meetings, interpretive programs and field tours extended the message to visitors. Project staff identified critical roosting sites and installed information signs at public

access points and, with consent of landowners, private lands close to active shorebird areas.

The BoFSP partnered with local community organizations to jointly finance and construct an interpretive facility to inform visitors and residents about migratory shorebirds. The structure and its information panels, video and brochure reinforce local awareness and inform tourists about the conservation ethics promoted by the program. A proactive approach was undertaken with the tourism industry by offering information intended to familiarize visitors with 'wildlife-friendly' practices.

The initiatives with the bloodworm harvesters, agricultural community and the BoFSP advance the goals established for the NAWMP and the Canadian Shorebird Conservation Plan. Multi-lateral (NAWMP, NABCI) and bilateral (APF) agreements and international conventions (Ramsar, WHSRN), regional (EHJV) and national (NAWCC) supporting infrastructure, effective partnerships (EHJV, BoFSP) and evaluation processes (research) contribute to leverage financial and human resources to deliver flyway conservation activities at the local level. The conservation community recognizes and promotes the synergy that results from

- greater collaboration among governments, public agencies and NGOs;
- the sharing of information and pooling of expertise and resources; and
- combining forces to deliver specific conservation activities on-the-ground.

Conserving migratory waterbirds depends not only on the commitment of many individuals but also on exchanges between networks of many different people. For conservation to be effective, these networks need to possess both practical ability and scientific know-how at all stages of migratory flyways. As there is a wide imbalance in capacity across flyways, it is thus important to develop and sustain capacity in areas where resources and experience are relatively low. This requires strategies and programmes that address training, institutional strengthening and network development.

The workshop reviewed capacity building strategies, many of which are summarised in the following papers which describe activities in west and east Africa, Central Asia and the Caucasus, and made the following recommendations:

Frameworks for establishing and implementing sub-regional strategies for capacity building need urgently to be developed. These should draw on the experiences of existing sub-regional initiatives in West Africa (Ndiaye), Central Asia (Solokha *et al.*), East Asia-Australasia and elsewhere.

Within such programmes, it is important to carry out a comprehensive training needs analysis, and to incorporate in these the requests for training and other aspects of capacity building, which will ensure a 'bottom-up' approach.

Training programmes for waterbird conservation and research should address the following main target groups:

- scientists, field workers and data managers;
- Government and local officials together with those involved with non-governmental organisations;

- Those managing wetlands or other protected areas; and
- community leaders and community groups.

They must in addition ensure the training of trainers, which is vital for execution of training.

Sub-regional training programmes should incorporate:

- academic training;
- practical training, for delivery through both regular, established courses and *ad hoc* initiatives in response to need and local situation;
- on-site field training; and
- the transfer of know-how through exchange.

These should be tailored according to needs of the target groups, to ensure that training programmes are appropriate.

In order to maximise partnerships and information exchange across the globe, it will be most cost-effective to develop transferable training modules, which may then be adapted for different levels or target groups.

Training materials in appropriate languages and formats, such as training manuals and tool-kits should be developed and disseminated.

Given that the need for training is widespread and long-term, exit strategies or self-supporting mechanisms need to be built into sub-regional training programmes to ensure their continuity.

This can include marketing training programmes, to raise funds for their execution and to gain strong local, national and international support.

## Building capacity in Africa through a regional training programme

Abdoulaye Ndiaye, Tim Dodman & Cheikh H. Diagana

Wetlands International, West Africa Programme, PO Box 8060, Dakar-Yoff, Senegal. (email: ablaywet@sentoo.sn)

Ndiaye, A., Dodman, T. & Diagana, C.H. 2006. Building capacity in Africa through a regional training programme. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 884.

This paper discusses the results of a training programme implemented after a training needs analysis had been carried out with all partners. The analysis identified the following targets: field technicians, administration officers, students and women's groups. During the implementation of the project, a large monitoring programme, waterfowl surveys, networking, exchange visits and some short courses and field projects were organised.

There has been a lack of expertise in the West Africa region on wetland issues. The impetus for training at the sub-regional level came from the strategy discussed at Djoudj National Park in Senegal (1996). From February 1998 to April 2001, several regional and national training courses were organized with a total of 492 participants. The following countries hosted at least one training course, either Regional or National: Burkina Faso, Niger, Togo, Cote d'Ivoire, The Gambia, Guinea Conakry, Nigeria, Congo Brazzaville, Liberia and Madagascar. The ten national training courses trained 220 participants and seven regional courses trained 140. A field exercise called a "trans-boundary training course" was successfully held in Ghana, as was a joint course with IUCN in Saint-Louis USA. A field project in Mali has also trained around 100 people. Due to the Ramsar Convention requirement, 12 people have been sent to the Netherlands for a qualification in Wetland Management Planning. As experience built up, support has been offered to universities teaching wetlands issues to post graduate level in Ouagadougou (Burkina-Faso) and Dakar (Senegal).

Training started with data collection and management for the African Waterfowl Census (AfWC) coordinators, as until now census activities have often been not standardized. Women were the second target of training: the regional course gathered together women involved in wetland natural resources in a type of exchange visit. The third target was the decision makers (key stakeholders) mainly Deputy Ministers and General Secretaries at the ministries in charge of wetlands. A workshop was held to inform them about the need for a Wetland National Policy and the mechanisms for implementation, biodiversity programmes with wetland components, and the need to support the Ramsar convention and key partners.

There are still several challenges to overcome as there is a big gap between different regions and their wetland knowledge. The problems faced were:

- Communications – it was very difficult to exchange information with some countries or even send an invitation for a workshop.
- Civil wars / rebellion are common in Africa and have disorganized the programme to some extent, particularly in Sierra Leone and Liberia.

- Lack of funding was also a big challenge as we had only one key donor. Other funding possibilities were explored mainly with stakeholders using the wetland resources, such as tour operators, hotel managers and hunting associations.
- Language barrier - the working languages are English and French, however interpreters have to be used frequently which are very costly.

Conservation of migratory waterbirds is integrally linked to the maintenance and protection of wetland areas along their flyways. Various international conventions and agreements such as the African-Eurasian Waterbird Agreement (AEWA) and the Ramsar Convention are integral in providing technical and legal standards and mechanisms for their coordination. However, for strategic conservation of site networks along flyways additional investment is needed to ensure that:

- Activities are coordinated
- International conventions and agreements are implemented
- Understanding of flyway site networks is improved
- Best practices are disseminated
- Communication and training networks are established.

The African Waterfowl Census network remains the most vital network within the continent. Building on this, other networks have been created liaising with wetlands endorsed by the Ramsar convention. The African Partnership, a new initiative, is also creating good linkages within the different institutions for a good programme on capacity development mainly on wetland. The key partners within the continent are the international scientific partners such as Birdlife International, IUCN, WWF, and others at national, local and international level.

Looking to the future, different courses should continue to be organized at all levels: the Wetland Management Course should be launched soon to meet the requirements of the West African Sub-region. The existing centres should be strengthened to develop liaison with projects, and the courses should be given a formal qualification status. The cost of language interpretation for courses is an issue, and either an adequate budget needs to be provided or courses should be with participants from one language zone only.

### ACKNOWLEDGEMENTS

We are grateful to all who have participated in the development of the training programme and its implementation. We acknowledge financial support from the Dutch Ministries mainly the DGIS and LNV. Countries hosting meetings have also played an important role in the success of the programme.

## Building capacity in Central Asia and the Caucasus to promote waterbird research and conservation

Solokha, A., Hagemeyer, W. & Mundkur, T. 2006. Building capacity in Central Asia and the Caucasus to promote waterbird research and conservation. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. pp. 885-888.

### ABSTRACT

This paper gives an overview of conservation frameworks and expert institutions in Central Asia and the Caucasus. It describes how Wetlands International has contributed to capacity building at both regional and local level through promoting international conventions, developing a flyway action plan, strengthening the specialist network and other catalysing activities during the period 2001-2004. Although considerable progress has been made in improving co-operation and co-ordination, strengthening institutional capacity and raising awareness, there remains a need for better training courses and public education and awareness programmes to promote waterbird and wetland conservation at all levels. The establishment of a Wetland Training Centre would facilitate the development and implementation of appropriate training and education programmes across the region.

### INTRODUCTION

During the time of the USSR, waterbird research and protection in the republics of Central Asia and the Caucasus were supported and co-ordinated through implementation of government programmes. Scientists from various local academic institutions, universities and nature reserves conducted a broad range of studies on the ecology, distribution and migrations of waterbirds. Waterbird experts from leading scientific centres, primarily in Moscow and Leningrad (now St Petersburg), also made a major contribution to these studies. The exchange of information and co-operation between specialists and institutions were promoted through publications, regular conferences and missions. With the accession of the USSR to the Ramsar Convention on Wetlands in 1975, five wetlands in Central Asia and the Caucasus were designated as Wetlands of International Importance, or Ramsar sites, and another 49 sites from this region were identified as Wetlands of National Importance (Skokova & Vinogradov 1986).

Since the disintegration of the Soviet Union in 1991, there has been a substantial decrease in research and conservation activities relating to waterbirds and wetlands in the region. The main reasons for this were a lack of government funding, a shortage of specialists and a breakdown in the former links between people and organizations. However, the political changes that have occurred in the new independent countries have opened up new opportunities for co-operation with international organizations and sponsors. As a consequence, various local projects were developed and supported, including some on wetland and water-

bird conservation (Krever *et al.* 1998, Krever *et al.* 2001).

In general, however, research and conservation work on waterbirds and wetlands in Central Asia and the Caucasus remained at a low level until 2001-2002. With the exception of Turkmenistan and Azerbaijan, none of the countries in the region was involved in the regular mid-winter waterbird counts carried out within the framework of the International Waterbird Census organized by Wetlands International. This resulted in underestimation of many waterbird populations and a lack of contemporary information on their wintering habitats. The capacity of government agencies, non-governmental organizations and research institutes to carry out research and conservation

Chatkal State Nature Reserve, Uzbekistan is a biosphere reserve covering the southwestern end of the Chatkal'skiy Range in the western Tien-Shan Mountains. Photo: David Stroud.

activities relating to waterbirds and wetlands was very limited. In comparison with other regions of the Western Palearctic and Asia-Pacific, the level of co-operation and exchange of information within Central Asia and the Caucasus was very weak. The main inter-governmental treaties dealing with the conservation of wetlands and migratory waterbirds, primarily the Ramsar Convention on Wetlands and the African-Eurasian Migratory Waterbird Agreement (AEWA), were in need of much better representation in the region.

Training, networking and raising awareness were required in Central Asia and the Caucasus to build the capacity of local organizations and to improve efforts to conserve wetlands and waterbirds. This paper gives an overview of conservation frameworks and expert institutions in the region, and describes activities carried out by Wetlands International during the period 2001-2004 that have contributed to capacity building at both regional and local level.

## FOCAL AREA

In accordance with the majority of current political and geographical opinions, Central Asia is here taken to include the countries of Kazakhstan, Kyrgyzstan, Tajikistan, Turkmenistan and Uzbekistan; the Caucasus region is taken to include Armenia, Azerbaijan, Georgia and Russian territory (North Caucasus) extending north to the Astrakhan and Rostov administrative regions (*oblast*). The study area is therefore located within the southern and south-western parts of the former USSR.

The sub-region of Central Asia and the Caucasus has enormous importance for migratory waterbirds because it is located at a crossroads between migration routes extending from the Russian Arctic and Siberia towards southern Europe and Africa to the west and the Indian subcontinent to the east (Isakov & Shevareva 1968, Scott & Rose 1996). The region contains a number of very large wetlands including the coasts of the Sea of Azov, Black Sea and Caspian Sea, Issyk Kul and Lake Balkhash, as well as many other lakes and reservoirs. Several million waterbirds breed, migrate through or spend the winter here.

**Table 1. Accession to international conventions and agreements directly relevant to the conservation of waterbirds in Central Asia and the Caucasus (as at July 2006).**

Country	International treaties

Notes:

+ : Countries are Contracting Parties

(+) : Countries are not Contracting Parties to the CMS, but participate in the CMS Memoranda of Understanding, particularly in the MOUs on Siberian Crane *Grus leucogeranus* and Slender-billed Curlew *Numenius tenuirostris*.

## OVERVIEW OF FRAMEWORKS AND INSTITUTIONS INVOLVED IN THE CONSERVATION OF MIGRATORY WATERBIRDS

### International and regional conventions, agreements and other initiatives

There are four key inter-governmental treaties relevant to the conservation of migratory waterbirds in Central Asia and the Caucasus:

- Convention on Biological Diversity (CBD).
- Convention on Wetlands (Ramsar Convention).
- Convention on the Conservation of Migratory Species of Wild Animals (Bonn Convention or CMS).
- African-Eurasian Migratory Waterbird Agreement (AEWA; an agreement under the CMS).

As at the end of 2004, all countries in Central Asia and the Caucasus are Contracting Parties to the Convention on Biological Diversity; seven countries (all except Kazakhstan and Turkmenistan) are Contracting Parties to the Ramsar Convention; three countries, Georgia, Tajikistan and Uzbekistan, have signed the Convention on Migratory Species (CMS); and only Georgia and Uzbekistan are Contracting Parties to the African-Eurasian Migratory Waterbird Agreement (Table 1).

In addition to the above legally binding treaties, the Asia-Pacific Migratory Waterbird Conservation Strategy: 2001-2005, a non-legal co-operative initiative co-ordinated by Wetlands International, covers Russia and the Central Asian countries (including Azerbaijan), as well as the countries in South Asia. This Strategy promotes the establishment of a site network for the conservation of migratory waterbirds in the Central Asian Flyway.

The key conservation framework in the Central Asian region is the Regional Environment Action Plan (REAP), developed and implemented by the Interstate Sustainable Development Commission (ISDC) and other government and non-governmental organizations with the support of the Asian Development Bank and UNDP. In the field of biodiversity protection, REAP aims at establishing an ecological network in Central Asia (UNEP/GEF Central Asian Econet project), including a network of important wetlands.

### International non-governmental organizations

Working in collaboration with governments, conventions and with each other, various international non-governmental organizations (NGOs) promote waterbird and wetland conservation in Central Asia and the Caucasus. Side by side with Wetlands International, the following international NGOs are active in the region:

- BirdLife International
- International Crane Foundation (ICF)
- World Wide Fund for Nature (WWF)
- World Conservation Union (IUCN)
- Flora & Fauna International

### Governmental and inter-governmental organizations

The conservation of migratory waterbirds and their habitats is mainly the responsibility of national ministries or committees for the protection of either environment, nature, natural resources or forest. Issues relating to the protection and use of wetland resources can also be shared with other agencies,

e.g. ministries of agriculture.

There are two key inter-governmental organizations responsible for conservation and wise use (including wetland and biodiversity issues) in Central Asia. These organizations are:

- Interstate Sustainable Development Commission (ISDC), with its Secretariat currently based in Ashgabat, Turkmenistan, until 2006; and
- Interstate Water Commission, with its Secretariat based in Tashkent, Uzbekistan.

These organizations are represented by government officials and have close links with each other.

### Local technical institutions and NGOs

There are many national educational, research and non-governmental organizations involved in the conservation of migratory waterbirds in Central Asia and the Caucasus. Universities, biological institutes of the National Academies of Sciences and research institutes (e.g. fishery research institutes), located in capitals and other big cities, work primarily with scientific and co-ordination issues at national and provincial level. Nature reserves and national parks are responsible for research and conservation of particular wetlands and their biodiversity, and thus play a critical role at site level. In the region under review, there are nearly 20 nature reserves and national parks working with wetlands and waterbirds, including such well known reserves as Astrakhansky NR in Russia, Sevan NP in Armenia, Kyzylagach NR in Azerbaijan, Naurzumsky NR in Kazakhstan, Issyk Kul NR in Kyrgyzstan, Tigrovaya Balka NR in Tajikistan and Turkmenbashi (formerly Krasnovodsky) NR in Turkmenistan. At national level, all technical organizations can co-operate with each other through state co-ordination programmes.

Among local NGOs involved in waterbird and wetland conservation, the science-oriented ornithological units deserve special mention. These have been established in many countries (Armenia, Azerbaijan, Russia, Kazakhstan), and work with support mainly from BirdLife International or its partners.

### WORKING TOWARDS INCREASING REGIONAL AND LOCAL CAPACITY

Capacity building in Central Asia and the Caucasus was promoted in 2001-2004 through organizing workshops and training courses, raising the awareness of stakeholders and the general public, and establishing a waterbird specialist network.

### Promoting wetland and waterbird conservation initiatives

Wetlands International monitors the status of collaboration between countries and international conventions dealing with wetlands and waterbirds, and promotes further accessions to these conventions. This promotion is being achieved through raising awareness of the importance of waterbirds and their wetland habitats and facilitating contacts between conventions and the responsible national agencies. For example, Wetlands International has been assisting the Government of Turkmenistan in joining the Ramsar Convention on Wetlands. It is anticipated that in 2005 the two remaining countries, Kazakhstan and Turkmenistan, will become Contracting Parties to this Convention.

Wetlands International promotes implementation of the Asia-Pacific Migratory Waterbird Conservation Strategy (APMWCS) in Russia and the Central Asian countries. The Russia Federation has participated in this initiative since 1996, and has nominated a total of ten sites to the Crane, Anatidae and Shorebird Site Networks along the East Asian-Australasian Flyways. Due to administrative reorganization over the last few years, the Russian Ministry of Natural Resources has been unable to send its representative to the annual meetings of the Asia-Pacific Migratory Waterbird Conservation Committee (APMWCC) and nominate new important sites to the site networks. Nevertheless, the Ministry has been kept informed of the outcome of meetings and has been encouraged to renew its active participation in the implementation of this initiative.

In the Central Asian region, a representative of the Scientific Information Centre (SIC) of the ISDC based in Ashgabat was invited to attend the APMWCC meetings in 2002-2004. With the assistance of the SIC ISDC, the APMWCS: 2001-2005 was translated into Russian to increase the awareness of decision-makers and the general public concerning waterbirds and the APMWCS, and thus promote implementation of this strategy in Russia and the Central Asian countries.

### Development of an Action Plan for the Central Asian Flyway

The development of an Action Plan throughout the Central Asian Flyway is one of the project goals. A draft document was presented at the first Central Asian (Central Asian-Indian) Flyway Workshop, which was organized in Tashkent, Uzbekistan, from 18-22 August 2001 in conjunction with a Central Asian Outreach workshop, and co-funded by the CMS. Official representatives from 15 Range States, as well as international experts and representatives of the relevant international conventions, participated in the meeting and contributed in reviewing the Action Plan and developing it further.

Both workshops were also important in terms of gathering general information along the flyway and identifying government agencies, NGOs and research institutions responsible for the conservation of waterbirds and their habitats in the range states. Official delegations were encouraged to strengthen co-operation in the region to promote waterbird and wetland research and conservation. During the period 2001-2004, the Action Plan was given further consideration at Ramsar COP8, CMS COP7 and AEWA MOP2. It is anticipated that the Action Plan will be finalized and approved at the second Central Asian Flyway workshop planned for 2005.

### Establishing co-operation at regional and local level

Useful relationships were established with the Interstate Sustainable Development Commission (ISDC) and its Scientific and Information Centre (SIC). Founded by the governments of all Central Asian countries and supported by international agencies, the ISDC co-ordinates environmental protection and sustainable development across the region. Currently the SIC ISDC assists in the implementation of the Asia-Pacific Migratory Waterbird Conservation Strategy: 2001-2005, and its representative is a member of the APMWCC. Wetlands International attended the regional workshop and ISDC meeting in February 2004 in Dushanbe, Tajikistan, to give a presentation on the activities of Wetlands International and to discuss issues

relating to regional co-operation in the wise use and conservation of wetlands.

Wetlands International seeks to co-operate with WWF within the framework of the UNEP/GEF Central Asian Econet project. Officially endorsed by ISDC and included as a component in the Regional (Central Asian) Environmental Action Plan, the Econet project aims to establish a network of protected areas to secure conservation of biological diversity at all levels and promote sustainable development in the region. Wetlands International has developed a preliminary list of internationally important wetlands in the Central Asian region based mainly on the Ramsar criteria relating to migratory waterbirds. This list has been submitted to WWF for use in the establishment of the Central Asian ecological network. It is anticipated that incorporation of important wetlands in this project will provide additional emphasis and tools to strengthen wetland conservation and wise use in the region. The list of internationally important wetlands in Central Asia can serve as a basis for working with other organizations, such as ICF and CMS, to support the establishment of a site network along the Central Asian Flyway.

### Co-ordination of the IWC and strengthening a specialist network

The International Waterbird Census (IWC) is a long-term monitoring programme which is being run throughout the world under the co-ordination of Wetlands International. In addition to its considerable scientific value, the International Waterbird Census can serve as an important tool for strengthening communication and linkages between specialists and facilitating the building of organizational and personnel capacity. In 2003 and 2004, waterbird counts were carried out in Russia and most other countries in Central Asia and the Caucasus as part of the IWC, and nearly 50 professionals and amateurs were involved in this work. Training of field observers to increase their skills in waterbird identification and counting was included as part of the mid-winter surveys, and was provided by IWC national co-ordinators and Wetlands International staff.

The mid-winter census in Central Asia and the Caucasus often entailed visits to remote wetlands that were difficult of access. In order to travel to such wetlands, local teams of counters co-operated with the relevant local organizations. For example, in Uzbekistan, Azerbaijan and Krasnodar Province in Russia, the counters obtained logistic support from hunters' associations and nature reserves.

In November 2003, a Central Asian Co-ordination Workshop was organized at Issyk Kul, Kyrgyzstan, in collaboration with the State Forest Service of the Kyrgyz Republic. Nearly 30 participants from across the sub-region came together to review the status of co-operation in Central Asia and increase their professional skills in wetland study and survey techniques. A brief field course was specially organized to provide basic training for rangers from the Issyk Kul Nature Reserve. This workshop was very successful in building institutional capacity in the Central Asian region and promoting further co-operation and collaboration under the IWC and other wetland related projects.

In order to raise awareness of the needs of wetland and waterbird conservation in Russia, Central Asia and the Caucasus, the Russia Office of Wetlands International maintains a web-site in the Russian language, and this includes, in particular, information on the progress of the Central Asian Flyway project.

Several international collaborations have assisted the conservation in Central Asia and the Caucasus. Visit of AEWA's Technical Committee to Chatkal State Nature Reserve, Uzbekistan, 2003. Photo: David Stroud.

### CONCLUSION

This overview of work conducted in Central Asia and the Caucasus during the period 2001-2004 shows that some progress was achieved in developing co-operation and co-ordination, strengthening institutional capacity and raising awareness. A number of government agencies, research institutes and non-governmental organizations were involved in one way or another in waterbird and wetland research and conservation. A specialist network was significantly enhanced and strengthened through training and a concerted monitoring programme. However, there remains a need to enhance training courses and public education and awareness programmes to promote waterbird and wetland conservation at all levels. The establishment of a Wetland Training Centre would facilitate the development and implementation of appropriate training and education programmes across the region.

### ACKNOWLEDGEMENTS

This work has been made possible thanks to the project "Towards a Strategy for waterbird and wetland conservation in the Central Asian flyway", supported by the Dutch Ministry of Agriculture, Nature and Food Quality. The authors express their gratitude to Gerard Boere, Marcel Silvius, Simon Delany and Olga Anisimova (all from Wetlands International) who initiated this project in 2001.

### ABSTRACT

The wetlands of eastern Africa support internationally important assemblages of plants and animals, and are a vital source of livelihood and water for many societies. The combined human population of Burundi, Djibouti, Eritrea, Ethiopia, Kenya, Rwanda, Sudan, Tanzania and Uganda is estimated to be about 200 million. The region has an area of about 5.6 million km<sup>2</sup> of which only 4.5% is open water/wetlands. Wetland conversion to agriculture often provides only short-term benefits and can pose long-term problems. The ever-increasing human population density coupled with the scarce water resources in Africa have put African governments under increasing pressure to allow further exploitation and drainage of wetlands. Lack of sufficient up-to-date information to guide policy and development programmes for the respective Africa governments is considered as one of the causes for the continued loss and degradation of wetlands. To fill this information gap, it was recognized that a standardized system for monitoring wetland biodiversity and making the data and information available to governments and other stakeholders was required. In 2002, a project was implemented to build and maintain capacity in the monitoring of wetland biodiversity in eastern Africa and to provide the necessary information required for wetland conservation. This paper describes the capacity building process leading to: (1) the development of a wetlands database with query tools; (2) the provision of training in the use of the wetland monitoring database; (3) the launch of the Wetland Biodiversity Monitoring Scheme (WBMS) to provide data for use in wetland conservation and development of site management plans; and (4) training in the development of a wetland site management plan in each of the nine partner countries.

### INTRODUCTION

In terms of biodiversity, the wetlands of eastern Africa consist of a broad range of habitat types, from the vast Rift Valley lake systems to the Nile River and floodplains, papyrus and mangrove swamps, flooded forests and shallow coral reefs (Hughes & Hughes 1992). They support internationally important assemblages of plants and animals according to the Ramsar Convention criteria, and are a source of livelihood for many human populations. The combined human population of Burundi, Djibouti, Eritrea, Ethiopia, Kenya, Rwanda, Somalia, Sudan, Tanzania and Uganda is estimated to be about 200 million, on a landmass of about 5.6 million km<sup>2</sup>. This landmass is covered by only about 4.5% of open water, and has a coastline of about 5 361 km (The World Fact Book 2002). The actual area covered by wetlands of all types in eastern Africa (and indeed in the whole of Africa) has yet to be quantified. According to Stevenson & Fraser (1999), a rough estimate of the area covered by wetlands in Africa is about

1.25 million km<sup>2</sup>. More than 1.07 million km<sup>2</sup> are inland wetlands, with about 0.1 million km<sup>2</sup> described as marine/coastal wetlands and a further 0.05 million km<sup>2</sup> described as artificial wetlands (i.e. reservoirs, rice fields and sewage works). The average rate of loss of Africa's wetlands is estimated at 2% per year (OECD 1996). However, rates of loss of 9% to 15% per year have been recorded in specific catchment areas in Africa (Hollis 1993, Taylor *et al.* 1995).

In eastern Africa (and indeed throughout Africa), wetlands have been lost and degraded as a result of human activities. The main destructive activities include drainage, construction, pollution, siltation (due to soil erosion), and the introduction of alien species (Howard & Matindi 2003). Human population increase, rising poverty and, in recent years, extremes in climate have acted as the drivers of these changes and placed increasing pressure on wetlands and other renewable natural resources. Unlike in the developed world, many African government bodies are under growing pressure to allow further exploitation of wetland resources and to allow development and extensive drainage of wetlands, principally for agriculture. Although wetland drainage and cultivation can make a key contribution to food and livelihood security in the short term, in the long term there are concerns over the sustainability of this utilization and the maintenance of wetland benefits (Dixon & Wood 2003). The unregulated use of agrochemicals has also been a source of problems in recent years, and the construction of dams has resulted in new pressures on the biodiversity of many wetland sites. The loss or degradation of wetlands has serious consequences for the plants and animals that occur in wetland habitats. For example, migratory waterbirds depend on a chain of suitable stopover (wetland) sites to rest and feed. The loss of these stopover sites is among the major threats to migratory waterbirds (Nasirwa & Bennun 1999). Regardless, given the social, economic and cultural importance of wetlands for humans, it is in the best interest of all societies that they look after their wetlands and continue to benefit from wetland services and functions. This can best be achieved by incorporating a wetland biodiversity-monitoring programme into the management planning process for wetlands. The monitoring process would provide the necessary information to African governments and stakeholders. This information would guide the process of formulating appropriate policies and aid in the designing of development projects to be in harmony with efforts to conserve and utilize wetlands on a sustainable basis.

### DEVELOPMENT OF WETLAND AND WATERBIRD MONITORING IN EASTERN AFRICA

Biodiversity monitoring encompasses a wide variety of activities and has been defined in many different ways. Here we use the term "monitoring" to describe five key processes in relation to wetland data. They are Collection, Collation, Management,

Analysis and Dissemination. Biodiversity monitoring generates data that can be used both to assess status and underpin management planning. It is therefore a key process in the wise use of wetlands. Experience from many different parts of the world has demonstrated that named, “badged”, and appropriately funded monitoring schemes are an extremely efficient way in which to assess trends in the biodiversity status of sites

Over the years, the eastern Africa region has benefited from considerable investment in training facilities focused on science-based nature/wildlife management. It also has a relatively extensive network of protected sites and a long history of inter-organizational collaboration for conservation. During the 1990s, there were a number of cornerstone meetings that clearly identified the capacity needs of African states in relation to management planning for wetlands, and how regional states might use these to fulfil requirements under international agreements. The IUCN Species Survival Commission also produced a comprehensive analysis of conservation needs in sub-Saharan Africa, as part of the Biodiversity Conservation Strategy Programme. In 1998, Wetlands International held a meeting in Dakar (Senegal) at which a number of requirements were identified for wetland biodiversity conservation in Africa. The inaugural meeting of the African-Eurasian Migratory Waterbird Agreement (AEWA, Bonn Convention) in Cape Town in 1999 also identified specific conservation and research needs as part of the AEWA Action Plan.

The eastern Africa region has a number of training facilities and programmes for training in relation to site management plans. It also has a waterbird monitoring scheme, the African Waterbird Census (AfWC) established in 1990 (Perennou 1991). Since the early 1990s, most countries in eastern Africa have participated in the AfWC and contributed data to it in varying degrees. During the period 1999–2001, seven countries submitted their data to Wetlands International. In this period 152 sites were surveyed and the average total number of waterbirds counted in the month of January was 1.6 million waterbirds of a total of 160 species (Dodman & Diagana 2003). The AfWC collects and disseminates information on waterbird populations, but has also collated basic information about wetland habitats. There have also been many independent initiatives by both governments and NGOs in relation to the collection or collation of biodiversity and land-use data at a variety of spatial and temporal scales.

Despite all these activities, at the end of the 1990s, there was still the need to standardize data collection and to make monitoring data more accessible through a regional database. There was also the need to focus the collection and use of data towards addressing specific regional and national pre-set goals. Immediately prior to the 10th Pan-African Ornithological Congress in 2000, the Wildfowl & Wetlands Trust (WWT) took part in a four-day roundtable discussion with African NGO partners and statutory agencies in Kampala, Uganda, at a development workshop organized by the Wetlands International – Africa Office. The result of the meeting was the submission of a bid to the UK Government’s Darwin Initiative to develop and launch a dedicated wetland biodiversity monitoring scheme. This would both benefit from and enhance the work undertaken under the auspices of the AfWC and other programmes and fulfil the needs listed above. The bid was successful, and May 2002 saw the start of a three-year project involving WWT, Wetlands International and nine eastern Africa partner organizations. The project aimed to: (1) provide training in wetland monitoring and site manage-

ment planning; (2) establish a “badged” wetland biodiversity monitoring scheme; (3) create a regional wetland monitoring database; and (4) make use of monitoring data for conservation.

## PROJECT OUTCOMES

### Training in wetland monitoring and site management planning

In November 2003, the project conducted a training course/workshop at the Kenya Wildlife Service Training Institute (KWSTI) in Naivasha, Kenya. Twenty-one participants took part in the training course/workshop: they were the national focal points and their counterparts (two from each country), as well as representatives from Wetlands International, WWT and KWSTI. The training course/workshop was tailored to set up a framework for monitoring and database management, and strengthen institutional and volunteer network capacity to collect wetland biodiversity data. Other aspects covered by the workshop included how to develop and implement standardized procedures for collecting wetland biodiversity data across the eastern African region. To guide the training course/workshop, the project produced a training manual. In September–October 2003, the project sponsored two trainees (the national focal points for Ethiopia and Sudan) to participate in the East Africa Wetlands Management Course (now renamed the International Course on African Wetland Management – ICAWM) held every year at the KWSTI. Apart from benefiting from the training in wetland management, trainees also developed a draft management plan for a wetland site in their own country as part of the course. Equipped with the skills to train others and a training manual, the national focal points now have tools to train others at national and site level.

### Wetland Biodiversity Monitoring Scheme for eastern Africa launched

On 18 November 2003, the project launched the Wetland Biodiversity Monitoring Scheme for eastern Africa (WBMS) in Nairobi, Kenya. WBMS is a collaboration between organizations in nine eastern Africa countries, to collect, manage, analyse and disseminate information on wetland biodiversity. The scheme has a regional secretariat based in Nairobi, Kenya, and nine national organizers. A network of volunteers is co-ordinated to collect data from a range of wetland sites, and the resultant data are stored and managed on the WBMS database. The scheme provides a framework for standardized monitoring of wetland biodiversity in the eastern Africa region. The aim of WBMS is to generate scientifically robust data to underpin the conservation, wise use and management of wetlands in eastern Africa. WBMS activities are planned and organized within the framework and network of the AfWC, and national focal points of WBMS are currently the National Co-ordinators of the AfWC. The WBMS Steering Group oversees the management of the range of core WBMS tasks, to guide the implementation of new WBMS developments, and to identify WBMS priorities. Members of the WBMS Steering Group are the national focal points from each participating country. Where appropriate, ex-officio members representing other relevant organizations such as Wetlands International and WWT also play a role in the Steering Group. The Steering Group meets at least once every year. So far the Steering Group has met twice during the project period. Most of the work carried out by the Steering Group is via email. A list-server to enhance quick communication between the Steering Group, collaborators and supporters of the project and scheme has been

established. The project has also produced a brochure and developed a web-site to publicize and market the scheme.

### THE DATABASE

The project has provided each national focal point with computer hardware and software to improve storage, analysis and dissemination of wetland biodiversity data for use in wetland management planning and biodiversity conservation. The database is designed to ease data entry, and ensures that wetland biodiversity data are stored in a compatible and consistent format within the region. The hierarchical structure of the database enables storage of data to the level of sections of a site, but also to the level of combined sites, depending on how the data were collected. However, data collection is encouraged primarily at the site-section level to allow more robust use of the data for conservation purposes.

### THE WAY FORWARD

This year (2004/05), the project will sponsor another six candidates for the ICAWM course in October-November 2004. It is anticipated that through this course the project will deliver six more draft management plans. During the course of the year, it is projected that the WBMS database will be fully populated with the backlog of wetland and waterbird data from the AfWC. The next stages will be to encourage the use of these data for research, case work, public awareness and education, development of more site management planning, species management plans, site designation (under Ramsar etc.), and national reporting under conventions. Procedures on how to collect data on other parameters of wetland biodiversity are also among the next steps on the project calendar. The Steering Group is working on the terms of reference of its committee that will guide procedures for running WBMS after the project phase. The project is also developing a strategic work plan for WBMS and working on an exit strategy. The objective of the exit strategy is to establish WBMS as a fully-fledged wetland biodiversity monitoring scheme for eastern Africa.

### DISCUSSION AND CONCLUSIONS

There are differences among eastern African countries in the political and institutional set-up in which waterbird and wetland work is carried out. This presents a challenge in evaluating the level of training and training needs required at the regional level. For this reason, there is need for co-ordination and continuous re-evaluation and updating of the training manual as more information about wetlands is gathered. The establishment of the WBMS, WBMS Secretariat and Steering Group provided the structures needed to oversee the implementation of this work. Meanwhile, the database provides easier ways of handling data and hopefully this will enable focal points to elucidate wetland biodiversity trends in eastern Africa. The data exchange mechanism will allow bilateral and multilateral site or species management plans to be developed. This will enable adjacent countries to address issues affecting cross-border wetland sites.

The structures set up by this project (i.e. to improve communication at regional level and especially the formation of the Steering Group) should boost communication between key players and also work as a forum to discuss wetland issues at a regional level. This will build and strengthen the capacity of wetland biodiversity monitoring in eastern Africa, as well as encourage countries to

participate more regularly in the AfWC and other wetland-related initiatives at international level. The training in wetland management and the production of draft management plans are key to capacity building for wetland management at national level. The establishment of the Steering Group to co-ordinate the scheme secures the implementation of the WBMS Strategic Workplan as well as boosting the activities of the AfWC. These outcomes ensure an increase in wetland monitoring, training activities, implementation of management plans, and national reporting on wetland issues in the eastern Africa region. The challenges of WBMS will be fund-raising, increasing the wetland biodiversity parameters monitored, increasing coverage and ensuring ongoing training, implementation of management plans, and maintaining the database after the project phase. These issues are, however, being addressed by the exit strategy.

## The role and potential of the Central-Asian Scientific Information Centre of the Interstate Sustainable Development Commission (SIC ISDC) for studying wetlands and waterbirds

Bakhar Tashlieva

International Fund for the Aral Sea Interstate Sustainable Development Commission Scientific-Information Centre, 15 Bitarap Turkmenistan St., Ashgabat, Turkmenistan 744000. (email: sic@online.tm)

Tashlieva, B. 2006. The role and potential of the Central-Asian Scientific Information Centre of the Interstate Sustainable Development Commission (SIC ISDC) for studying wetlands and waterbirds. *Waterbirds around the world*. Eds. G.C. Boere, C.A. Galbraith & D.A. Stroud. The Stationery Office, Edinburgh, UK. p. 892.

The Central-Asian Scientific Information Centre of the Interstate Sustainable Development Commission (SIC ISDC) is one of various Central Asian organizations and initiatives which coordinates regional co-operation in the area of nature protection and sustainable development. These include the development of regional strategies (programs and action plans) on sustainable development; and the organization, coordination and management of related projects and action plans.

In June 2002, at the seventh meeting of the Asia Pacific Migratory Waterbird Conservation Committee, SIC ISDC made proposals regarding the development of a regional network of experts, cooperation with government departments and agencies, wide public access to information, training, and support for scientific research and monitoring.

During this time SIC ISDC were assisting Wetlands International in the implementation of the Asian Wetland Inventory, raising awareness of waterbird conservation issues, and capacity building in the Central Asian region. The SIC was also keen to assist Turkmenistan and other Central Asian countries becoming signatories to the Ramsar Convention.

Currently, SIC ISDC is mandated to support the development of a wide regional database on ecological issues and sustainable development within the region. Following a series of national seminars in all Central Asian countries on indicators for sustainable development for use in the integrated evaluation of the state of the environment, several indicators on environmental quality (water, land, air, biodiversity) and socio-economic conditions have been prepared and introduced in each Central Asian countries. During the seminars, issues of water resources and wetlands, in particular their biodiversity, were a priority. In the future SIC ISDC could play a role in supporting the coordination of the Asia-Pacific Migratory Waterbird Conservation Strategy in Central Asia.

SIC ISDC also coordinates activities of all conventions and international agreements in Central Asian countries. All these countries are signatories to the Convention on Biological Diversity (CBD), but currently only Uzbekistan, Tajikistan and Kyrgyzstan are signatories to the Ramsar Convention, although Kazakhstan and Turkmenistan are preparing to sign.

In Turkmenistan, wetlands occupy 20% of the total surface area and have extremely important economic, environmental and cultural values. Their role as water regime regulators and as habitats for flora and fauna and for animal species, especially waterbirds for hunting, are important.

Protection of these wetlands and their flora and fauna can only be achieved by a combination of far-sighted national policy in each Central Asian country combined with coordinated international efforts.

Establishing an effective decision-making system for environmental protection and sustainable development is of special importance. This requires good public relations and an understanding of the role of ecological factors in socio-economic planning. To create such a system, sound environmental information is an essential pre-requisite in the development of actions plans for environment protection and sustainable development.

Information requirements arise at all levels of society and the provision to the decision-making process with reliable information requires filling information gaps, and broad access to information. Each participant in sustainable development processes is simultaneously both a user and supplier of information.

In the provision of training on environment and sustainable development at all levels of management in Central Asian countries, international cooperation is also needed. Training should include technical aspects of collection, evaluation and transfer of data, as well as assistance to government bodies in the use of such information.

Governments also need to consider the support of governmental and non-governmental organizations so as to create effective and coordinated information exchange mechanisms at national and international levels, including data formats, forms of access, distribution and communication.

SIC ISDC has carried out an inventory of existing data on indicators/criteria of sustainable development, as stipulated by "Agenda 21" and priority ecological problems of REAP.

Regarding biological diversity, the geographical landscapes of Central Asia are very varied with low populations in the mountainous territories of Kyrgyzstan and Tajikistan steppes, and the deserts and semideserts of Kazakhstan, Turkmenistan and Uzbekistan. Rivers, valley floor, *tugai*, and oases contribute to maintaining the biodiversity of the region. The biological diversity of this arid belt, comprising more than a half of all species in Eurasia, including: 7 000 species of higher plants, 900 vertebrates, and 200 000 invertebrates. The region is an overlap of Asian and Mediterranean floras with a high index of endemism (up to 20% species of higher plants).

The extensive development of arable agriculture, use of toxic chemicals, salinization, overgrazing, deforestation and cutting of *tugai* vegetation in river floodplains are all resulting in environmental degradation and loss of biodiversity.

The implementation of sound environment and sustainable development policies will be essential to maintain genetic biological diversity for the benefit of future generations and their livelihoods.

On the final evening of the conference, conference participants acknowledged Gerard Boere's leadership in international waterbird conservation. He has been a major influence on the development of international structures for migratory waterbird conservation during the last three decades, initially through his research on migratory waders in the Dutch Waddensea; his activities to guide and promote non-governmental conservation and research organisations; his development and promotion of AEWA; effective involvement with several international biodiversity treaties (including the Ramsar, Bonn and Berne Conventions, as well as CAFF); work for the Dutch government to promote bilateral co-operation on waterbird and wetland conservation with Russia and Ukraine especially (notably in the arctic); and latterly his further strengthening of the international programmes and activities of Wetlands International. This photograph, taken on 7 April 2004, shows His Royal Highness The Prince of Wales discussing waterbird conservation matters with Gerard Boere. Photo: Dougie Barnett.

## Species index

The species index is based on the listing of waterbird species and populations of the fourth edition of Wetlands International's (2006) *Waterbird Population Estimates* (Wetlands International, Wageningen, The Netherlands. 239pp.). It has been supplemented by other bird species referred to in this volume. Non-avian species have not been indexed. The taxonomic sequence of families adopted in this index follows that of BirdLife International ([www.birdlife.org/datazone/species/taxonomy.html](http://www.birdlife.org/datazone/species/taxonomy.html)). Sequencing of species within families for traditional waterbirds follows *Waterbird Population Estimates*.

Following the presentational style of *Waterbird Population Estimates*, IUCN Red-listed species are indicated by colour as follows:

**Black** Species not known to have unfavourable conservation status

**Red** Globally threatened species. IUCN threat status appears after the scientific name, using the following codes:

CR Critically Endangered  
EN Endangered  
VU Vulnerable

**Green** Threatened species considered to be at a lower risk of extinction. IUCN threat status appears after the scientific name, using the following code:

NT Near Threatened

Also included are species in the following IUCN threat category:

DD Data Deficient

**Blue** Extinct species

Page numbers relate to the first page of each paper within which the relevant species or population is mentioned. Page numbers in **bold** indicate photos of the species concerned within the indexed paper.

As well as indexing to species level, to aid further uses of the data contained within this volume, for 'traditional' waterbirds only, an attempt has been made to index to the level of populations/races using information on distributional limits in the third edition of *Waterbird Population Estimates* (2002). In many cases such allocations are obvious from the geographic context of the paper (or is specifically stated within), but it should be stressed that any such allocations are based on personal judgement only and should not be taken as definitive unless stated as such by the authors of the papers concerned.

## Geographical index

Page numbers relate to the first page of each paper within which the relevant country or territory is mentioned. Page numbers in bold indicate illustrations of the places concerned within the indexed paper. Generally indexing has been undertaken to the level of countries, although a few major sites within countries have also been included, especially where these are the subject of several papers.

Adriatic Sea	560
Afghanistan	285, 287, 292, 562, 624, 690

## Subject index

Page numbers relate to the first page of each paper within which a subject is mentioned. Page numbers in bold indicate relevant photos within the indexed paper.

- ACAP See International conservation strategies and initiatives; Agreement on the conservation of Albatrosses and Petrels
- Action Plans** 7, 29, 63, 81, 113, 155, 189, 195, 206, 217, 218, 234, 263, 269, 320, 332, 339, 349, 350, 373, 453, 471, 501, 600, 602, 608, 614, 619, 629, 640, 643, 733, 760, 822, 889
- Canadian Shorebird Conservation Plan 207, 213, 643, 682, 701, 881
- Conservation Assessment and Management Plan (CAMP) 760
- Mexico National Shorebird Conservation Plan 213
- US Shorebird Conservation Plan 60, 157, 197, 207, 213, 643, 682, 701, 832
- AEWA See International conservation strategies and initiatives; Agreement on the conservation of African-Eurasian Migratory Waterbirds
- African Waterbird Census See survey, monitoring and surveillance; International Waterbird Census
- Aircraft 633, **635**, 690, **754**, 784, 817, 829, 874
- Albatrosses 7, 10, 29, 113, 186
- Alerts See Early warning systems
- Alien species See Non-native species
- Armed conflict See Conflicts and conflict resolution
- Asian Waterbird Census See Surveys, monitoring and surveillance; International Waterbird Census
- Atlases See Bird atlases
- Bag limits See Hunting
- Bag statistics See Hunting
- Banding See Movements and population definition; ringing
- Behaviour** 207, 252
- Monogamy 207
- Polygamy 207
- Sexual selection 207
- Bird atlases** 245, 296, 339, **491**, 500, 568, 569, 574, 582, 590, 595
- Tanzania Bird Atlas 245
- Bird catching See Hunting
- Capacity building** 7, 29, 81, 257, 287, 292, 324, 339, 349, 350, 447, 453, 608, 619, 643, 690, 731, **836**, 848, 878, **883**, 884, 885, 889, 892
- CEPA See Communication, education and public awareness
- Climate and climate change** 7, 29, 50, 63, **88**, 120, 128, 127, 138, 197, 214, 263, 277, 283, 296, 350, **385**, 385, 398, 405, 418, 480, 514, 524, 582, 614, 619, 640, 643, 690, 705, 717, 729, 765, 767, 784, 889
- Arctic Climate Impact Assessment (ACIA) 120
- Distributional change 277, 283, 398, 480, 514, 582, 619, 649, 697, 705
- Drought/desertification 269, 277, 292, 309, 514, 614, 624, 643, 643, 687, 697, 725
- El Niño Southern Oscillation (ENSO) 88, 181, 346, 405, 418, 457
- Intergovernmental Panel on Climate Change (IPCC) 88
- Inter-Tropical Convergence Zone (ITCZ) 218
- North Atlantic Oscillation (NAO) 398, 405
- Sea level rise **88**, 346, 398, 717
- Severe weather 673
- UK Climate Impacts Programme (UKCIP) 398, 784
- Co-management See Conflicts and conflict resolution; community involvement
- Communication, education and public awareness** 7, **29**, 81, 155, 189, 195, 204, 214, 218, 265, 269, 275, 277, 287, 292, 309, 315, 319, **320**, **324**, 332, 349, 372, 374, **380**, 410, 453, 482, **600**, **608**, 629, 643, 682, 690, 711, 731, **779**, 784, 795, **831**, 832, **833**, **836**, 838, 841, 847, 870, 874, 876, **881**, 884, 885
- Flagship species 189, 320, 608, 690, 812
- International Migratory Bird Day **833**
- Shorebird Sister Schools Program (SSSP) 832
